The apparatus shown in fig. 1, which has been invented by A. MANONCOURT, 76 Boulevard Saint-Germain, Paris, and is known as the "Ligaturateur universel" renders it possible to make with rapidity ligatures for tubes of any diameter. It is used in horticulture, for attaching watering-hose, in wine and spirit warehouses where wine, cider, beer, vinegar, alcohol, etc., have to be handled, and also in explosion motors (for the circulation of water).

The body of the apparatus *C* ends in a foot *P*, this projects slightly, and has a notch at its extremity. In the body, an endless screw *V* can turn, this is worked by a milled head, and the nut *E* carries a slotted stud in the groove.

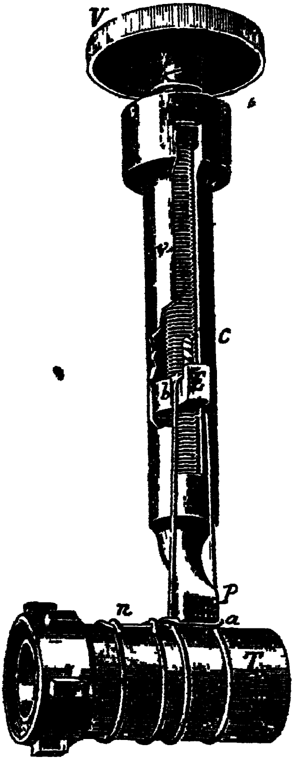

Fig. 1.
« Ligateur universel »
MANONCOURT

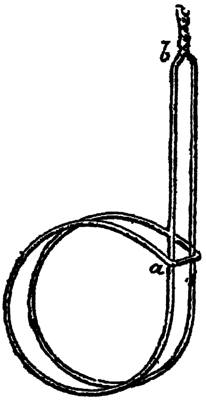

Fig 2.
Ligature made by
this apparatus

The ligatures are prepared in advance (fig. 2), they are rectangular in shape, their width *a* being equal to that of the foot *P*, and their length *b* exceeding the external circumference of the tube. These ligatures may consist, as the case requires, of round or flat wire or of a flat piece of steel with two parallel arms. A slip-knot is made round the tightening tube, as is shown by fig. 1. After having pushed the stud *E* as near as possible to the foot *P* (the milled head *V* having been unscrewed) it is placed on *b*, the free part of the ligature, the foot being in *a*. The head *V* is screwed home, in order to tighten the ligature; if necessary a few taps of the hammer can be given to make the wire take the shape of the tube, a second tightening blow is given, and the apparatus is pushed forward. The milled head is then unscrewed, and the wire cut, leaving two little hooks that are hammered down, as is seen at *n*. According to the length of the juncture, 2 or 3 ligatures are placed, one beside the other.

The apparatus usually employed has a total length of 0.23 m., and a travelling distance of 0.12 m. It is furnished with a certain number of ligatures suitable for tubes varying in diameter from 0.01 m. to 0.06 m.

A similar, but smaller, apparatus also exists; the total length of this is 0.14 m. and its travelling length is 0.07 m. It is especially suited for laboratory work, as it allows of narrower ligatures being used, such as are needed for vacuum rubber-tubing, gas-burners, ovens, etc.

A stronger apparatus worked by a winch-head is made. The total length of this machine is 0.48 m., while its travelling length is 0.30 m. This is intended for tightening ligatures of considerable diameter, and made of a material that is compressed during the operation. It is used in making bales of fibre, cotton, fascines and faggots, and for clamping boxes, ringing casks, etc.

RURAL ECONOMICS

550 - **The Cost of Threshing in France.** — DE MONTARD G., in the *Journal d'Agriculture pratique*, Year LXXXV, No. 2, pp. 29-30 Paris, January 13, 1921.

In a recent article, RINGELMANN has shown how much it is to the interest of agriculturists to form cooperative threshing societies (1).

The author had to do with such a cooperative society in a district where it is the custom to pay, not for the hours worked, but for the hectolitre of grain threshed. Before the war contractors asked from 60 to 70 centimes per sack of grain when threshing-machines without a straw-stacker were used, and 10 centimes more when the apparatus was furnished with this modern appliance. A difference of 10 centimes was always made between the threshing-price of wheat and that of other cereals (2). In 1920 farmers that supplied wood for the engines were charged from 3.50 fr. to 4 fr., whereas the others had to pay 4 to 5 fr. It appears that as much as 6 fr. per sack was asked when the threshing-machine was provied with a straw-stacker; the same price being paid for all cereals.

The Cooperative Society was started during the war by two motor cultural syndicates in the same canton. The threshing machine used was oneof *Ransomés*, a speedy worker bought as a bargain in 1917 for 7500 fr. The number of the members was 20. As the properties were much divided, the number of threshing-floors was somewhat greater, there being about 30. The hectolitres threshed from July 21 to September 5 (1) were 4514 in all (wheat 1738, oats 2729, rye 2 (2), barley 38, and spelt 7).

---

(1) See *R.*, Mar. 1921, No. 333.)*Ed.*)

(2) The prices were raised in years of bad crops. The contractors used small, simple threshing-machines which left the grain unwinnowed (small machines driven by motor power or horse power), payment being made not per sack, but by the heap of 12 sheaves handmade sheaves). The machines are rarely used. (*Author*).

Net Cost of Threshing One Sack on 5 Farms.

Total cost	—	**117.90**	—	**251.85**	—	**359.00**	—	**307.80**	—	**583 95**
Cost of threshing a sack of cereals . .	—	5.63	—	4.65	—	2.39	—	3.00	—	3.20

Each member's share of the expenses was based on the following

I. — *Wages.* — Each member pays for the days the mechanic and grain-feeders spend on his property. The grain-feeders wages were 10 fr. per day. One syndicate paid its mechanic 25 fr. The mechanic of the other syndicate only received 12 fr. but the syndicate paid for the threshing of his little crop, providing him with paraffin, oil and grain-feeders work, and remitting the sack tax.

II. — *Oil, paraffin.* — Each member provides his oil and paraffin. The syndicate has purchased these commodities this year.

Oil if bought through a cooperative society, can be sold to the members at 3.60 fr. per litre. The net cost of petrol and paraffin at the Station is 240 fr. and 165 fr. per hl., respectively.

III. — *General expenses.* — Under this head come: —

a) Repairs; these were very considerable this year, the machine having been driven carelessly during the last season. There was one heavy item; a new driving-belt.

b) Insurance premiums; these were somewhat low.

c) The wages of the mechanics and grain-feeders during removals or repairs.

---

(1) The work was interrupted for a few days during the local fairs.

(2) As a binder is little used on account of the sub-division of the properties, and the presence of plantations of trees etc., rye-straw is used for binding, and all the rye is threshed at the time it is harvested before the threshing season.

d) The oil and paraffin used on the road when changing threshing ground.

e) The petrol required for starting the machine; heavy oil, cleaning, rags etc.

f) Sundry expenses (meetings, correspondence, returning packing materials, advances of money, etc.)

g) Amortisation and interest paid on parts of threshing machine.

h) A payment of 0.10 fr. per sack to the motor cultural syndicate lending the tractor. (1)

i) The threshing expenses of the mechanic of the second syndicate. In order to cover all the expenses under the head of general expenses a tax of 0.90 fr. is levied on each sack of wheat and of 0.80 fr. on each sack of oats.

An examination of the appended table will show, that the cost of threshing a sack of grain varies greatly according to the crop.

The figures given show that:

1) As a rule, it is to the interest of a cultivator to belong to a cooperative threshing society.

2) He must choose machines that meet his requirements. A large tractor and thresher are not needed for a small crop. The reason that this rule was not carried out in the case entered in column 1, is because the small property lay between two larger ones where the thresher was being used, and which belonged to the same owner. A cooperative society that is well established can have 2 machines: a large thresher for large threshing-grounds, and a motor thresher for small ones.

3) Large yields are to be aimed at: columns 3 and 4 refer to two threshing-grounds where the work lasted the same time and neary the same amounts of oil and paraffin were used. The rich crop paid 0.60 fr. per sack less than the other. Thus cooperation puts a premium on production.

551 - **Studies on the Economic Valuation of Fodders.** — I. JOVINO, S., Della razione e dei foraggi più economici, in *Le Stazioni sperimentali agrarie italiane*, Vol. 48, No. 6, pp. 556-582, 8 tables, Modena, 1915. — II. GRABER, H., Neue Richtlinien der Fütterungspraxis, in the *Wiener Landwirtschaftliche Zeitung*, 1920, No. 20; extract from *Biedermanns Zentralblatt*, year 49, No. 12, p. 463. Leipzig, December, 1920. — III. GOUIN, R., La valeur marchande des aliments du betail d'après leur valeur nutritive, in the *Journal d'Agriculture pratique*, year 85, Vol. 1, No. 14, p. 276. Paris, April, 9, 1921.

I. THE MOST ECONOMICAL RATION AND FODDERS. — The author begins by giving some data concerning: 1) The decrease in the average digestibility of foods that results from the amount fed, that is to say the ration; hence the law of the "*final degree of digestibility*", namely, the digestibility of the last of the infinitesimal amounts of food into which the author supposes the daily ration to be divided; 2) the "*degree of utility*" of the food, or the proportion between the energy or substance the animal actually obtains from the ingested food (all the losses in transformation being subtracted) and the total amount of the food; 3) the decrease in the *average and final degrees of utility* with the increase in the ration.

---

(1) This arrangement will have to be altered, for the use of motor ploughs is much less common now owing to the cost of paraffin, difficulty of finding a driver etc, and the amortisation of the tractor would be insufficient. (*Author*)

This having been enunciated, the author expresses the final degree of utility in the function of the amount of the food, or ration x: —

$$y = a\,x^2 + h\,x + c$$

and obtains, by integration, z as the average degree of utility;

$$z = \tfrac{1}{3}\,a\,x^2 + \tfrac{1}{2}\,h\,x + c$$

By cow-shed experiments, where the total utilisation of the food is calculated by the daily weighing of the cattle, milk, butter or cheese, according to the zootechnical production, the constants of the function z may be calculated by means of 3 simple equations, and inserted into the previous equation. This having been done, if m represents the market price of 1 kg. of food after subtracting its intrinsic fertilising value, p the market price of the refined product, the most economical rations is given by

$$m\,dx = p\,y\,dx.$$

$$\text{or by } y = ax^2 + hx + c = \frac{m}{p}$$

The author describes the cow-shed experiments carried out during the winter 1913-1914 upon 3 Schwyz milch-cows belonging to the "R. Podere dimostrativo" of Matera (Basilicate), in which the food given consisted of a special mixture consisting of linseed cake, wheat sharps, sulla hay, mangolds and cereal straw. The analysis is given; 3 to 4 experimental rations contained respectively 12-24, 13.87, 15.50 and 17.13 kg. of dry matter per head, fed at successive periods varying from 6 to 9 days. The author concludes from the results of the experiments, that: — 1) Taking the average of the 3 cows, the most economical ration was (under the conditions of the market at the time), 33 of dry matter per 1000 parts of live weight if the milk was to be sold, and 29 if it was to be made into "mozzarelle"; 2) an excess of food is more wasteful the greater the age of the animals, and the more remote the date of calving; 3) KELLNER's rules, in this case, were in complete agreement with practical results.

The author then deals with the question of selecting the most economical fodders on the market, and shows that it is a mistake to begin by neglecting all the products already on the farm according to some system of nutritive unit; the only rational system is that which is based on the forage substances existing on the farm and which compares the cost of certain quantities of foods, whether unmixed or mixed, that are *isonutritive* among themselves, that is to say, contain the same amount of digestible albumen and starch equivalents, as these are the two great indices of the intrinsic nutritive value of forage. Given 3 foods with the following percentage composition:—

Food	Digestible albumen	Starch Equivalents
f'	e'	a'
f''	e''	a''
f'''	e'''	a'''

and with which it is desired to make (using *v* kg. of the 2nd and *w* kg. of the 3rd) an isonutritive mixture wth 100 kg. of the 1st we shall have: —

$$\left\{ \begin{aligned} v &= 100 \frac{a' e''' - a''' e'}{a'' e''' - a''' e''} \\ w &= 100 \frac{}{a'' e''' - a''' e''} \end{aligned} \right.$$

Isonutritive mixtures having been made of farm products and foods bought on the market, a single ingredient is selected for reference (if possible a cheap one) and with this are compared from the point of view of cost, the other foods on the market, preference being given to the isonutritive substances which are inexpensive and, at the same time, adapted to the special animal product required.

The author mentions practical instances.

II. NEW VIEWS CONCERNING FODDERS AND THEIR USES. — The albumen contained in foods is better used in milk production than in the production of fat. For this reason, GRABER approves of HANSSON's suggestion that in determining the cost of food production, the digestible albumen should be multiplied by the factor 1 43, in order to obtain the *milk value* (*M W* = Milchwert) of the foods, and not by 0 94, as is done by KELLNER in order to obtain the *starch value* (*S. W.* = Stärkewert) forages to be used for fattening stock.

The author speaks of the value of amides, enzymes, and more especially vitamines (which he calls *biophores*) in feeding, and in the production of animal energy or substance. He explains why raw or cooked beets are equally good for milk production, whereas raw or slightly steamed potatoes increase the milk yield more than boiled potatoes. He also shows the reason why cooking foods is, as a rule, rather useless than injurious, and why the economic objections raised against the use of germinated grain are as groundless as those directed against silage.

The author does not consider the present chemico-agricultural means of estimating forage sufficiently exact, and he advises agriculturists to use the once celebrated system of PIRQUET devised for estimating the value of various foods in the maintenance of the human body.

PIRQUET took as the unit of nutrition the *Nem* (Nahrungs-Eiheits-Milch), which represents the cost of production of 1 gm. of normal milk containing 3.5 % albumen, 3.7 % fat and 5 % sugar. (1). There are multiples of this unit, such as *Kn* (*Kilonem*), *Hn* (*Hectonem*) etc. The author expresses the multiple 100 *kn* by *Pq* (= 1 Pirquet). In the human body, feeding with 1 *Nem* produces 567 small calories.

In rationing, PIRQUET adopt as a reference size, the height of the human body when seated ("Sitzhöhe") expressed in *cm.* and represented by the symbol *Si*. The measurement is taken from the horizontal plane on which the person is seated to the top of his head. Si^2 gives the intestinal, or absorption, surface, or *Siqua*, in sq. cm., and $\frac{Si^3}{10}$ represents the weight of the body in grammes, in the case of men of normal height. A man engaged every day in arduous work requires an amount of normal milk equal in volume to the *Siqua* for every 1 cm. of height; this is expressed by *Siquanem* and represents the food maximum. On the other hand $\frac{1}{2}$ *Siquanem* only represents the maintenance ration, and from $^4/_{10}$ to $^7/_{10}$ of the production ration for work ranging in nature from moderate to very arduous.

In order to apply the PIRQUET system to stock foods, GRABER first shows that by dividing the starch value of these substances by 16.43 (Starch-value of 1 quintal of normal milk), or the milk-value by 18.15 (N. W. nutritive unity) of 1 quintal of normal milk), the units *Pq.* are obtained. The author considers that there is complete agreement between the facts deduced by PIRQUET from the calories of transformation, and the practical data, both as regards meat and milk production.

In order to show the amide and vitamine content of the foods, GRABER suggests adding to the figures representing the nutritive units expressed in *Kn* or *Pq* the letter *a*, if the food is rich in starch, and *h* if it has a high vitamine content. Thus, to produce 10 kg. of milk with 500 kg. of live weight, it would be said that an average of 30-33 *ahkn* were needed, less being required if the forage was green, fresh and succulent, that is to say, rich in *a* and *h*, and more if it was dry. If the vitamines of seeds only develop after germination *h* is put in brackets. Thus, the food value of 1 quintal raw peas is expressed by 4 (*h*) *Pq*.

III. MARKET VALUE OF CATTLE FOODS RECKONED ACCORDING TO THEIR NUTRITIVE VALUE. — The considerable variations in the price of food stuffs at the present time makes it very necessary to find out which are the most economical. The author, while frankly admitting that the present methods of determining the value of cattle foods which are based on nutritive and imaginary units are wholly conventional, and do not give accurate results, nevertheless considers the least imperfect of the methods to be: — *a*) The nutritive units calculated from KELLNER'S starch values and adopted in France in the compilation of MALLÈVRES' tables; *b*) the Danish method in which the nutritive unit is represented by a kg. of barley-corn which is almost always $^2/_3$ of the starch value (1)

---

(1) The PIRQUET method, founded on the comparative food value of woman's milk is also widely used in America. Cf. *Die Ernährung der Pflanze* year 17, Nos, 5-6, p. 85, Berlin, March; 1921. (*Ed.*)

The author describes the methods of estimating the economic value of cattle foods calculated by means of the different nutritive units adopted by MALLÈVRE, KELLNER, WOOD and HALNAN, GRANDEAU, and by Danish workers.

If the choice is between oats, groundnut cake and hay at the present market prices, calculation shows that groundnut cake gives the cheapest nutritive unit, no matter by what method the calculation is made (2).

552 - **Probable Profits from the Cultivation on the Banana in India.** — See No. 509 of this *Review*.

553 - **The Importance of the Stock Reared on Large Estates as a Source of National Food Supply in Germany.** — *Deutsche Landwirtschaftliche Tierzucht*, year XXIV, No. 33, p. 337-339. Hanover, April, 1920.

The socialistic and land-distribution schemes at present being carried out in Germany, which will inevitably bring about the subdivision of the large country estates for the purpose of solving the problem of obtaining an adequate food supply for the nation, are a matter of serious anxiety to experts and the interested parties. The chief points under discussion are the advantages and disadvantages, from the standpoint of political economy, of the small farm.

The author, taking as his basis a pamphlet published by the Union for the Reform of Country Estates " Reformbund der Gutshöfe " and entitled " Communal Provisioning and the Country Estates " (*Städtische Versorgung und Gutsbetrieb*), proposes to demonstrate the incontestable superiority of the well-managed large farm, as regards the amount of stock reared, over an equally well-managed smaller holding, and further to show that the parcelling out of a large estate among small holders entails disadvantages that from the point of view of political economy far outweighs any advantages that might accrue to any individual small holder.

The following arguments and examples have been selected from a large amount of statistical material: —

1) An estate in Upper-Hesse, situated in two communes in the neighbourhood of Friedberg. The average communal land is richer than that of the estate.

The following figures show the consignments of products made during the year 1918.

---

(1) In Scandinavia, the barley value method is also adopted, but if local barley is used, the barley-value, especially from the point of view of milk production, is 72 % of KELLNER's starch value. Cf. *R.*, February 1921, No. 177.

(2) MARENGHI is of opinion that the nutritive unit (leaving the farm fodders out of account) could be used in commercial transactions but only to show the compensation to be given, on account of the slight difference between the guaranteed value and the found value of the fodder. See *R.*, Feb. 1920, No. 248. (*Ed.*)

Estate (40 hectares under cultivation)		Communes (93 hectares under cultivation)	
Consignments of dairy produce:			
78 cows . . .	155 415 litres of milk	187 cows . . .	44 220 litres of milk
» . . .	4 932 pounds of butter	» . . .	no butter
per cow	1 992 *litres of milk*	*per cow* . . .	236 litres of milk
» »	63 *pounds of butter*	» » . . .	no butter
Consignments of butchers' beasts:			
36 cows and heifers		37 cows and heifers	
28 calves		70 calves	
per 100 *ha.* of *land:* 15.5 *cows and heifers*		*per* 100 *ha of land:* 8 *cows and heifers*	
per 100 ha. of land: 11.8 calves		per 100 ha. of land: 15.2 calves.	

2) An estate in the *Bezirk* of Giessen with an area of 134.50 ha. is situated in a Commune farming 316.25 ha. The consignments made in 1918 were as follows.

	Milk	Meat
Consignment from the estate	99 550 litres	52.50 quintals
» » » commune	104 584 »	42.00 »
» » a portion of the communal land of the same area as the estate. .	44 500 »	18.00 »
Consignments from the estate as compared with those from the communal land . . .	224 %	292 %

3) A very interesting comparison was made by the "Reformbund der Gutshöfe" in the *Bezirk* of Budingen, between 5 estates and 6 communes belonging to that *Bezirk*. The figures refer to 1918:—

Consignments of Milk.

	Communal farms	Estates
Total consignments	481 232 litres	472 950 litres
Average number of cows (according to official census)	919	260
Area cultivated	1 938.10 ha.	687.60 ha.
Annual yield per cows.	524 litres	1 819 litres
Per 100 ha of total area	24 830 »	68 783 »
Consignments made from the estate compared with the communal consignments · per cow	—	347 %
Per 100 ha of total area.	—	277 %

Consignments of Butchers' Beasts.

	Communal farms	Estates
Cattle total consignments	254	108
Small stock (calves, swine, goats	277	107
Cattle consignments per 100 ha of area . .	13.1	15.7
Small stock	14.3	27.2
Cattle consignments from the estate compared with the communal consignments	—	120 %
Small stock	—	190 %

The statistics given above come fiorm official sources as regards cases 1 and 2, whilst the data respecting No. 3 were compiled by the " Reformbund der Gutshöfe " under the direction of experts. Emphasis must be laid upon the fact that the extra productivity of the two estates was obtained from fertile soil worked by peasants recognised as being progressive. Had the conditions of soil and climate been less favourable, the differences in the agricultural production (" Ertragsunterschied ") of the communal farms and of the estates would have been still more accentuated, seeing that under such conditions, the latter enjoy superior technical and economic advantages As regards meat production, it is seen that the small holdings are not by any means of supreme importance for the provisioning of urban centres, as has also been proved by thé enquiries set on foot in the Darkehmen *Bezirk* and confirmed by Dr. ULRICH KAHRSTEDT in *Ein Beitrag zur Frage des Siedelungsgesetzes* (Study in the Question of the Law of Home-Colonisation), Printing Office of the *Deutsche Tageszeitung*, S. a. à. r. l. Berlin. As regards the regions in question (the Republic of Hes and the Province of Hesse-Nassau), the above statistics show very clearly that small farms in these districts have no sure future before them, any more than in East Germany. Where large consignments of meat have been made, this has only been done by certain urits (*Wirtschaftseinheiten*) which have given themselves up wholly to the stock-breeding industry to the neglect of all other branches of agriculture, and at the expense of a consumption of food stuffs that is by no means justifiable under present conditions. Further, if the large estate were to develop one branch of agricultural industry to the detriment of the others, its production in this special line (Sonderleistungen) would be as superior to that of the smallholdings as its general production has been shown to be.

It may be urged against the argument of the great provisioning-value of the relatively larger number of stock kept by the peasant-farmer, that the number of draught-cattle per unit area is very large, owing to the farming-methods adopted (" Wirtschaftsform "). Draught-cattle give but little or no meat and milk, all the food they consume going to supply the energy used in their work, so that they reduce the human food supply, either directly or indirectly. The use of draught-cattle, even where it is inevitable, is the great disadvantage of the above-mentioned farming methods. Again, as regards the employment of any kind of machine, the large farm is in a far better position than the small one, and is able to reduce the cost of draught-cattle, even where the motive power is still exclusively furnished by animals.

From what has already been said, it would appear that the large estate is superior to the small farm, not only in total food production, but also in the amount of food produced per unit area.

The author is of opinion that these differences of production are not confined to the region of Upper Hesse, but exist in all the districts of the South and West of Germany where the subdivision of landed property has taken place.

554 - **Methods of Fixing the Price of Milk** (1). — I. MERTZ, I. and DESMOULINS, I., in their Study entitled *Le Payement du lait à la matière grasse*, pp. 1-90. Librairie Agricole de la Maison rustique, 26 Rue Jacob, Paris, 1920. — II. MURRAY, A. H., in the *Agricultural Gazette*, Vol. XCI, No. 2408, pp. 201-202. London, February, 1920. — III. PORCHER, C. and VITOUX, H., in *La Vie Agricole et Rurale*, Year X, Vol. XVIII, No. 7, pp. 99-101. Paris, February, 1921. — IV. RAUCH, in the *Deutsche Landwirtschaftliche Tierzucht*, Year XXIV, No. 49, p. 510. Hanover, December 3, 1920.

The problem of fixing the price of milk upon a settled basis, especially the price of milk bought by Co-operative dairy societies and dairy industries for the manufacture of butter, cheese, condensed milk, etc., has been studied by different authors. The following is a summary of their articles on the subject.

I. — This study is divided into two part; in the first, the authors give advice regarding the creation of a Co-operative Dairy Society, and the choice and fitting up of the premises; in the second, they show the necessity of estimating the value of milk according to its fat content, which would introduce a new basis for the price and testing of milk, and a different method of dairy book-keeping, and demonstrate the great advantage of the new system over payment by weight, viz., 1) the better testing of milk delivered by farmers; 2) the individual estimation of the milk supplied; 3) the economy realised by the cooperative society; 4) the stimulus to great production by means of selection and feeding; 5) payment in proportion to the richness of the milk supplied, its acidity being taken into account, so that each member receives his due.

The price of the milk should be estimated from samples taken every day, mixed and tested every week in a GERBER apparatus. The three or four careful texts thus made during the month, would permit of the estimation of the exact amount of butter fat supplied by the members, who should be paid by dividing the receipts at the end of the month equally among the number of kg. of butter made at the factory during the month ; the general expenses being divided among the members in proportion to the members of litres of milk supplied by each of them respectively to the factory during the month.

---

(1) See *R.* Feb. 1921, No. 210. (*Ed.*)

As regards the testing of milk which is to be paid for according to its fat-content, the authors lay great stress upon the fact that it is most important that the quantities sampled should be in proportion to the amounts of milk delivered ; a precaution usually omitted by Co-operative societies.

If all the milk supplied by a member could be collected and kept from one testing time to the next, it would fill a basin, but the flask only contains a certain proportion, and in order for this proportion to be equal, it is necessary that the sample taken every day should be proportionate to the amount of milk measured each day. If equal samples are taken the *average richness* differs greatly from the *resulting richness* according to the amounts of milk supplied, and its fat content at the different times the samples are taken ; and can be either higher or lower than the latter, a difference which gives rise to serious errors at the expense of either the producer or the cooperative society.

The individual *resulting richness* is the richness of all the milk supplied by a member if it were collected every day in a basin until the time of testting.

Calculation of individual error. — Supposing, that during a month of 30 days, a member has supplied N. litres of milk divided as follows :

On the 1st day, *A* litres giving *a* gm. in the GERBER apparatus (or *Aa* gm. of fat)
» 2nd » *B* » » *b* » » » » (or *Bb* » »)
. . . .
. . . .

If it were possible to collect all the milk, these N. litres would contain $\Sigma\, Aa$ gm. of fatty matter, and its fat content per litre would be :—

$R_1 = \frac{\Sigma\, Aa}{N}$; this being the resulting difference, whereas the average fat content would be :

$$r_1 = \frac{\Sigma a}{30}$$

The deviation in the fat content due to equal sample-taking is thus :

$R_1 - r_1$ or $\frac{\Sigma\, Aa}{N} - \frac{\Sigma a}{30}$, and the formula for the individual error is :

$$E_i = \frac{\Sigma\ [a\,(30\,A - N)]}{30.\ N}$$

which is cancelled, for $N = 30\,A = 30\,B = 30\,M$ or $A = B = M$ } that is to say, when the member supplies equal volumes every day.

The authors not only advocate that the price of milk should be based upon its fat content, but urge that a deduction ought be made in the case of all milk with an acid content varying from 25° Dormic to the degree at which natural curdling sets in, since it is only fair, that milk which has been carefully collected, kept, and dispatched, should fetch a higher price than an equally rich milk which contains impurities, for if it is acid, it entails loss upon the co-operative society. In order to assess this deduction, the authors suggest a method by which the excessive acidity A^0 measured at the factory can be divided under 3 heads: $A^0 = a^0 + t^0 + r^0$

a^0 = acidity of the milk when it leaves the farm. This is the fault of the member himself.

t^0 = acidity due to transit. The loss to be equally divided between the member and the factory.

r^0 = acidity due to retention in the dairy. The loss to be borne by the dairy-owner only.

II. — In England, milk is still usually bought by quantity, no account being taken of the quality of the product. The author remarks that this unjust method is disadvantageous to the producer, dairy-owner and consumer, but hits most hardly the producer who handles his milk with scrupulous cleanliness, and devotes care to the selection and proper feeding of his cows.

Although some cheese or butter-making establishments buy milk according to its fat-content, the general custom is to pay a fixed price per gallon of milk without considering its quality, provided that it contains not less than 3 % of fat and 8.5 % of solids not fat, these being the legal limits. The author gives a short account of the successive systems of buying milk that existed in Ireland before the price was regulated by the fat content, and states that none of them, even the most primitive, was so bad as that still practised in England.

Two systems of buying milk according to its fat content are adopted in Ireland: —

1) Each producer is paid according to the number of kg. of fad supplied during the month; this is determined by testing, and controllet by the actual results when the amount of butter obtained is known at the end of the month: the number of kg. of fat is calculated by multiplying the kilograms of milk by the average fat content obtained by testing; the product being divided by 100. As regards making the tests, the author mentions the great difficulties entailed by taking equal samples.

2) The average test-sample of the milk from each producer is taken every week, or every month. Each estimation is multiplied by the number of litres of the milk tested, and the product is then divided by the total number of litres of milk.

The owners of creameries are very partial to this method, which not only produces the largest quantity of cream, but economises time, power and labour. In all well-managed creameries, the milk is weighed on its arrival, in order to eliminate any factor that might interfere with the estimation of its true market value.

II — The authors endeavour to show that, if in most foreign butter-making countries the price of milk were based on its fat content this would appear to be an incomplete method of regulating the milk trade, for in addition to the fat content, the solids not fat should be taken into account, and also the freshness of the milk which depend upon special coefficients That is to say, the milk should be as fresh as possible, and be sufficiently rich in all its constituents for the following reasons —

Although payment based on fat content is relatively fair when the milk is to be made into butter it only serves to conceal fraud when whole, or nearly whole milk is to be made into cheese concentrated milk, milk powder, etc, in which case, not only the fat content but also the amount of solids not fat together with freshness of the milk must all be taken into consideration Payment according to fat content is especially unsatisfactory as regards the fat-free extract for as the authors observe the skimmed milk is regarded almost as a residuum which encourages watering the milk If the watered milk contains the amount of fat present in unadulterated milk it would fetch the same price as the latter and the purchasers therefore (the greater number of persons engaged in the dairy industry) would be greatly defrauded seeing that they would not have

	Fat content	Fat content	Butter yield	Calculated from the butter yield only at 12 4 mark per kg	Calculated from butter yield and milk yield			Difference

received all the fat-free extract to which they had a right. The economic effect of this measure upon the dairy industry would be considerable, as is shown by the following simple calculation.

If in the manufacture of concentrated milk, two milks are used having the same fat content per litre, but different amounts of solids not fat (80 gm. in the first case, and 95 gm. in the second), a saving of 1220 litres (or a gain of 11.1 %) would be obtained in making 1320 kg. of condensed milk, if milk No. 2 were used; further, there would be 13.8 % less water to be evaporated, and more sweetened natural milk could be produced than with sample No. 1.

IV. — RAUCH regards the question from the point of view of both producer and consumer, and shows the undesirableness of the incomplete estimation of milk by an extract from the account-book of a dairy (reproduced on p. 635) which brings out the injustice of payment according to butter-yield.

The calculation of the butter-yield is carried out by means of the tables compiled by HELM, HITTCHER and FORSTER, the skim milk being entirely left out of account.

AGRICULTURAL INDUSTRIES

555 - **Production and Utilisation of Maize Oil in the United States.** — SIEVERS, A. F. (Chemical Biologist, Drug, Poisonous and Oil Plant Investigation), in *United States Department of Agriculture Bulletin* No. 904, pp. 1-23, figs 11, Washington D. C., Oct. 29, 1920.

This bulletin deals chiefly with the production of maize oil from the germ of maize kernels. The two proceeds of degermination are given: the dry milling process, used for making hominy proesses such as grits, flakes, meal, flour and hominy feeds: the wet process used in the manufacture of starch, glucose and related products. The methods of degerminating differ materially in these 2 processes.

Details are given of:— the methods employed in the extraction, handling and disposing of the crude oil; the utilisation of maize oil; the effect of colour and condition of the maize on the yield and character of the oil; the economics of maize oil production.

The appended tables show:— The fat, moisture and free fatty-acid content of material produced in representative maize-products mills; the estimated cost of the process of production of maize oil; and the comparison of the revenue obtainable from the germs used for oil extraction. Tables I and II (p. 637) reproduce the more important data with reference to the above mentioned points.

The net revenue for extraction is estimated at 23.67 cents per bus. of maize (wet process) and 16.17 cents per bus. (dry process); the balance in favour of extraction against disposal for feeding stock amounts respectively (wet and dry processes) to 15.27 and 5.75 cents per bus.

In closing the author describes briefly the methods employed in the production of edible oil, and discusses future prospects. He considers that the amount of maize oil used for edible purposes in the future will be determined by the quantity available rather than by any question as to its utility. Maize oil is not always obtainable is sufficient quantities to meet the demands, and this has often led to the use instead of cotton-seed oil.

TABLE I. — *Composition of material produced by the wet and dry processes of degerminating maize.*

	Material analysed	Wet process (starch mills)	Dry process (hominy mills)
Free fatty acids	Crude oil	1.11	2.39
	Refined oil	(1) 0.10	(2) 0.13
Fat	Germs	17.88	42.23
	Oil cake	6.82	8.70
	Feed	5.92	4.38
Moisture	Germs	6.96	4.37
	Oil cake	5.81	7.74
	Feed	11.35	10.15

(1) A single analysis — (2) Average of 3 analyses

TABLE II. — *Oil left in oil cake when operating on wet and dry processes of degerminating maize.*

	Wet process	Dry process
Germs obtained from 1 bus of maize	4.17 lb.	3.47 lb.
Oil in germs	18.00 %	45.00 %
Oil left in cake	6.00 %	9.00 %
Oil obtained from 1 bus. of maize	0.532 ib.	1.372 lb.
Cake obtained	3.637 ib.	2.097 lb.
Oil in the cake	0.2182 ib.	0.1887 lb.

556 - **The Resistance of Vinegar-Eels to Different Agents.** — PASSERINI, N. (Director, of the Agricultural Institute at Scandicci), in *Le stazioni sperimentali agrarie italiane* Vol. LIV, Parts 1, 2, and 3, pp. 15-16, Bibliography of 22 works. Modena, 1921.

Vinegar-eel (*Anguillula aceti* Müller) very frequently occur in wine-vinegars, and PASTEUR has shown that they hinder acetification; according to the author, however, they do no appreciable harm to the vinegar, when once it is made. No cases of disturbance due to the presence of vinegar eels in the human digestive system have ever been recorded, although these organisms are sometimes found in the faeces, etc. As the presence of *Ang. aceti* is considered detrimental to vinegar, the author has tried to find some means of destroying these intruders, and has extended his researches to substances which, owing to their toxic character, cannot be used in industry. He summarises the results obtained on the same subject by other investigators, and describes his own work; some of his results are summarised as follows:—

Vinegar-eels are very resistant to many chemical substances, adult females being even less affected than the males and young individuals; further, they have the power of gradually adapting themselves to these agents. Their resistance varies much according to their origin, which explains the very various results obtained by different authors. Vinegar-eels can live for several days in vinegar containing:— 18 % actic acid 10 % tannic acid; 5 % tartaric acid, 16 % citric acid; 8 % lactric acid 45 % succinic acid. They can exist in contact with:— 1 % boric acid 2 % formic acid; 2 % pyrogallic acid. They are much more susceptible to mineral acids such as 5 per 1000 hydrochloric acid, 5 per 1000 nitric acid, and 1 per 1000 sulphuric acid, although they are able to resist even these for some time.

Sulphur dioxide, if introduced in large quantities, kills all the vinegar-eels in time. They can withstand 4 per 1000 carbolic acid, and 3 per 1000 salicylic acid; and are very resistant to the halogenes.

The most active metals are those most quickly attacked by vinegar.

The vinegar-eels live a long time in a 4 % solution of sodium chloride. and in more concentrated solutions of other metallic salts. In equal amounts, potassium salts are less active than sodium salts. A 1 per 1000 solution of chloride of mercury causes the death of these organisms in a few hours, and a solution of potassium cyanide kills them, but only after some days.

Anguillula aceti is extremely resistant to alkaloids.

In an atmosphere of oxygen and hydrogen, it lives at least 1 month; carbonic acid renders it motionless in 12 days, but without killing it. Many individuals die after 5 days in acetylene, whereas others can resist for over 15 days.

In distilled water, vinegar-eels die in a few days; they will, however, live for 1 month in spring water.

In 2 % in volume of 12 volume hydrogen peroxide some of the "eels" survived for 1 week, and even longer. The reagent which is most injurious to them is carbon bisulphide; the aqueous solution (at 1 per 1000) kills the "eels" very quickly if it is mixed with the vinegar in the proportion of 1 : 4 or more. If 0.5 per 1000 of mustard flower is added to the vinegar, the "eels" live for a fortnight, or even longer. A 5 % dose of Dalmatian pyrethrum (powdered flower-heads) was inactive for 1 ½ months.

Filtration is not a certain method of entirely freeing vinegar from "eels." At a temperature of 47.5° C. they all die, but in practice it is advisable to raise the temperature to 50° C. The prolonged action of cold (— 12° C.) destroys them, rapid thawing being more fatal than slow thawing.

Vinegar-eels die without heating, if the vinegar is exposed to sunlight for several hours. A rise of temperature much below the point that destroys them accelerates the action of the solar rays; the author has shown that ultra-violet rays are those which are most harmful. Exposing these "eels" to a Kromayer lamp and to a Schott and Gen apparatus for 13 hours had, however, an absolutely negative result; similarly no effect was produced by 1 hour's exposure to X rays, or by 24 hours' action of radium emanations (1 cgm. of bromide).

The exclusion of air, which would seem to be the easiest way of freeing vinegar from these parasites, is one of the least certain methods, for they can live for a long time at the expense of the small quantity of oxygen in solution in the vinegar. Even if all contact with the external air is excluded, the "eels" can survive for over a week. They can even live some days in vinegar that has been previously boiled and kept from contact with atmospheric air.

It takes a fortnight to kill them all in a barometric vacuum Olive-oil, or vaseline, placed on the surface of the oil has absolutely no effect, for the air can pass through the oily layer, or find its way between it and the walls of the vessel.

Drying the air kills vinegar-eels very rapidly; only in one case did the author find life not to be extinct.

557 – **Chinese Wax.** — see No 500 of this *Review*.

558 – **Studies on the Price of Milk.** — See No 554 of this *Review*.

559 – **Method for the Detection of Abnormal Milks.** — Baker, J. C., and Van Slyke, L. L., in *Technical Bulletin, No. 71. New York Agricultural Experiment Station*, pp. 1-14. Geneva, N. Y., June, 1919.

The method employed was based upon the use of brom-cresol purple as an indicator.

Clark and Lubs were the first to suggest the use of this indicator in connection with milk cultures. They made use of the dye then known as dibrom-ortho-cresol-sulfon-phthalein (*Journal of Agricultural Research*, Vol. 10, p. 105, 1917). This dye can be purchased from Hynson, Westcott and Dunning, Baltimore M. D.

One drop of a saturated water solution of this dye is mixed with 3 cc. of milk, and the colour is observed. Normal fresh milk gives a greyish-blue shade. The production of a darker or lighter colour awakens suspicion in regard to the normal character of the milk. The colour is made lighter by acids, acid salts, formaldehyde, and also by heating above the usual point of pasteurisation. The colour becomes deeper blue in the case of milk from diseased udders, watered milk, skimmed milk, and milk containing alkali or alkaline salts. In the inspection of milk, a sample is taken for further detailed examination in the laboratory. If the colour is sufficiently lighter or darker than normal it indicates the probability of some abnormal condition.

The method has been applied and 570 samples of market milk examined. Watered milk is thus easily detected, and also milk containing ex cessive numbers of leucocytes. A standard of colour can be prepared by which comparison can be made and conclusion more easily reached as to the normality or abnormality of samples examined.

560 - **Carbon Dioxide Content as a Basis for Distinguishing Heated from Unheated Milk.** — VAN SLYKE, L. L., and KEELLER, R. F., in *Technical Bulletin* No 78. *New York Agricultural Experiment Station*, pp. 1-7, Geneva N. Y., March 1920.

The object of this investigation was to ascertain whether the heating of milk under the pasteurisation conditions, changes the carbon dioxide content in such a way as to establish a means of knowing whether milk has been pasteurised or not. It has been found necessary, therefore, to study such other conditions as may affect the carbon dioxide content in the usual method of handling milk, from the time of milking to the time of delivery to the consumer.

Conclusions

1) The content is not appreciably affected by the method of milking.

2) The content rarely drops below 3 to 3.5 % by volume, when milk stands under ordinary conditions, even for periods of 20 to 40 houns after milking.

3) The content is not appreciably changed by passing through the separator, and only extreme and prolonged stirring reduces the carbon dioxide below 3 % by volume.

4) Heating milk under the conditions required for pasteurisation reduces the carbon dioxide content to, and usually below 2.5 % by volume.

Consequently, the authors consider that, when the percentage of carbon dioxide by volume is not more than 2.5 %, it is safe, in general, to assume that the milk has been heated to the temperature of pasteurisation.

561 - **Amount of Acidity and Coagulation in Fresh Milk.** — See No 471 of this *Review*.

562 - **Butter Hydrometer.** — BRUNO, A., in the *Annales des Falsifications et des Fraudes*, No 144-145, pp. 543-545. Paris, October, 1920.

The hydrometer devised by the author allows of the water content of a butter sample being estimated very accurately, in a few minutes, without the help of a laboratory.

Description. — The apparatus consists essentially of a stand, a float, and a lead weight The stand is graduated ana surmounted by a flat plate

The graduated scale consists of a scale of 20 divisions from 0 to 20; each division represents 1 gm of water per 100 gm. of butter. The densimeter is enclosed in a metal-case, which serves as a gauge, the inner cover consists of a small alcohol lamp. The apparatus is completed by an aluminium cup, a spatula and a pair of forceps.

Mode of operation. — This is very simple. The case is filled with pure water to within a few centimetres of the top. The hydrometer is immersed in the water, care being however taken that the plate remains dry.

About 5 gm. of the butter to be examined is taken up with the spatula and placed in the cup, which is put on the plate. Little pieces of butter are added, or removed, so as to bring the zero mark to the level of the water.

The cup is then removed, and held over the flame of the little lamp, in order to melt the butter completely The butter is further heated gradually, until it assumes a deep red colour. Then the cup is placed on the plate of the hydrometer. The observer then waits till the instrument has regained its equilibrium, and reads off the figure at the water level as before, thus obtaining the number of grammes of water per 100 grammes of butter.

PLANT DISEASES

GENERAL INFORMATION

565 – **Decree of the President of the French Republic, of March 8, 1921, Prohibiting the Importation of Living Plants, Fruits and Seeds of the Chestnut, as a Guard Against *Endothia parasitica*** (1). — *Journal officiel de la République française* Year LIII, No 66, p 3076 Paris, March 11, 1921

Art I — Importation and transport into France of living plants, fruit and seeds of chestnuts coming directly or indirectly from the Far East is forbidden, including also countries which have not adopted preventive and control measures against the disease caused by the fungus *Endothia parasitica*.

Art II — In observance of the prohibition presented in Art. I, importation authorisations will be allowed by the Ministry of Agriculture on conditions fixed according to the advice of the Consultive Committee on epiphyte

566 – **The Imperial Bureau of Mycology.** — *Royal Botanic Gardens, Kew, Bulletin of Miscellaneous Information*, No 2, pp 94-95. London, 1921.

The Imperial Bureau of Mycology is the outcome of a proposal unanimously adopted by the Imperial War Conference in 1918 that a central organisation should be established for the encouragement and co-ordination of work throughout the Empire on the diseases of plants caused by fungi, in relation to agriculture.

The headquarters are situated at Kew and have the advantage of proximity to a fine library and the collections of the Royal Botanic Gardens, with the Director and Staff of which the Bureau will work in co-operation.

Dr. E J. Butler, late Imperial Mycologist, Director of the Research Institute, Pusa, and Agricultural Advisor to the Government of India, has been appointed Director, The Committee of Management consists of some of the foremost biologists in the country.

The funds of the Bureau are entirely provided by contributions from the various self-governing Dominions, India, Egypt and the Soudan, and the non self-governing Colonies and Protectorates. It will work broadly on the lines of the existing Imperial Bureau of Entomology at South Kensington. It will be a central agency for the accumulation and distribution of information and for the identification of specimens sent in from all parts of the Empire. It is proposed to issue, as soon as funds permits a periodical journal through which those interested in mycological work in regard to agriculture will be kept informed of progress elsewhere.

DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS.

567 - **Fruit Fungi Observed in Belgium.** — MARCHAL EL. and MARCHAL, EM., in the *Bulletin de la Société royale de Botanique de Belgique*, Vol. LIV (New Series, Vol. IV), pp. 1-31, 2 pl. Brussels, 1921.

A contribution to the study of fungi that live on fruits in Belgium. The experiments, which were made from the purely mycological standpoint, were carried out during 1915-1920, in the district of Namur, in the neighbourhood of Gembloux, on succulent fruits, and especially stoned fruit, of which the late varieties, particularly if kept for some time, are subject to the attack of very varied parasites. Several thousand specimens were examined, 815 being made the object of special investigation and cultivated in different media.

This study of fruit-fungi has enabled the authors to identify 64 different kinds, among which there are 24 varieties or species hitherto unknown to science, a description in Latin being given, and 21 forms new to Belgium.

568 - **Observations on the Perfect Form of the Oak Oidium in Italy** (1). — PEYRONEL, B., in *Le Stazioni sperimentali agrarie italiane* Vol. LIV, Parts 1-3, pp. 5-10. Modena 1921.

On November 1, 1920, at a short distance from the last houses of Rome, the author found, on the leaves of shoots of *Quercus Robur* vars. *sessiliflora* and *pubescens* (= *lanuginosa*), which were thickly covered with the well known white patches produced by oidium, a large number of perithecia. These fructifications usually resembled small brown or nearly black spots; a few, which were, however, not fully ripe, were orange-coloured. The perithecia were present almost exclusively on the adult leaves, being very rare on the younger leaves of the top of the shoot, especially in the case of *Q. Robur* var. *sessiliflora*, whose leaves are more succulent. They occurred generally on the upper blade of the leaf, but when this had become withered through the attacks of the fungus in its conidial form, the perithecia were often found also on the lower surface

On the 5th of the following December, the author saw, at the distance of some kilometres from Rome, other leaves of *Quer. Robur* var. *pubescens* bearing quite ripe perithecia.

According to PEGLION, the formation of perithecia is due to abrupt falls in the temperature following periods when the thermometer has been rather high; this suggestion would appear to be confirmed by the meteorological data registered during October, 1920. The author, however, is of opinion that a rapid lowering of the temperature is only the indirect cause of perithecia formation, and that the real cause is the dryness. In speaking of dryness, it must be understood that the proportion between the superficial evaporation or transpiration of the fungus, and the amount of sap the latter can absorb from the host plant must be very high for the fungus to run any danger of perishing from want of moisture. As is well-known, cold arrests the physiological functions of a plant, and interferes to a special extent with the circulation of the sap; in the case in question, this effect was all the greater on account of the lateness of the season, and hence the plant was inclined to shed its leaves and enter into the winter resting-period. The effect of rapid falls in the temperature persists for some days after the cause has ceased. The periods of these abrupt changes were accompanied, even at night, with unusual dampness of the atmosphere, which reached its height between October 26 and 29.

---

(1) See *R.*, February 1920, No, 264 (*Ed.*)

It is easy to understand that, given all the above-mentioned circumstances, which conspired to bring about the drying-up and death of the fungus, the latter was obliged to produce more resistant organs than the delicate mycelium and conidiophores. The author indeed believes that, in the Ascomycetes, perithecia instead of being a means of sexual reproduction — which is often non-existant or abortive in many of these fungi — are true organs for resisting unfavourable surrounding conditions, and drought in particular, for when the temperature is low, even the most delicate fungi suffer little, provided they are not growing in too dry a medium.

The author thinks that the perithecia found on *Q. Robur* var. *sessiliflora* and *pubescens* are to be attributed to *Microsphaera quercina* (Schw.) Burr.; whereas, on the other hand, those seen sporadically before 1907, on oaks in Portugal (*Oidium quercinum*, Thüm, on *Q. racemosa*, in Italy, (*Microsphaera* on *Quercus* sp.), and in Switzerland (*Microsphaera* on *Q. Robur* var. *pedunculata*) are to be regarded as belonging to *Micr. Alni* (D. C.) Wint.

If this view is accepted, the " oidium " of the oak must be regarded as a separate form, quite distinct from *O. quercinum* Thüm , to which, for reasons of priority, belongs the name of *O. gemmiparum* (Ferr. Pezr. (= *Q. quercinum* Thüm var. *gemmiparum* Ferr. *O. alphitoides* Griff and Maubl).

571 – **" Sirah" Vine Resistant to Oidium and Mildew in Italy.** — See No. 512 of this *Review*.

572 - **The Pre-Soak Method of Seed Treatment: Means of Preventing Seed Injury Due to Chemical Disinfectants and of Increasing Germicidal Efficiency.** — BRAUN H., in *Journal of Agricultural Research*, Vol. XIX, No. 8, pp. 362-392, figs 9, tables 13, pl. 14, bibliogr. of 10 works. Washington D. C. July 15, 1920.

The use of disinfectants to prevent seed injury is generally attended by retarded seed germination. Pathogens on the seed coats, present in dry bacteria, fungus spores, or dormant mycelium, are usually in a resting stage, and as such, require the use of disinfectants in a fairly strong concentration :— 1 : 80 for copper sulphate, and 1 : 200 or 1 : 320 for formalin which often act very detrimentally on the germinating wheat seed. The use of lime after copper sulphate, while beneficial to a certain extent, does not entirely prevent seed injury, nor has the detrimental effect of formalin been up till now fully counteracted. The economic importance of the annual loss of grain due to seed treatment is such that, during the recent war, the War Emergency Board of the American Phytopathological Society conducted an elaborate series of tests of standard grain disinfectants.

In the course of investigations on the black chaff bacterial disease caused by *Bacterium translucens* var. *undulosum* (1) under the direction of Dr. E. F. SMITH a new and effective treatment was employed.

Greenhouse and field experiments here reported showed that this detrimental effect can be eliminated for standard varieties of wheat by allowing the seeds to absorb water for 6 hours before submitting them to the treatment with formalin or copper sulphate soaking for a period of 10 minutes and covering for 6 hours (here designated the pre-soak method). is better than leaving in water for 6 hours. Similar results were obtained in experiments with barley, oats and maize.

The saturation of the seed cells and cell walls with water during the pre-soak period appears to be the factor counteracting the injurious effect on seed germination by diluting the disinfectant beyond the point of injury as it diffuses into the tissues and also by considerably decreasing the amount which may penetrate into the tissues later. In addition to this, it tends to stimulate dormant bacteria and fungi into vegetative activity, thereby rendering them extremely susceptible to the subsequent action of the disinfectant.

Actual stimulation of germination has been observed repeatedly in pre-soak-treated seeds, a factor which minimises the danger of exposure to the attack of soil organisms during this susceptible period.

The bacterial blackchaff disease of wheat can be controlled without any injury to seed germination, by a 6 hour pre-soak of surface - infected seeds in water, followed by a 6-hour treatment with formalin 1 : 400.

In practice, wheat seeds after being screened, should be soaked in water for 10 minutes at about 6 a. m., drained, covered and set aside moist until noon, then soaked with formalin 1 : 400 for 10 minutes, drained, covered and set aside moist until 6 p. m., and then spread out to dry over night to be planted the next day.

---

(1) See *R.* Oct.-Dec. 1919, No. 1268. (*Ed*)

It should be noted that this treatment increases the bulk of the dry grain about 25 %.

In applying this method to other kinds of seeds, the length of time for the 2 parts of the process *i. e.* the pre-soak period and the subsequent disinfectant treatment period, should be governed by the following factors: *a*) the rate of absorption of water by the seeds ; *b*) the susceptibility of the seeds and pathogens to the disinfectant , *c*) the respective periods necessary for the beginning of seed germination and of vegetative activity of the pathogens.

In no case should the pre-soak period be continued up to the time seed germination begins. The length of time necessary for the seeds to absorb about 30 % of their weight of water is suggested as the length of the pre-soak period when not conflicting with other factors involved.

573 – **Injury to Wheat Seed Resulting from Drying after Disinfection with Formaldehyde.** — HURD, A. M. (Office of Cereal Investigations, Bureau of Plant Industry, United States Department of Agriculture), in *Journal of Agricultural Research*, Vol XX, No. 3, pp. 209-243, tables 16, pl 6, bibliogr of 77 works. Washington, D. C, Nov 1, 1920.

The investigation of the post-treatment action of formaldehyde on seeds was begun in 1918 in the plant pathology laboratories of the University of California as a part of the cereal-smut eradication campaign conducted by the U. S. Dept. of Agriculture, and lasted over a period of 9 months. The seeds treated were left for 10 minutes in a 0.1 % solution of formaldehyde followed by a draining period of 10 minutes.

The outstanding fact shown by these experiments is that all the seed treated with formaldehyde solution and then dried by exposing to the air, was either killed or seriously injured after 3 to 6 days, while that treated at the same time and stored at the same temperatures, but kept damp by sealing in jars, was practically uninjured up to the time it was destroyed by moulds. No injury was caused by treating wheat with either a 0.1 % (1 : 40) or a 0.2 % (1 : 20) solution of formaldehyde, if the seed germinated immediately after treatment.

To detect the presence of formaldehyde on treated seed, TOLLEN'S (1) " silver mirror " aldehyde test was used. This injury to seed after drying is apparently due to a deposit of paraformaldehyde on the seed which forms as the formaldehyde solution evaporates. The former, being volatile is constantly breaking down into formaldehyde gas, and thus concentrated and within such close contact with the seed, penetrates slowly.

Humidity is evidently a determining-factor in seed injury during storage. There was no injury in an atmosphere containing 70 % humidity and above, when the seed was not attacked by moulds. A lower percentage encouraged injury, especially intermediate humidity contents, as it was found that seed stored in an absolutely dry chamber was almost uninjured. Temperature may also be an important factor, but its relation to the problem has not yet been determined. For the maximum seed injury as a result of drying after treatment with formaldehyde it is evident however that there should be an optimum atmospheric humidity to permit first, the formation of paraformaldehyde, and second, formaldehyde gas in the seed.

---

(1) TOLLEN'S reagent is made by dissolving 3 gm silver nitrate in 30 gm water and 3 gm. sodium hydroxide in 30 gm water The silver oxide precipitate produced dissolved by adding ammonia (s. g., 0 923) (*Author's note*)

Aeration of the treated seed is advisable in order to hasten evaporation of paraformaldehyde, and the consequent escape of the gas from around the seed. It was found for example that barley was less susceptible to post-treatment injury when dried after soaking in a 0.1% solution (probably due to protection afforded by the glumes), but when stronger solutions were used the injury was very severe.

Seed dried for 1 hour by being thinly spread on towels in the laboratory and then sealed in bottles was uninjured after weeks of storage: but seed dried longer, although not injured by rapid drying was injured upon being sealed, probably because of the concentration of gas in the bottle as a result of decomposition of the paraformaldehyde on the seed. Treated seed dried from 5 to 24 hours was more severely damaged upon being sealed than when dried for a longer time.

Sorghums were found to be uninjured by either a 0.1% or a 0.2% solution of formaldehyde even after weeks of drying (probably due to protection by glumes or thick seed coats).

Dry storage injury can according to the author, be entirely avoided by simply washing the seed with water after treatment.

574 – ***Sclerotinia Minor* n. sp. Injurious to Lettuce, Celery and Other Crops in the United States.** — JAGGER, I. C., in *Journal of Agricultural Research*, Vol. XX. No. 4, pp. 331-334, pl. 1. Washington, D. C., Nov. 15, 1920.

SMITH recorded in 1900 the occurrence of a fungus similar to *Sclerotinia Libertiana* Fuckel, which, however, produced much smaller sclerotia, in green houses, Massachusetts, where it was causing destructive rot of lettuce. DUGGAR (1909) states that a similar fungus occurred on lettuce in the vicinity of both Boston and New York City It was collected in 1912 and again in 1914 at South Lima in Western New York, where it seemed to be well established and was causing considerable injury to lettuce grown on muck soil In 1914 it was collected also on lettuce in a greenhouse at Rochester. N. Y. In the autumn of 1919, the fungus was frequently noticed on celery and lettuce in the vicinity of Philadelphia. During the winter of 1919-1920, the author observed the fungus causing distinct damage in a single field of lettuce at Sanford (Florida).

The fungus causes a very rapid decay and collapse of growing lettuce plants. The disease produced is almost identical with that caused by *Sc. Libertiana*. A soft, watery decay may begin at any point on the plant, but usually on the lower leaves, which rest on the ground, or on the stem near the ground. The rot spreads very rapidly and usually the main stem and bases of the leaves are soon attacked. The result is a rather sudden collapse of the whole plant which is rapidly converted into a soft, watery mass. When the decayed mass is pulled apart, the spaces between and around the decayed leaves and stem are found to be filled with white wefts of mycelium, which in a few days are replaced by numerous small black sclerotia. General observations indicate that the fungus possibly causes a rather more rapid decay and collapse of plants than is caused by *Sc. Libertiana*. The wefts of white mycelium in decaying plants are less conspicuous and the sclerotia are much smaller and much more numerous than in plants attacked by *Sc. Libertiana.*

On several occasions, portions of culture media covered with mycelium of the fungus have been placed on growing lettuce plants. When moist conditions have followed the inoculation, characteristic rapid decay has invariably resulted. H. H. WHETZEL found that the fungus was capable of attacking a large number of different plants.

As a result of 10 years experimental investigation, the author concludes that the fungus in question may be considered as a distinct species of *Sc. Libertiana.* As it seems to agree with no species hitherto described it is designated by the name of *Sc. minor* n. sp.

575 - **Bacterial Disease of the *Richardia*, in England.** — BEWLEY, W. F. (Experimental Station, Cheshunt), in *The Gardener's Chronicle*, vol. LXIX, No. 1787, p. 152, London, Mar. 26, 1921.

A disease of the Richardia which is causing serious losses to commercial growers of this plant is being investigated. The first symptom of the disease is the arrested development of the aerial portions. This persists for some weeks and is followed by a yellowing and withering of the leaves. The adventitious roots are brown and watery, finally becoming merely empty tubes, and the rot spreads into the corm itself, where local soft rots occur around the base of the roots. Finally, in an advanced stage of the disease, the greater portion of the corm becomes rotten, leaving only a healthy portion at the base of the leaves. Frequently eelworms (*Anguillulidae*) and spring-tails (*Collembola*) are present, but they are only secondary, the primary cause of the disease being bacterial.

The casual organism has been isolated and shown to be pathogenic. It is a bacillus, but apparently not identical with *Bacillus aroideae* Townsend, described as producing a rot of the leaves and corms of the *Calla aethiopica* (= *R. africana*). It is, however, identical with an organism which has been under investigation for some months, and which rots tomato fruits, potato tubers, turnips and cabbage stalks. The disease may be transmitted in drainage water and cow dung. Heavy watering assists the progress of the disease, while dry treatment helps the plants to recover. Once the disease symptoms appear it in advisable to give water only in the form of overhead dampings, and all diseased plants should be isolated at once. Preliminary experiments indicate that successful control of the disease may be accomplished by removing the corms from the soil and treating them with formaldehyde solution, mercuric chloride or hot water.

576 - ***Gloeosporium Bombacis* n. sp. a Melanconia Injurious to the Ornamental Malvacea, *Bombax insigne*, in Brazil.** — PUTTEMANS, A., in the *Bulletin de la Société de Pathologie vegetale de France*, Vol. VII, Part 3, pp. 74-75. Paris, 1920.

In a nursery-garden situated in the neighbourhood of São Paolo (Brazil), five or six specimens of *Bombax insigne*, which were 1 to 2 metres high, were attacked almost simultaneously by a disease causing the death of all the green shoots.

There appeared on the cortex of the green shoots, large irregular patches of a light-brown colour, which subsequently changed to a darker brown. Then, some rounded or oval bodies of a lighter shade and from 8-10 mm. in diameter developed at certain points; these soon proved to be the acervoli of a species of *Gloeosporium*, which the author regards as new to science, and has described under the name of *Gl. Bombacis*.

Later, the cortex of the plant became whitish and of an almost horny consistency; subsequently, some new shoots grew out of the lignified part of the stem which had remained healthy, a ring of wound callus having been formed.

These fresh shoots were in turn attacked by the parasite. The young plants would certainly have perished, had they not been carefully sprayed with Bordeaux mixture. It is also possible that the change which took place in the meteorological conditions helped to arrest the disease, which destroyed 10 % of the specimens it attacked, but has not again made its appearance.

577 - **The Effect of the Polyporea, *Fomes fulvus* on the Almond Tree in Italy.** — RIVERA, V., in *Le Stazioni sperimentali agrarie italiane*, Vol. LIV, Parts 1-3, pp. 114-118. Modena, 1921.

In the province of Aquila in the Abruzzi, old almond trees are often found to be attacked by *Fomes fulvus* (Scop.) Fries. The fungus is easily recognised by its conspicuous fructifications, which generally grow on the outside of the branches, and usually very near the points of pruning. Most of the trees that harbour the parasite appear withered; the branches on which the fructifications appear dry up first and, as a general rule, the whole tree soon afterwards dies. The wood shows signs of alterations that are often of a serious character, and are either limited to special zones, or extend over large areas affecting the cambium, parenchyma, vessels, fibres, and the cells of the medullary rays. In the first stage, these tissues turn black and later on, are replaced by a yellowish-white substance. The alteration of the wood proceeds from above downwards, and is most advanced in the portion of the branch bearing the fructifications of the parasite, and least in the parts at the greatest distance from it. In cases of serious infection, the wood is altered to such an extent, that its loss of weight and consistency renders it of little use, not only for timber, but even for fuel.

The mycelium of *F. fulvus* sometimes grows to an extraordinary extent, forming in the cambium zone, a thick continuous felt-like layer, easily detached from the wood.

Occasionally the fructifications of the fungus are absent. This happens in the less serious cases; if the tree is cut, only one or more inter-radial zones are affected, and usually the disease is limited to one branch, or part of the trunk; in such a case, the fungus lives at the expense of its own mycelium. According to observations ranging over a considerable time, the author thinks that he can affirm that the development of the mycelium in the host plant usually continues for some years, the fructifications only being formed when the tree is about to wither, and a difficult period is beginning for the parasite owing to the exhaustion or serious affection of its host.

There is another case in which the fungus brings about the death of the tree in a less direct, but no less inevitable manner. Sometimes almond-trees are uprooted because they are seriously infected by the fungus, or have died from its attacks, in which case, young trees are planted in their place, or within a radius of from 6-10 m., in order to fill up the gaps, and seem to do well for a variable number of years, when suddenly, without any symptom of disease, they die. As no mycelium is found on the roots of young trees succumbing in this manner, it can only be supposed that their death is due to some more or less toxic substance, which is not easily dissipated through the soil, and is produced by chemical changes taking place in the old, dead, and perhaps rotten roots, or else to substances produced either by the fungus or its host and which have remained in the soil during the life-time of the diseased tree.

As to the origin of the malady, and the way in which the fungus passes from tree to tree, it must be remembered that rows of almonds are regularly destroyed. This would seem, at first sight, to argue that the fungus finds entrance by way of the roots, but the long series of observations made by the author has provided another explanation of the phenomenon in question. As a matter of fact, the lower parts of the trees, and especially the roots, are the portions least affected, for the top of the tree suffers most from the parasite, the portion nearest to the fruits being chiefly selected for attack; hence this is the earliest seat of infection.

If it is also remembered that the fruits are the point of attack, and that almond-trees are generally pruned in rows, it can easily be seen that pruning operations are the most general means of spreading the disease, and of introducing the fungus into the tissues of its host.

The pruner with his infected knife passing from tree to tree actually inoculates healthy individuals with the disease. From the point of section, the mycelium would spread through the living culture medium provided by the tree itself, and would continue increasing for several years, only producing fructifications when its dying host rendered its existence precarious.

When once the almond-trees begin to wither owing to the attacks of the fungus, little can be done to save them.

An efficacious method of preventing the spread of the disease would, however, be to persuade the grafter to sterilise his knife either chemically, or by means of heat; in this way, the infection could not be conveyed during pruning operations.

WEEDS AND PARASITIC FLOWERING PLANTS

578 – **Common Weed Seeds Found Amongst Alfalfa Seed in New South Wales.** — See No. 493 of this *Review*.

579 – **Weed Control Measures in Canada.** — CUMMING, M., BRADT, E. P., ROY, L. P., HOWITT, J. E., and MCCAIG, J., in *The Agricultural Gazette of Canada*, Vol. VII, No. 6, pp. 484-488, figs 6. Ottawa, June 1920.

Report of the latest measures taken in the control of weeds by the municipal councils in conjunction with experimental work in the provinces of Nova Scotia, New Brunswick, Quebec, Ontario and Alberta.

Co-operative experiments in weed eradication have been conducted during the past 8 years with the Ontario Agricultural College. The results obtained permit the following conclusions:

1) Good cultivation, followed by rape sown in drills provides a means of eradicating both Perennial Sow Thistle (*Sonchus oleraceus*) and Twitch Grass (*Agropyron repens*).

2) Rape is a more satisfactory crop to use in the destruction of *A. repens* than buckwheat, and will act as a destructive agent to both *A. repens* and *S. oleraceus* to a greater degree when sown in drills and cultivated than when sown broadcast.

3) Thorough deep cultivation in the autumn and spring, followed by a well cared for hoed crop will destroy Bladder Campion (*Silene inflata*).

4) Wild mustard may be prevented from seeding in oats, wheat or barley by spraying with a 20 % solution of iron sulphate, without any serious injury to the standing crop or to a fresh crop of clover.

INJURIOUS INSECTS AND OTHER LOWER ANIMALS

580 – **Foreign Coleoptera Observed in Latium.** — LUIGIONI, P., in the *Atti della Pontificia Accademia Romana dei Nuovi Lincei*, 1 pp Rome, December 19, 1920.

In order to control the scale-insects *Diaspis pentagona* and *Aonidiella aurantii*, Prof. F. SILVESTRI liberated, in Rome, in 1910, several specimens of *Rhizobius lophantae*, an Australian coccinellid, which is a natural enemy of the two above-mentioned pests. No-one, however, has observed whether *Rhizobius* has become acclimatised and has increased in numbers. Beween the end of October and the end of November, 1920, the coccinellid was found in large numbers in a garden near Rome, but only on the leaves of the ivy and geranium.

The curculionid *Pantomorus* (*Aramigus*) *fulleri*, which is possibly a native of the United States or of Mexico, does injury to citrus trees and a number of other plants. The author found, early in October, 1916, two specimens of this insect in a garden in Rome, where it seemed so far to have done but little harm. Many other specimens of *Pant. fulleri* were discovered in October, 1920, in a garden on the outskirts of the same city.

Spermophagus subfasciatus (fam. *Bruchidae*), which was introduced accidentally with some beans from Brazil (1) was found, in 1917, in Sicily

---

(1) See *R.*, May 1918, No. 605. (*Ed.*)

(near Messina), and also repeatedly on the walls of houses in the centre of Rome ; it was also collected in summer in fields in the vicinity of the city

Coccotrypes dactyliperda, a native of Africa and of the East Indies, where it lives as a parasite on *Phoenix dactylifera, Areca Catechu*, and *Hyphaene thebaica*, has been found in many parts of Italy (in the Trentino it is said to attack the olives) and has also been met with occasionally in Rome, on the city walls. It has also been caught on the wing, at dusk, in villas in the suburbs of the town.

581 - **Fruit Flies Introduced into Egypt.** — ADAIR, E. W., in *The Agricultural Journal of Egypt*, Vol. X, pp. 18-20. Cairo, 1920.

The existence of 4 species of fruit flies. (Diptera, Fam. *Trypaneidae* syn. *Trypetidae*) has been reported in Egypt :—

1) *Ceratitis capitata.* Wied., on oranges, guavas, peaches, etc.

2) *Dacus longistylus* Wied., in *Calotropis procera.*

3) Undetermined species, collected from fruits of *Zizyphus Spina-Christi* coming from Assiout.

4) Undetermined species, collected from *Carthamus tinctorius*, coming from Ibrim in Lower Nubia ; this Dipteron probably attacks the terminal inflorescences.

Three other species have been obtained from imported fruit. None of these appeared to have existed in the country previously and as they are all very injurious, precautions should be taken to avoid their spread.

1) *Chaetodacus zonatus* Saund : a specimen of this dipteron has been collected from a damaged mango confiscated at Port Said.

2) *Dacus oleae* Gm. obtained from green olives sent from Cyprus to Alexandria; the sample was received October 30, 1916 and an adult emerged on January 20 the following year.

3) *Rhagoletis (Carpomyia) pardalina* Big., attacks Curcurbitaceae.

582 - ***Degeeria collaris*, a Dipteron Reported as a new Parasite of *Galerucella luteola* in Italy.** — THOMPSON, W. R., in the *Bulletin de la Société entomologique de France*, Year 1920, No. 10, pp. 180-184, 1 fig, 1 pl. Paris, 1920.

From adult specimens of the elm Galerucella (*Gal. luteola* Müll) collected in the spring at Bevagna, in Umbria, the author bred, at the end of May, 1917, numerous specimens of *Erynnia nitida* R. D. as well as a tachnid dipteron already known as an endophagous parasite of the larva and adult forms of the elm Galerucella, and also some individuals of a tachnid which was determined as *Degeeria collaris* Fall.

It is probable that the larvae of *D. collaris*, like those of *E. nitida*, over-winter in the body of their host. The larvae of the latter insect pupate in the remains of *G. luteola*, but those of *D. collaris* leave their host when they reach maturity and pupate in the open.

The article contains detailed morphological information respecting this new parasite of the elm Galerucella.

583 - **The Golden Backed Woodpecker (*Brachypternus aurantius*), Bird Useful in Agriculture on India.** — FLETCHER, T. B., and INGLIS, C. M., in *The Agricultural Journal of India*, Vol. XV, Pt. 5, pp. 481-484, pl. 1 (col.). Calcutta, Nov. 1920.

The Golden backed woodpecker (*Brachypternus aurantius*) is common in India and Ceylon.

Ants appear to constitute a large part of its normal daily food, which consists almost entirely of insects; in addition to the ants, it feeds also on numerous small beetles, caterpillars and bugs, and occasionally on buds and fruits.

An examination of the stomachs of 16 birds captured at Pusa showed 3921 insects of which the great majority were ants, and it is notable that only one of these 16 birds was found to contain any longicorn beetle larvae, although observation renders it certain that this bird does feed to some extent on wood boring insects. In Eastern Bengal it is stated to feed on the larvae and pupae of *Hoplocerambyx spinicornis*, a longicorn borer pest of sal (*Shorea robusta*), and in Madras it is stated to be very partial to toddy-palms, which may be due to the fact that these trees are infested by *Oryctes rhinoceros* and *Rhynchophorus ferrugineus*. At Pusa many of the dead branches of *Dalbergia Sissoo*, tapped by this woodpecker, are infected with the termite *Coptotermes heimi* which probably provides a certain amount of nourishment to the bird.

Although not much is yet known of *B. aurantius* from the biological aspect, it is only right to include it amongst the useful birds from the agricultural standpoint.

In Bengal, Burma, Madras, Bombay and Assam, this bird is protected by law throughout the whole year.

584 - **"Tanglefoot," a Means of Controlling *Operophthera* (*Cheimatobia*) *brumata* and *Hibernia defoliaria*, Macrolepidoptera Injurious to Fruit Trees in France.** — PAILLOT, A., in the *Comptes rendus des séances de l'Académie d'Agriculture de France*, Vol. VII, No. 10, pp. 274-277. Paris, 1921.

In the Rhone Valley, as in many other parts of France, the caterpillars of *Oparophthera* (*Cheimatobia*) *brumata* do great injury to the fruit trees. A method of controlling these pests which has long been adopted in the valley, consists in placing round the trunk, at a man's height, a band of viscous substance which prevents the wingless females from ascending the tree for the purpose of laying their eggs. Most of the mixtures used have a tar basis, and have the defect of drying too rapidly; further, they are harmful to the trees, and so cannot be directly applied to the cortex of the plants requiring protection.

Since November, 1918, the Entomological Station of Saint-Genis-Laval (department of the Rhône) has been making experiments with an American speciality known as "Tanglefoot," which is widely used in the United States. The first trial of this viscous mixture was carried out by applying it to the trees of the Station garden, which had all been injured to some extent in the spring by the caterpillars of *Op. brumata*, and also by the larvae of *Hibernia defoliaria*. "Tanglefoot," being innocuous to the tree, can be directly applied to the cortex, which greatly simplifies the operation, by means of a wooden spatula; the layer must be sufficiently thick, and the width of the band should be about a hands-breadth. It is reckoned that a vessel containing 1 kg. is sufficient for the protection of twenty tree-trunks of average girth. The trees upon which the experiments were made remained quite immune from the attacks of *Op. brumata*, not only for the next year, but also for two subsequent years.

With a view to determining the real value of "Tanglefoot", a large number of experiments were carried out against *Op. brumata* and *Hib defoliaria* in 1920, in the Departments of the Rhône and of the Drôme, as well as in the northern part of the Department of the ardiche. The results proved that "Tanglefoot" is the most perfect viscous mixture at present known. Its use should be encouraged and popularised in all districts where much injury is wrought by *Op. brumata* and *Hib. defoliaria.*

In every case, not only the females but also males of both macrolepidoptera were captured by means of the viscous bands; the proportion of males being always very large, although they are provided with normal wings

"Tanglefoot" might be purchased by a Cooperative Society formed for the purpose, or by syndicates or other agricultural organisations. In the latter case, it would be necessary to make joint purchases, in order to reduce the cost of carriage and insurance. The question of direct State assistance in the form of exemption from Customs Duties might also be taken into consideration.

585 - ***Pyrausta nubilalis*, Microlepidopteron Injurious to Maize, and *Stilpnotia salicis*, Microlepidopteron Injurious to Poplar Trees Two new Insect Pests Recenty found in Canada.** — Mc Laine, L. S., (Division of Foreign Pests Suppression, in *The Agricultural Gazette of Canada*, Vol. 7, No 10, pp. 793-794. Ottawa Oct 1920)

On August 10, 1920 at Lorraine Station, Welland County (Southern Ontario), some suspicious looking larvae were found infesting maize. The caterpillars were small and the amount of damage done was light. Searches were made eastward and along the shore of Lake Erie and it was noticed that the intensity of attack increased until it was finally centred in the vicinity of Ridgeway and Crystal Beach. Specimens were identified as the European maize borer, *Pyrausta nubilalis* Hubn (1). According to the latest reports the infested area extends from Fort Erie on the east to Dunnville on the west along the Lake Erie shore, and about 20 miles inland On August 23, samples of caterpillars also proving to be *P. nubilalis*, were reported on the maize in the vicinity of St. Thomas; 5 % of the plants in the fields examined were found attacked by the pest. Judging from the search work results up to September 5, this second (St. Thomas) outbreak was more intensive and widespread than the first, and extended from Straffordville (Elgin County) on the east to Rodney on the west, and Strathroy on the north.

---

(1) See *R.*, Oct.-Dec. 1919, No. 1289; *R.* Apr. 1920, No. 474. (*Ed.*)

[584-585]

In the latter part of July, 1920, an outbreak of caterpillars was noticed in New Westminster B C. A collection was made, the moths reared and adults of the satin moth (*Stilpnotia salicis* L.) were obtained (a pest already well known in Europe and Asia which often severely attacks poplars and willows). The first record on the American Continent was, made in the spring of 1920, when it was discovered in the vicinity of Boston (Massachusetts).

586 - **The Bean Weevil (*Acanthoscelides obtectus*) in Austria** (1) — TSCHERMAK, E, in the *Wiener Landwirtschaftliche Zeitung*, Year LXXI, No. 17, pp 102, 6 figs. Vienna, February 26, 1921.

The presence of *Bruchidius obtectus* (= *Acanthoscelides obtectus*) was observed for the first time at Vienna by the author in 1918, when he only found three beans attacked by the insect

In 1919, the weevils were somewhat more numerous, but still only a few seeds were affected. In 1920, the bean-crops were infected by these pests, the attack being quite unexpected. Beans in the neighbourood of Vienna suffered in the same way, especially the white varieties, the coloured varieties being less attacked.

The author mentions the control measures usually adopted against this coleopteron.

587 - ***Pectinophora gossypiella*, Microlepidopteron Injurious to Cotton in Montserrat and St. Kitts, West Indies** (2) — *The Board of Trade Journal and Commercial Gazette*, Vol CVI, (New Series), No. 1266, pp 239-240 London, March 3, 1922.

The Pink Boll worm (*Gelechia gossypiella* = *Pectinophora gossypiella*) was found in cotton plantations on November 5, 1920, in Montserrat, and on November 15, in St. Kitts. These are the first recorded occurrences of this pest in the West Indies.

Investigations proved that the pink boll worm has not been found in Antigua and Nevis; in Montserrat and St. Kitts, it is, however, now well established. The distribution has followed very much the same lines on each of these islands. Apparently introduced at or near the port, the insect has spread considerably to the north along the western coast; it has spread but little to the south and east.

Only one theory so far appears to furnish an explanation of this invasion. This concerns a steam-ship coming from Brazil and having a cargo of Brazilian cotton and cotton seed (this has not been fully authenticated). During the first fortnight of June 1920, the ports visited were in Montserrat, St. Kitts and Antigua. Just at this time there would have been cotton growing near the sea in a suitable condition for pink bollworm attack, these coming from the caterpillars in the seed in the ship's hold. At Antigua, however, there would only have been a small amount of cotton near the anchorage, and that was old cotton, which was being destroyed at that time. The new crop was not planted in that part of Antigua until August.

---

(1) See *R.* May, 1918, Nos. 605 and 606. (*Ed.*).

(2) See *R.* March 1919, No. 405. (*Ed.*)

Allowing about 4 ½ to 5 weeks for each generation of *Pect. gossypiella*, there would have been time for the development of some four or five generations of pink bollworm from the time of its introduction in June until its discovery in November.

The spread has been almost entirely with the wind or across its prevailing direction, and very little against it.

Several measures of control have been suggested and the advisable precautions which should be taken in districts so far unattacked.

588 - **Studies on the Life-History and Habits of *Eutettix tenella*, the Beet Leafhopper, in Idaho and California.**— STAHL, C. F., in *Journal of Agricultural Research*, Vol- XX, No. 4, pp. 245-252, pl. 2, bibliogr. of 7 publications. Washington D. C. 1920.

Summary of observations bearing on the life history and habits of the beet *Eutettix tenella* Baker (Fam. Jassidae) made during the past few years at Jerome, Idaho, and in the sugar beet growing regions of California.

A description is given of the egg, nymph and adult stages; there is little difficulty in distingiushing the beet leafhopper from certain species of *Agallia* and *Cicadula* 6-*notata* Fallen, although there is a distinct resemblance between *E. tenella* and these species.

E. tenella deposits its eggs on various plants (*Salsola Kali* var. *tenuifolia*, *Erodium cicutarium* and *E. moschatum*, *Chenopodium* spp. and *Atriplex* spp.); it, however, apparently gives preference to the sugar beet. The maximum number of eggs deposited by one female alone was 247. The incubation period ranges from 10 to 15 days, and the nymphal period from 25 to 52 days.

There was only one brood in Southern Idaho, but in California two and even four generations have been notified.

In Southern Idaho the earliest record of the leafhopper in the cultivated sugar beet fields was in June; oviposition begins as soon as the adults appear and continues throughout the season. After the crop is finished, the hibernation period commences.

In California, the leafhoppers first appear in the spring, about April 1, and continue until cropping time; attention is directed chiefly towards wild vegetation. There is no true hibernation in the districts of California under observation.

The following three species of egg parasites have been reared and studied (given in order of importance): *Polynema eutettixi* Girault, *Abbella subflava* Girault, and *Anagrus giraulti* Crawford. As parasites of the nymphs and adults two species have been reared *viz. Pipunculus industrius* Knab., and *P. vagabundus* Knab; and the first of these was quite effective. Dryinid parasites, also were reared but are considered of negligible importance from the economic standpoints.

589 - **Enemies of the Edible Date in India.** — See No. 507 of this *Review*.

590 - ***Hemerocampa pseudotsugata*, New British Columbia Tussock Moth Injurious to Douglas Fir (*Pseudotsuga Douglasii*), in British Columbia.** — Mc DUNNOUGH, J, in *The Canadian Entomologist*, Vol. LIII, No. 3, pp 53-56. London, March, 1921.

A macrolepidopteron determined by E. H. BLACKMORE (1918) as *Hemerocampa vetusta gulosa* Hy. Edw. has been reported during the past few years, as damaging the Douglas fir (*Pseudotsuga Douglasii*) in certain districts of British Columbia.

A number of eggs of the species was collected in the spring of 1920 at Chase, B. C. and from these a limited number of adults were obtained at Ottawa. These were fed until half grown on hemlock (*Tsuga canadensis*) and were then transferred to *Ps. Douglasii*. The moths emerged in the first week of July, an earlier date than that given by BLACKMORE.

After close observation of the different stages of development of the macrolepidopteron in question, the author was led to consider this a new species which he described in detail under the name of *Hem. pseudotsugata.*

591 - ***Pissodes notatus*, Coleopteron Injurious to Pines in Uruguay.** — TRUJILLO PELUFFO A, in *La Propaganda Rural*, Yr. XIX, No. 410, pp. 2. Montevideo, 1920.

In various pine forests along the coast of Maldonado (Uruguay), a small insect has been notified which has caused damage to young plantations leading to the loss of thousands of trees. Although the plantations suffered considerably, groups of five or six trees were left standing.

A visit to the district, made on September 4, 1920, resulted in observations giving evidence of the fact that on the trunks of several pines showing signs of obvious injury or already dried up, were certain larvae. These, on transportation to the laboratory for breeding purposes, changed to nymphs (the first were observed on September 18) and later (October 6) to perfect insects, which proved to be the Curculionidae *Pissodes notatus*.

On a second visit made on October 9, the insect was found again in the nymph stage in other pine forests.

It seems probable that the Coleopteron in Uruguay produces two generations per year

As a means of control, it is recommended to root up all the wasted trees and those on the verge of wasting as the coleopteron shows a marked preference for trees already weakened for other reasons. When a plantation has been attacked by this insect, it is advisable to carry the uprooted trees to a selected spot, and construct a fire in such a manner as to thoroughly burn the bark and destroy the parasites which are hidden therein. Trunks thus treated may be used afterwards for various purposes.

The Agricultural Institute of Algeria

By M BRUNEL

Director General of Agriculture, Commerce and Colonisation, Algeria

(*Communicated by* M LOUIS-DOP, *Delegate for Algeria, Vice President of the Institute*).

At a time when everyone recognises the prime importance of intensifying agricultural production by rational improvement of the soil, with the object of re-establishing economic equilibrium in the world, and, consequently, the necessity of extensive technical instruction for agriculturists, especially those in the Colonies, the *Agricultural Institute of Algeria* merits especial notice.

This Institute originated in the conversion, unanimously asked for by the Algerian Assemblies in the Session of October, 1920, of the institution founded in 1905 at Maison-Carrée (Algiers) under the title of "École d'Agriculture algérienne"

It seemed indeed that the new name was more suited to the functions of the institution as it had to deal with both teaching, agricultural experiments, and the diffusing of agricultural knowledge. It perpetuates, at the same time, the progress made by the institution since it reopened after the war, in October, 1919, and the standard of the education there given

Regarding the progress made by the School itself it suffices, so as to show its importance, to record that it had 211 pupils on its books from 1905 to 1914, an annual average of 23, whereas in 1919 and 1920 there were 152, or 76 pupils in each year. It should further be noted that in that number, besides 65 pupils of Algerian origin, there was an almost equal number — 64 — of young men from the mother country as well as 23 foreign students (Swiss, Italian, Greek, Russian, Syrian, etc.).

By its situation, equipment and organisation, and thanks to the staff of distinguished scientists and technicians which it has been possible to provide, the Institute in question ranks indisputably among professional agricultural institutions of the first class.

The following description of the principal characteristics of the Institute will be of interest:—

AIMS. — The Agricultural Institute of Algeria provides the theoretical and practical instruction necessary for the scientific working and management of a country estate or an agricultural industry in North Africa, or in other countries in the Mediterranean basin; it also trains the pupils for settling in distant possessions. It appeals especially to young men from Algeria, France, or other countries, who, either on their own account or in the employment of others, wish to engage in agriculture in Algeria or in the neighbouring protectorates.

It is quite equally suitable for those who may have to practice husbandry in regions with a climate similar to that of North Africa, regions which occupy, as is well known, immense areas in various parts of the world. Greece and the other Balkan States, Syria, Egypt and Turkey, in particular, have every interest in sending students in increasing numbers. To these regions, so prosperous and populous in olden times, called to a brilliant renaissance thanks to Latin genius and modern science, this institution is a means of providing the expert young agriculturists which will be so greatly needed

Its very wide curriculum makes it moreover a real school of general colonisation. To young men who have passed out of Schools of Agriculture in France or in foreign countries and who wish to familiarise themselves with the special conditions of North African agriculture, to those who being no longer of an age and, though lacking the time for complete study, are, however, desirous of passing a period in a new environment, the Agricultural Institute at Maison Carrée provides the means of getting in touch with the country in conditions and an environment which are rarely to be found in a private farm.

SITUATION. MEANS OF STUDY. EQUIPMENT. ANNEXES. — Placed on the plateau which dominates the town of Maison-Carrée (12 000 inhabitants), 2 km. from the sea, in excellent conditions of hygiene and salubrity, the Agricultural Institute is situated only twenty minutes from the centre of the town of Algiers, at the opening of the rich plain of the Mitidja, at the junction of the railways which leaving Algiers lead, to the West, towards Oran and Morocco, and to the east towards Constantine and Tunis. It thus occupies the centre of that North Africa, so fortunately placed, of which Algeria will continue to be the jewel Near the Institute are situated important estates provided with the most up-to-date equipment, the celebrated vineyards of the Mitidja plain and the hills of Sahel, extensive nurseries of American plants, the magnificent orange gardens of Blida and Boufarik, the celebrated Chasselas vines ot Guyotville. In the neighbourhood there are also many factories that are closely connected with agriculture, notably large flour mills, chemical and fertiliser factories, distilleries, a large brewery, a sulphur refinery, brick-fields and potteries, to which have been quite recently added a wool cleaning factory and a very important cold store capable of dealing with more than 2500 sheep a day.

Taking into consideration the close proximity of the town of Algiers with its immense intellectual and scientific resources (University, Pasteur-Institute, Museums, Libraries and Laboratories of all kinds, Agricultural and Geographical Societies, College of Commerce and Hydrography, commercial and industrial courses, etc.); adding that the pupils of the Institute at Maison-Carrée can imbibe numerous lessons in the great North-African port situated in the centre of the great Mediterranean route at equal distances from Gibraltar, Malta, and Marseilles, from the Suez Canal and Northern Europe, port of call for the numerous shipping companies which serve the Levant and the Far-East, which became before the war the second largest French port in tonnage and for whose enlargement an expenditure of 200 000 000 francs has just been provided, it can not but be recognised that the environment could not have been better chosen for the training of well informed cultivators.

The material equipment of the Institute is not a whit behind its situation. It has all the premises and arrangements required for internal students and is equipped with the latest hygienic improvements. Sixty boarders can be comfortably housed. In addition, the Management is anxious to build a " Maison de famille " to which would be admitted, under similar conditions to those of the boarding house of the Institute, such day students as desired admission.

The facilities for study available at the Institute are considerable and perfectly adapted to the required ends.

The teaching given at the Institute closely resembles that of the French National Agricultural Schools or of foreign higher-grade institutions for agricultural teaching, but of course it is specially adapted to the special conditions in view of which it was founded.

There are 29 professorships held by 17 professors or assistant professors on the permanent staff of the Institute, all well-known specialists; and there are 12 professors on the external staff, professors at the University of Algiers or members of the Management. Applied and practical work is ensured by 6 " chefs de travaux " under the direction of the competent professor. The professors are provided with laboratories where the pupils are trained in research and manipulation: — Laboratories of Chemistry and Oenology, of Physics and Technology, of Agricultural Geology, Mineralogy and Chemistry, of Botany and Plant Pathology, of Agriculture, of Seed-Testing, of Viticulture, of Agricultural Zoology, of Zootechnology, furnished with varied collections of material required for analyses and micrography and also photographic studies.

There is also a meteorological Station at the Institute and, assisted by the Laboratory of Botany and Plant Pathology, it will serve as a basis for the organisation of a service of agricultural weather-forecasting. Special mention should be made of the teaching of Farm Engineering each of the various branches of which (Agricultural Machinery, Hydraulics, and Farm Buildings, Electrotechnology, Surveying and Levelling) is taught by a special professor.

The material means of study on which this teaching is based includes: A Laboratory of Agricultural Machinery with rooms for testing engines and machinery and an exhibition hall 600 sq. m. in area; very extensive work shops where the pupils are trained to make repairs and work iron and wood; and the equipment required for the Professorships of Mechanics, Electrotechnology, Hydraulics and Farm Buildings which are arranged in the adjacent premises.

The whole building, which has just been finished, constitutes a very important Station of Farm Engineering to which are attached, in addition to the four professors already mentioned, assistant and working instructors (these latter for the necessary manual labour).

The increase in mechanical tillage has led the Institute to add an Apprenticeship School for Farm Mechanics, and to establish a Practical Centre of Mechanical Tillage at its estate at Berteaux (see below) with the object of accustoming its pupils to the handling and driving of power-farming machinery over large areas

Besides the lecture rooms and three amphitheatres (one of which can hold 300 pupils), the Institute has at its disposal, for teaching, purposes, extensive Libraries which receive a very large number of agricultural and scientific journals and publications.

The pupils of the Institute are familiarised with all forms of agricultural work on 3 estates of a total area of over 500 hectares which the Institute owns, 80 hectares at Maison-Carrée, with vines, fodder crops, market garden, botanic garden; 15 hectares at Rouiba, with experimental vineyard, and orange garden; 425 hectares on the high plateaux of the Department of Constantine at Berteaux:— farming on a large scale, dry-farming, breeding, power farming).

ORGANISATION OF STUDY AND INSTRUCTION. — The Agricultural Institute of Algeria has adopted a curriculum which permits of complete instruction being given to its pupils in two years

The pupils enter for the first year's course at Maison-Carrée on October 1. The course commences with the revision (with essential complementary instruction) of subjects, the knowledge of which is essential for understanding the technical courses, and by a rapid study of generalities (physics, history, politics and economics) relating to North Africa and other regions in the Mediterranean basin. The courses constituting agricultural instruction proper then follow in rational order up to the end of the course.

Thr first year studies are suspended about June 15 to enable the pupils to go to the annexe at Berteaux for a period of practical instruction.

To prevent the number of pupils from making teaching difficult, the following arrangement has been adopted:— At the end of the first year the pupils are divided into two groups:— In the first those who have already carried out reaping and threshing or who can do so with their relatives or on private farms; in the second the remaining students.

The first group begins the vacation on or about June 10. — The pupils in the second group go on that date to the annexe, where they take part for about six weeks in the work of reaping and threshing, in mechanical tillage and all other work done at this season.

The pupils of this group then have their holiday until early in September Those who so desire are permitted to prolong their stay at the annexe during the month of August on condition of making themselves useful on the estate.

During September, the pupils of both groups, either singly or in small sections, go under the direction and control of the professor concerned, and take part in the gathering of the grapes, and wine-making, either in co-operative cellars or with private persons.

When this new period is ended the second group goes on holiday while the first group goes to Berteaux to take part in the seasonal work (ploughing, sowing, etc.), mechanical tillage and other work already done by the second group.

By helping in the farm work at the annexe when there is much to do, the pupils live the life of colonists and receive the most practical of lessons. They learn, by use, the handling of implements and machinery, the driving of teams and the care of various animals; they are initiated into the keeping of farm accounts, the cost of materials and of work, the management of a farm; in short they learn for themselves the practical difficulties which the farmer has to deal with. About November 15, the two groups of the year meet at Maison-Carrée to take their second year's course which ends on July 13.

When going from Maison-Carrée to Berteaux and *vice versa* as well as during their stay at the annexe, the pupils visit as many interesting farms and installations as possible in the eastern part of Algeria and the corresponding southern territory (oasis of Biskra-Touggourt).

For the Easter holidays are substituted one or more excursions in the second year, as much as possible in the west of the Colony so that the pupils visit the various agricultural regions of the country while under training. These tours are both useful and pleasant and form an excellent preparation for colonial life; as may be imagined, they are much appreciated by the pupils.

Besides these long excursions, numerous and varied shorter excursions are made under the supervision of professors appointed for the purpose.

Owing to this rational succession of periods of study and application and of essentially practical work which characterises the organisation of the course at the Agricultural Institute of Maison-Carrée, the Institute, without overworking the pupils, gives them a very complete technical and professional training.

They are thus initiated into the theory and practice of the colonist's work, thus answering the objections of those who consider that an Agricultural College should leave the students to learn practical agriculture after leaving the College so as to avoid subjecting them, during the theoretical course, to physical fatigue and to a prolongation of the time spent at the College, which would be a consequence of the introduction of practical work into the syllabus.

A judicious distribution of the examinations makes it possible to avoid the sudden stops, extremely deplorable for the training of the students, which are caused, in most teaching institutions by grouping these tests at the end of the academic year. The adjournment of the commencement of the second year also enables the students to profit by their stay at Berteaux, in the co-operative cellars and even the holidays for the revision of related subjects.

The students are required to carry out work themselves and this furnishes the best criterion of their power of judgement and sound appreciation of agricultural questions. The students who pass all the tests required by the regulations receive: —

1) The diploma of the Agricultural Institute of Algeria in the case of those who in the final classing obtain an average of not less then 13.

2) The diploma of Engineer of the Agricultural Institute of Algeria in the case of those who obtain an average of not less than 15, and with no mark below 13 in the final examinations.

The first six students of each year are admissible, as boarders or day students at their option, for a third year course either in the laboratories of the Agricultural Institute where they complete their studies and may even help as assistants, or at the Colonial School of Arts and Crafts (now established at Dellys while awaiting transfer to Maison-Carrée), where they learn the application of the industrial arts to agriculture.

The students of the Agricultural Institute of Maison-Carrée can also put in a period either at the Hamma Experimental Garden with a view to perfecting themselves in horticulture and arboriculture, or at one of the Experimental Stations which are in course of organisation in the Algerian departments and even in the Southern Territories. During these periods they are lodged and may be paid a remuneration proportional to their services.

Lastly, their admission to the National Colonial Agricultural College (at Nogent-on-Marne, Seine) enables them to acquire supplementary knowledge of a kind which facilitates their establishment and success in distant possessions.

OPENINGS OFFERED TO THE STUDENTS. — The particularly rapid progress of French North-Africa, the unlimited scope and the profitable investments which — from Gabes to Agadir — it offers to work and capital and the special attraction which it has to all those who have lived under its sky and experienced active life in its fields, still imperfectly developed, have, up to the present time, led most of the students of the Agricultural Institute of Maison-Carrée to settle there.

Thanks to the good professional training of these young men, Algeria, and the Protectorate of Morocco especially, offer them almost unlimited openings such as the management or establishment of farms, situations as agents and stewards, various situations in agricultural industries (wine-making, distillation, manufacture of oils and essences, preservation of food stuffs, dairying, etc.), as well as in numerous branches of commerce and industry in which knowledge acquired at the Institute (agricultural machinery trade, chemical products and fertilisers, hides, and wool, etc) can be utilised.

Syria also appears to offer an interesting field of work to energetic and enterprising former students of the Institute

According to the orders of the Governor General dated March 26, 1915, and in compliance with the provisions of the Decree of September 12, 1904, which makes adequate agricultural knowledge one of the conditions for obtaining free grants of land for settlement in Algeria, the diplomas of the Agricultural Institute of Maison-Carrée constitute a supplementary title which the Government will take into serious consideration when inquiring into the records of the applicants for a grant of land. Just as Morocco at present finds the fundamental elements of its colonisation, in the Algeria-Tunisian Colony, so, there is reason to think, with the protagonists of the "African Railway", that from the day — doubtless very near — when Northern Africa will be united by rail to other French possessions in Africa, its colonists will be attracted towards the Niger and the Congo, just as the Americans journeyed from the Atlantic coast right out to the Far West, and there is even in this direction also an interesting prospect of openings for the technicians trained at Maison-Carrée.

Although the Agricultural Institute of Maison-Carrée interests itself in directing its pupils towards undertakings due to private initiative, a certain number of them can also obtain situations in the Public Services of North-Africa, particularly those requiring agricultural knowledge (agricultural laboratories and services, farm engineering, tobacco growing service, topographical service, etc.).

A number of young students will thus find a means of acquiring a more complete knowledge of the country, while making a livelihood or while waiting until they are able to set up as farmers.

Lastly, in terms of the Decree of October 22, 1916, posts in the General Agricultural Service of Algeria are reserved for Candidates with diplomas of one of the French Agricultural Colleges or of theAgricultural Institute of Algeria.

RECRUITMENT AND ADMISSION OF STUDENTS. — The Agricultural Institute of Maison-Carrée recruits its students from those who have finished their course in the higher primary schools, establishments of secondary teaching (at least up to the first class) or the technical agricultural schools of France or of foreign countries. It cannot be too strongly recommended to parents who wish eventually to send their children to the Institute, to give them a good general education, which alone can supply solid and lasting foundations for professional instruction. Candidates must be fully 17 years of age at their entrance.

Admission can be allowed either after a competitive examination held yearly about July 10, or exceptionally without competition.

The competitive examination is entirely written, and can be taken in France, Algeria, Tunis, Morocco, in other Protectorates or Colonies (principal centres) as well as in foreign countries (French Consulates).

On the other hand, candidates who qualify for admission to National Schools of Agriculture, by the holding of the Baccalauréat or of a Higher Certificate of primary teaching or else who possess equivalent qualifications, may be admitted without competition up to the commencement of the academic year. Foreign candidates have to fulfil all the same conditions as to entrance as French subjects. They can also obtain admission to the Agricultural Institute of Algeria on production of degrees or diplomas of their native country equivalent to those required from French candidates.

In short, the Agricultural Institute of Algeria, by its situation, its equipment — for which considerable sacrifices have been agreed to in the Algerian budget — the qualifications of its teaching staff, the wide and remarkable means of study which it places at the disposal of its students, the high standard of its teaching and the perfect adaptation of this to the special conditions of agriculture in the North of Africa and regions with a similar climate, the variety of openings offered to its students, and by the low rate at which the cost of living is kept, deserves to be brought to notice.

An institution of agricultural teaching which can compare favourably with the most famous of similar estalishments in France or foreign countries, an agency for experiment and diffusion of knowledge, the importance of which is bound to increase as its work extends, the Agricultural Institute of Algeria — which is, moreover, an excellent instrument for colonisation — constitutes one of the most interesting of agricultural centres, and is destined to a most promising future.

SECOND PART
ABSTRACTS

AGRICULTURAL INTELLIGENCE

GENERAL INFORMATION

592 - **Agricultural Development of the State of Matto Grosso, Brazil.** — BECCARIA D'INCISA, J., in the *Annales da Sociedade Rural Brasileira*, No VIII, pp. 459-463, 2 figs, 1 map Rio de Janeiro, Feb. 1921

The State of Matto Grosso, which promises a rapid economic development, attracts ever increasingly the attention of scientists and practical persons, as well as the capital and the energy of several contractors helped by the intelligent, co-ordinating work of the President of the State, Don Francisco DE AQUINO CORREÃ.

The industrial future of the State is assured by its richness in minerals such as antimony, platinum, tin, iron, argentiferous lead, copper, mercury, lead, etc., and by the great waterfalls which can be used for powerful hydro-electric installations. In the south, on the Rio Paranà, a short distance from Tres Lagoãs, are the falls of Orobú Pungà, which could develop 650 000 HP, and on the border of Paranà, the " Sete Quedas ", able to furnish an estimated total of 8 million HP.

Agriculturally, the natural, ever-verdant pastures, the plains of the Paraguay and of its tributaries (whose pastures are enriched and fertilised every year by periodic inundation) and the plains of Vaccaria rival in fertility the Nile alluvions.

The State of Matto Grossl (1 556 275 sq. km.) is covered with immense forests, rich in copaiba, ipecacuana, coconut palms, cacao trees, etc., which only need labour to be suitably worked. Sugar cane gives spendid results throughout the country, and canes whose productivity is prolonged for 20 years are not infrequently met with. Sugar factories in fairly large numbers are already in existence along the Paraguay and the Cuyabá.

Tobacco, palms, bananas, maize (which grows to a height of 5 m.), cotton (which assumes an arborescent habit), lemon trees, orange trees, vines, vegetables, rice (which yields 2 crops a year) constitute a variety of sources of wealth which are, as yet, scarcely utilised. Coffee appears to give excellent results, better perhaps, in some zones than those of San Paulo, An enormous number of indigenous fruits make up the flora of Matto Grosso. Yerba Maté (the leaves of *Ilex paraguayensis*) is the monopoly of the Campanhia Matte Laranjerà which pays the State very high royalties.

The cattle of Matto Grosso, universally prized, belong to the Caracu and Zebu breeds. The improvement of these breeds has now been commenced by crossing them with breeds imported from Europe and the United States.

The following data of exports during 1904, gives an idea of the importance of cattle breeding:—

Coxim	800	head
S. Anna de Parahybo	71 291	»
S. Rita de Araguaya	1 895	»
Tres Lagoñs	376	»
Noroeste do Brasil	938	»
São Carlos	3 072	»
Porto Murtinho	3 777	»
Bella Vista	5 148	»
Ponta Porà	4 546	»
Nhú Verá	819	»
Porto Jguatemy	1 345	»
Porto XI de Novembre	34 090	»
	128 097	head

The chief breeding establishments are in the south and in the north; the following are some of the best known:— São João de S. Anastasio, Col. Barros, Miranda, Estancia Cia Ltda, Bandeira, Descalvado, Franceza, Porto Alegre, Joffre, Triumpho, and several others.

For sheep breeding, the establishment of Tres Barras, near Porto Murtinho on the river Paraguay, is well known.

593 - **Food Ration and Vitamines.** — DESGREZ, A. and BIERRY, H. in the *Comptes rendus des séances de l'Académie des Sciences*, vol. 172, No. 17, pp. 1068-1071. Paris, April 25, 1921.

On a previous occasion the authors investigated the specific food requirements of the organism (1) and basing their experiments on the indispensable factor of nitrogen balance they first inquired within what limits isodynamic nutritive principles could replace one another without injury to the organism, that is to say be physiologically equivalent.

Experiments on rats placed on synthetic diets deficient in vitamines showed that nitrogen equilibrium could be ensured, for a certain time, by fixed proportions of proteins, sugars and fats, in a given ration of sufficient energy value; that the minimum of each of the three elements depends on the chemical structure and the proportion of the two others; and, lastly, that the minimum of nitrogen is reached when a high percentage of a carbo hydrate is present in the ration.

What happens to an animal receiving a well balanced ration when one of the constituent elements of that ration is suppressed, while the percentage of the two others, or of one of them only, is raised in parallel, in proportion to the calorific power? This was the question which the authors investigated in the further experiments dealt with in this paper.

---

(1) See *Comptes rendus de l'Académie des Sciences*, vol. 171, 1920, pp. 1209 and 1393: *R.* July-August, 1920, No. 712. (*Ed.*)

Comparing these experiments with those of MAC COLLUM and DAVIS, DRUMMOND, and HINDHEDE (2), it appears that, on the one hand with food deprived of fat, containing only albumins and carbo-hydrates, but rich in vitamines, the growth of the young animal and equilibrium of the adult can be ensured, and that, on the other hand, in avitaminosis (lack of vitamines), the nitrogen-balance can only be maintained if the constituents of the ration are all present in certain proportions in the diet.

It must, then, be admitted that the quantities of the complementary factors *A* (fat soluble), *B* (water soluble) and *C* (antiscorbutic), required by the organism, vary not only with the kinds of food, but also with the proportions of these kinds present in the ration; it must equally be admitted that each kind of food exercises a functional rôle, in the chemical sense of the word, in the intermediate metabolism of the two others.

Already the fact that no substitution can exist between carbohydrates and fats, compared with the same albumen, and that the catabolism of certain aminic acids and fatty acids (cetogenic) is regulated by the sugars, indicated the importance of the chemical function and structure of the food. As the splitting-up of the proteins, sugars and fats comprise simultaneous phenomena, giving rise to products reacting on one another, it must be admitted that if, by the contribution of nourishment, these combinations are ensured, the reserves enter little or not at all into action. Different processes probably result, brought into action by the organism; some of which require the more or less essential assistance of vitamines.

594 – **Poisoning Caused by Vetch Seeds.** — See No 641 of this *Review*

595 – **Bovine Foot and Mouth Disease is not Transmissible to Man, and Human Aphthic Stomatitis is not Transmissible to Cattle.** — See No 644 of this *Review*

596 – **Work of the Agricultural Department, Dominica, West Indies.** — KEYS A., in *Royal Botanic Gardens, Kew, Bulletin of Miscellaneous Information,* No 2, pp, 67-85 London, 1921

The Agricultural Department of Dominica started as a Botanic Station 28 years ago and since then has made rapid progress in many ways.

The author gives a descriptive account of the work done by the Botanic Gardens from the economic aspect, and of various experiments and methods adopted as regards agricultural instruction in connection with the Department

---

(2) See *R*, Apr 1916, No 415, March, 1917, No 260, June, 1917, No 556, Jan. 1918, N° 2, Feb 1918, N° 125, Aug 1918, N° 34, Jan 1919, No 6, Oct-Dec 1919, Nos 1068 to 1072, Jan, 1920, Nos 3, 4 and 5, Feb 1920, No 157; Apr 1920, Nos 380 to 382 (*Ed*)

A survey of the collection of flowering trees and shrubs, palms and other ornamental plants such as *Pandanus* spp. Bamboos, Conifers, Succulents, etc. now in the Botanic Gardens, is made, followed by details of the economic section in the said Gardens. The latter collection comprises most of the principal economic plants in the tropics. Several kinds of coffee are grown, the two principal vanillas, cola nuts, most of the recognised rubber trees, landolphias, nutmegs, cinnamon, camphor, mangoes, mangosteens, durians etc. all either of medicinal or other economic importance. Manurial experiments were started in 1900 and 1907 respectively both on the flat and on the slope, to ascertain the manurial requirements of cocoa growing elsewhere in similar situations (1). The cocoa and lime yields, together with miscellaneous fruits and spices from other economic plants in the collection are a source of considerable financial support to the Department.

NURSERIES: — In connection with nursery work in the Tropics, the humus question demands careful attention, and the method adopted in the Botanic Gardens, where lime seedlings are grown on the same piece of land year after year is as follows: the beds and paths running between them are made the same width, the paths being filled with grass which has been trampled under foot, and thereby converted into a more or less decaying mass, are dug up and converted into beds, the beds of the previous year being made into paths. In this way the ground serving as paths for 1 year receives a good dressing of organic matter, and is rested for a period of 12 months.

Two large nurseries meet the requirements of the planters in Dominica. Budded citrus, sugar cane, rubber, coffee and miscellaneous stock are supplied to the new planter at any time required, to plant up newly cleared forest land. In addition to nursery plants, there is also a considerable distribution annually of seeds of rubber, coffee, green dressings, fodder grasses, shade trees, papaws and vegetables.

During recent years, efforts have been made to encourage planters to cultivate on the rotation system and change their former method of planting one crop to the exclusion of all others. Previously coffee was practically the only crop cultivated and the present staple crop, namely, limes, had not been thought of in Dominica; in fact, sugar seems to have predominated after the failure of the coffee crop, and limes only came in gradually with the decline of the sugar industry, when beet began to take an important place in the world's sugar supply, and the price of this commodity fell below the cost of production.

Of late years cocoa planting has been encouraged by the Department and every attempt has been made to extend its cultivation to districts which, prior to experimental work commenced on this crop, were considered unsuitable. The superior Criollo type refuses to thrive in any part of the island, but after much valuable work in budding and grafting of cocoa, a good medium grade can now be grown by grafting the Forastero type on the hardy Calabacillo stock. The latter type in itself yields a very inferior grade of produce, but its immunity from disease, as well as its indifference to soil and climatic conditions, makes it invaluable as a grafting stock.

---

(1) Results to be published in the Annual Agricultural Report, Dominica 1921.

Experiments were started in onion growing a few years ago, with a view to encouraging cultivation of this crop to supply local needs. Seeds were imported from Teneriffe and sown in the nursery, and seedlings distributed free of charge. Since then the demand for seedlings has rapidly increased. Onions have now become a remunerative crop, and, local needs having now been satisfied, it has been added to the list of exports.

In 1913, the Government started manurial experiments at the Lime Experiment Station, (moist compact soil) but owing to the serious damage effected by means of a hurricane in 1916, the plots were reorganised, and in 1917 the present system of experiments was inaugurated. Reliable and useful results cannot be expected for some time to come. It would appear, however, that a complete fertiliser (dried blood + basic slag + sulphate of potash) can be expected to give satisfactory results: It is expected also that mulch such as cut grass and bush will, when applied every 2nd year alternating with a complete fertiliser, become an important consideration in every practical scheme of plantation manuring.

Observations have also been made on budded limes, disease resistant stock and the effect of green dressing crops *i. e.*, horse beans (*Canavalia ensiformis*), *Tephrosia candida*, or weeds and grass clippings. The yield obtained from the plot of trees grown without green manure compared unfavourably with the others. There was also a great increase in yield from the trees grown with *Tephrosia* compared with those grown with horse beans, in the second year of bearing (139 barrels * per acre: 72 bar. per acre). This may be due to the height of *Tephrosia* and the consequent better protection afforded. When it is considered that the ordinary seedling lime tree does not usually commence to bear fruit until the 4th or 5th year, and even then only sparsely, the results here obtained demonstrate the advantages in planting budded trees. Observations made on lime cultivations by the Department, extending over a good number of years, have shown that the lime tree has a critical period, beginning at the time of planting in the field and continuing up to the 3rd year. An annual application of 2lb. organic nitrogen per tree in addition to green dressing crops, should be given during this period.

The present yield of limes from the 25 acres of the Experimental Station is approximately 2000 barrels per annum (1). This is estimated to rise to between 3 000 and 4 000 barrels per annum as the newly planted land comes into bearing and later to 6 000 and 7 000 barrels with all trees in full bearing.

---

* 1 barrel = 4½ cub. ft. capacity

(1) During a recent visit to Dominica S. M. DAVIS. (Chief Chemist to Messrs ROWNTREE Co , Cocoa Manufacturers, York) made investigations concerning the loss of citric acid which may occur in limes and in lime juice under certain conditions. Sets of 50 limes of various degrees of ripeness were hand pressed, the juice from each set measured, and its acidity determined. The yield in lb. of citric acid per barrel was as follows :— ripe yellow limes

A lime factory is now in process of construction where, if experimental work is conducted in conjunction with field operations, results might bring to light an improved means of working the present lime industry.

Experimental tapping tests are being carried on with *Hevea brasiliensis* on the Morne Bruce Lands.

AGRICULTURAL INSTRUCTION. — The only course of instruction for boys intending to take up. agricultural work professionally, is established in the Botanic Gardens. This does not however deal with livestock management, but is organised with a view to preparing the pupils to take up positions either as overseers or managers on planters' estates.

Courses of reading and examinations in practical agriculture were established under the direction of the Imperial Department of Agriculture for the purpose of enabling overseers on estates and others engaged in agricultural work to acquire knowledge that would be useful in connection with their practical work. The war however, upset these arrangements and they have not yet been re-established owing to the general unsettlement.

A system of Agricultural Cadet Training is, however, in practice.

A laboratory has been fitted up in the Botanic Gardens to enable the Department to deal with the analysing of lime juice, milk and other foodstuffs, soils and manures, etc. This does not interfere in any way with the central laboratory in Antigua supported by the Imperial Government for research work in the Leeward Islands in regard to the more important chemical investigations. All important matters are still submitted to the Government Chemist in that island; and only such work as mentioned above has been undertaken locally.

CROPS AND CULTIVATION

597 - **A New Classification of the Soil Moisture.** — BOUYOUCOS, G. (Michigan Agricultural Experiment Station), in *Soil Science*, Vol XI, No 1, pp 33-47, Bibliography of 9 works. Baltimore, January 1921

The water in the soil is now generally divided into 3 forms; gravitational, capillary and hygroscopic; but this classification is empirical and fails to reveal the true facts. The author's method which consists in determining the freezing-point by means of a dilatometer (1) allows of a clas-

---

5.3, yellow green 4 9, over-ripe 4.6, green 4 4, rotten 1 7 With lime juice, 200 lb stored 19 days was reduced to 184 lb. by evaporation, and the acidity from 12 1 oz. to 11 3 oz A loss was recorded of 1.7 oz. of citric acid per gallon.

During the first few weeks of storage, the loss of citric acid is on an average 5 % per week of the original content. Storage for long periods must therefore result in a big loss to the planter (*Agricultural News*, vol. XX, No. 492, p. 75 London, March 5, 1921).

(1) See *R*. 1917, No. 896; 1919, No. 567; Cf. also *R*. 1920, Nos. 388 and 945. (*Ed*)

sification of soil moisture founded upon a scientific basis and upon physiological principles. He divides it under the following heads:

Gravitational water : superavailable
Free water : very available
Unfree water { capillary-adsorbed
    combined { Water of solid solution
        Water of hydration

The gravitational water is that which, being in excess of the amount the soil is able to retain, can be drawn away by the force of gravity; the free water is that which freezes for the first time at the supercooling of — 1.5°C.; the capillary-adsorbed water is that which freezes finally at 4°C. and also in the temperature of —78° C., minus the free water. The combined water is that which does not freeze at all.

The procedure of the new method consists of introducing a definite amount of soil and water, or a soil of known moisture content, into the dilatometer, filling the empty space with ligroin, and then causing the soil moisture to freeze. It is first supercooled to —1.5°C in order to freeze the free water, then the contents of the dilatometer are thawed and frozen at the temperature of —15°C. for half an hour. Then they are thawed again and supercooled to —4°C where the capillary-adsorbed water freezes. When the contents come in equilibrium with the temperature 0 —4°C., they may be cooled to — 78°C., and brought back again to the temperature of —4°C. When the coefficient of expansion of water upon freezing and also the total water content of a soil are known, then it is easy to determine the water freezing at —1.5°C., that freezing at —4°C., and the water that does not freeze at all, even at — 78°C. On the basis of this classification, it was found that in some soils (in addition to the possible water of gravitation), only 2 forms of water exist, while in others there are all 3 forms, but in different proportions.

This new classification of the soil moisture gives a clearer and deeper insight into the actual condition of this moisture, its intimate and complex relationships with the soil, and its bearing upon many phenomena in the latter, such as the movement of moisture, evaporation, the wilting coefficient of soils, the availability and unavailability of moisture etc.

A direct comparison made between the wilting coefficient (1) of some of the soils employed by BRIGGS and SHANTZ and the dilatometer method results show, that the percentage of moisture which fails to freeze at the supercooling of —1.5° C. coincides very closely with the amount of moisture at which plants begin to wilt. In view of the close agreement that appears to exist between the wilting coefficient and the unfree water as determined by the dilatometer method, it would seem advisable to adopt this way of determining the factor which is more accurate, constant and convenient than the determination of the wilting coefficient by means of the plant. ALWAY's hygroscopic coefficient (1) seems to represent about the same degree of moisture as the combined water of the proposed classification (2).

598 - **Soil Ingredients Withdrawn by Various Fruits.** — COLBY G. E. (Chemist and Assistant Chief. Division of Chemistry. State of California Department of Agriculture) in *The Monthly Bulletin of the Department of Agriculture, State of California, Chemistry Number*, Vol. X, No. 1, p. 23., Sacramento, California, Jan. 1921.

For a number of years the author was engaged in the study of chemistry of fruits and among other data, a table is here reproduced showing the amounts of several important soil ingredients contained in 1000 lb. of various fruits in fresh condition.

The replacement of the vital soil ingredients, *viz.* nitrogen, phosphoric acid, and potash, withdrawn from soils by fruits, as shown in the appended Table, was begun years ago by employing for certain fruits, commercial fertilisers containing plenty of nitrogen and phosphoric acid, and to a comparatively limited extent, potash. Californian soils are scantily supplied with the two first mentioned ingredients, but contain ample potash.

The California Experiment Station recently received for examination a specimen of olive oil residue which consisted of a mixture of dried pulp and coarsely crushed pits of the olive containing 2.75 % of oil.

Fresh fruit (Lot of 100 pounds each)	Total ash	Potash (K_2O)	Lime (CaO)	Pospniric Acid (P_2O_5)	Nitrogen (N)
	Lb.	Lb.	Lb.	Lb.	Lb.
Almonds	17.29	9.95	1.04	2.04	7.01
Apricots	5.08	3.01	0.16	0.66	1.94
Apples	2.64	1.40	0.11	0.33	1.05
Bananas	10.78	6.80	0.10	0.17	0.97
Cherries	4.82	2.77	0.20	0.72	2.29
Chestnuts	9.52	3.67	1.20	1.58	6.40
Figs	7.81	4.69	0.85	0.86	2.38
Grapes	5.00	2.55	0.25	0.11	1.26
Lemons	5.26	2 54	1.55	0.58	1.51
Olives	13.50	9.11	2.43	1.25	5.60
Oranges	4.32	2.11	0.97	0.53	1.83
Peaches	5.30	3.94	0.14	0,85	1.20
Pears	2.50	1.34	0.19	0,34	0.90
Prunes, French	4.86	3.10	0.22	0.68	1.82
Plums	5.35	3.41	0.25	0.75	1.81
Walnuts	12.98	8.18	1.55	1.47	5.41

An analysis of this residue showed that it contained :—

Water 10 % ; organic matter 87.73 % ; ash (or mineral matter) 2.17 %.

---

(1) See *R.* 1917, No. 1114; 1918, Nos. 128 and 957.

(2) See *R.* 1917, No. 227. (*Ed.*)

Further analysis showed that the plant food content per 1000 lb. refuse was as follows :— nitrogen 8.04 lb.; phosphoric acid 4.30 lb; potash 4.90 lb.

The value of this kind of refuse as a fertiliser may be judged by the conclusion that the benefit of adding so much organic matter as is contained in this material is somewhat lessened by the quantity of oil and crushed but hard and non-decomposed olive pits. Also, as the plant food ingredients are known to exist chiefly in the pits, this material must be classed as slow acting, and not of a great value as fertilising agent.

599 - **Distribution of Titanium in Soils and Plants.** — GEILMANN (Arbeiten aus dem landwirtschaftlichen Versuchsfelde der Universität Göttingen), in *the Journal fur Landwirtschaft*, Vol. LXVIII, pp 107-124 Berlin, 1920

Recent lithological research has shown titanium to be one of the elements most widely disseminated in the earth's crust, of which it is said to form as much as 0.33 % (F. W. CLARKE). Given the high titanium content of clay, it might be supposed that larger or smaller quantities of this metal would be found in ordinary agricultural soils but, as a matter of fact, in scientific literature dealing with this subject, it is very seldom that any data are given respecting titanium, which is usually expressed as alumina. The author suggested the use of HILLEBRAND'S system of determination, which consists of a special method of disintegration followed by a colorimetric estimation, and used it himself in the examination of 30 soils (including peaty and calcareous types, sands and clays)

He found that the amount of titanium dioxide present varied from mere traces in the case of sandy loan, to over 1 % in that of clay. Further, there was a certain regularity in the distribution of titanium in different soils, clays containing most, clay loans less, and pure sands and clays. very little indeed. Nevertheless, some titanium was found in all the soils, and usually the percentage of the dioxide was such that its omission in analysis would have constituted a distinct error. Considerable quantities of titanium pass into an acid solution, and if they are not estimated, the determination of the alumina is not correct, for they sometimes equal, or exceed, the ordinary content of fertilising substances (in % of dry matter) (see Table II).

TABLE I. — *Percentage of titanium dioxide in various soils.*

Soils	Total titanium dioxide Per cent.	Titanium dioxide soluble in boiling 25 % H Cl Per cent.
Cultivated alluvium . .	0.325—0.355	0.081—0.100
Clay	0.952—1.008	0.083—0.086
Clay loam	0.667—0.619	0.090—0.097

The constant presence of titanium in the soil having been proved, it was important to determine how much was to be found in the ash of plants. For this purpose cultivated plants were selected, which with the exception of cacao, had been grown on the same alluvial soil containing 0.336 % of titanium dioxide.

Table II gives the results of these determinations.

TABLE II. — *Percentage of titanium dioxide in different plants.*

Plants	Ash per cent.	Titanium dioxide in the ash per cent.	Titanium dioxide in air-dried material per cent.
Horsetail	25.34	0.071	0.0180
Nettle	15.70	0.056	0.0088
Potatoes, leaves	6.89	0.269	0.0186
Potatoes, tubers	0.75	—	—
Lupins, straw	7.66	0.059	0.0045
Maize	11.05	0.032	0.0035
Mangolds (roots)	12.30	0.009	0.0011
Do. (leaves)	19.38	0.022	0.0042
Green oats	7.70	0.005	0.0004
Autumn wheat	9.52	0.004	0.0004
Beans	6.35	0.061	0.0039
Galega	7.51	0.059	0.0044
Pears	2.23	0.009	0.0002
Pear trees, leaves	6.67	0.057	9.0038
Pear trees, wood	4.35	0.007	0.0003
Apples	2.57	0.016	0.0004
Red cabbage	9.28	0.003	0.0005
Cacao seeds	4.34	—	—
Grass (5 samples)	8.78-9.71	0.021-0.027	0.0019-0.0027

All the plants, except the cacao seeds, contained titanium, the maximum amount being found in the potato leaves ; in every other case, the amount of titanium dioxide was below 0.1 % and often less than 0.05 % of the ash, and though it varies perceptibly, a certain rule seems to hold good, leguminosae, wheat and oats having the same titanium content, whereas that of meadow-grass is higher. The metal seems to accumulate by preference in the assimilating organs, which proves the truth of TRAETTA MOSCA'S statement (1), that titanic acid is of great physiological importance to plants (tobacco), since it acts as an oxidising catalyst.

The estimations made in the case of meadow grasses are also useful, as they show the possible effect of soil moisture on the absorption of titanium dioxide, but no differences worthy of remark were observed.

Chimica Italiana, XLIII, 437-440, 1914. (*Ed.*)

600 - **Comparative Investigation of the Microflora and the Nitrogen Content of Soils partially Sterilised with Calcium Sulphide.** — TRUFFAUT, G. and BEZSONOFF, N., in the *Comptes rendus de l'Académie des Sciences*, Vol. 171, No. 4, pp. 268-271. Paris, July 26, 1920.

According to the author's observations (*Comptes-rendus de l'Académie des Sciences*, Vol. 170, 1920, p. 168), the bacterial flora of soils treated with mixtures having a basis of calcium sulphide contains an abundance of a nitrogen-fixer, *Clostridium pasteurianum*, an the principal ammonifying bacteria of the soil (*B. mycoides*, *B. megatherium*, etc.).

As such a typical selection of micro-orgaisms was present, investigation of its influence on the soil nitrogen seemed desirable. The authors, therefore, estimated nitrogen contents of partially sterilised soils and in similar but sterilised soils, establishing at the same time their bacteriological control. The results obtained seem to prove that:—

1) By using a strong dose of aromatic carbides and sulphides in cultures in porous pots where oxidation is constant, this acrobic medium favours the loss of ammoniacal nitrogen by diffusion, and is unfavourable to the sustained growth of anacrobic bacteria such as *Bacillus butyricus*.

2) When, under the same conditions, the same soils, still contained in porous pots, bear plants, it is found that the loss of nitrogen is smaller.

3) Under conditions of cultivation in open fields and using a maximum quantity of 150 kg. of calcium sulphide per hectare, it is noted that, in spite of the large amount of nitrogen removed, the soil is never impoverished of this element.

601 - **The Part Played by Rain in Supplying the Water Table.** — DIÉNERT (Chef du Service de la surveillance des eaux d'alimentation de Paris), in the *Comptes rendus de l'Académie d'Agriculture de France*, Vol. III, No. 5, pp. 97-104. Paris, February 2, 1921.

The subject dealt with by the author is part of the problem which arises when any scheme of irrigation or water supply is under consideration.

The only basis upon which an engineer is able to estimate the amount of water that can be supplied by a given area of land is the rainfall registered by the various rain-gauges.

Of late years, however, certain new theories have been brought forward to the effect that rain is not the only source from which the water tables obtain their supplies.

It is, on the contrary, affirmed, that the condensation water produced by mists and dew, and even the water condensed on trees (1) all contribute to maintaining the level of this subterranean water.

Without entering into a discussion as to the merits of the different hypotheses, the author has tried to ascertain whether the readings of rain-gauges can, despite these new theories, still be used. In his studies, he utilised the systematic and accurate data collected regularly for many years by the City of Paris for the purpose of determining the water-flow of the Vanne in Burgundy, and of the Avre in Normandy. From the results of the calculations which he gives, the author draws the following conclusions :—

---

(1) See *R.*, March 1919, No. 280; *R.*, March 1920, No. 292. (*Ed.*)

There is a practically constant ratio between the water carried by a stream, from the moment where its flow begins to increase, until the time when it resumes its initial volume on the one hand, and the amount of water that has fallen on the perimeter during the same time on the other, provided that the period is not less than 2 years.

The data afforded by rain-gauges therefore are sufficient to enable hydraulic engineers to calculate the amount of water that can be obtained from a water-table for purposes of irrigation or water-supply, for if water from other sources assists in feeding the water-table, this contribution is closely connected with the rainfall of the region.

602 - **Watering by Imbibition in Market Garden Cultivation.** — STAPPAERT, E., in the *Revue horticole belge*, Year 2, No. 5, pp. 64-66, figs 1. Huy, May 1, 1921.

The system proposed by the author is intended especially for greenhouses. He tried it in 1917 and the results have been so conclusive that he has generalised its use in all the greenhouses belonging to the State School of Horticulture at Vilvorde used for the cultivation of vegetables in plots. At a depth of 35 to 40 cm., drainpipes 7 cm. in diameter are placed in the ground, without joints, but end to end as if for drainage. These pipes are laid level, the lines of pipes being about 1.50 metres apart. At the two ends of the lines, the last pipe is fitted with another pipe placed vertically so that water may easily be poured down it.

If the soil of the greenhouse is about level and if its length does not exceed 40 m., the lines of pipes are arranged lengthwise with the greenhouse. In case the ground is inclined or if the length exceeds 40 m., the pipes are placed so as to form lines parallel with the gable ends of the greenhouse. This arrangement is necessary so that the lines of pipes may be level and always about 35 cm. below the surface of the soil.

When watering is to be done, water is allowed to flow through the pipes by placing the end of a rubber tube into the pipe placed vertically, the other end of the rubber tube being fitted to the nearest water tap. If water is not laid on, it is poured into the vertical pipe from watering cans. The water is allowed to flow until it is seen, by looking down the vertical pipe placed at the other end of the line, to have reached the end of the line. The end of the rubber tube is then moved to the vertical pipe of the next line.

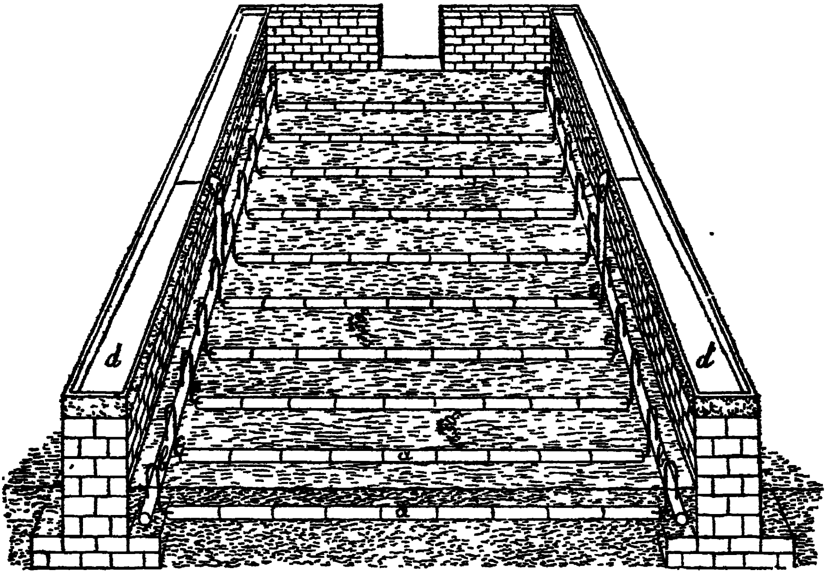
When the first watering is being done, especially if the lines of pipes are fairly long, it sometimes takes more than an hour for the water to reach the end of a line. This is because the earth absorbs so much at each joint of the pipes where the water escapes.

With the second watering, the time required diminishes and after three or four operations it scarcely takes a quarter of an hour for each line.

The water which flows in the pipes escapes into the soil at each junction of the pipes, saturates the surrounding soil and, by capillarity, mounts to the surface of the soil.

In successive waterings the water is poured alternately into the vertical pipe at each end of a line.

With this system it is also possible to distribute, to each line of pipes the rain water which falls on the roof of the greenhouse and to distribute it over the whole area of the covered soil. With this object a system of pipes 8 to 9 cm. in diameter, such as are used for hot water heating is connected with the down-pipe from the greenhouse roof, and divided into two sections so that each section forms a conduit joining up one end of each of the lines of pipes in front of which it is placed.



STAPPAERT system of watering by imbibition.

So that each line of pipes shall automatically receive the same amount of water, a small gas tube of about 1.5 cm. gauge is grafted on the pipe which holds the rain water and rising perpendicularly from it is bent at a certain height and turned downwards to enter the line of drain pipes. If all the bends of the small tubes are exactly on a level these tubes constitute so many communicating vessels and each will divert the same quantity of water into each line of drain pipes.

The drain pipes used are 30 cm. long and now cost 250 fr. per thousand.

603 - Plant Analysis in Relation to Manuring. — MÜNTER, F. (Stellv. Vorsteher der Agrik.-Chem. Versuchsstation Halle), in the *Journal fur Landwirtschaft*, Vol. LXVIII, pp 207-224 Berlin, 1920.

The author had remarked that, in studying the relations between the results of elementary analysis and the need of fertilisers, it was not suitable to make use of spring barley; much clearer indications, however, are obtained with sugar beet, which is much more exacting in the matter of manuring. The following information resulted from observations both on barley and beet on loess silt soils:—

a) Nitrogenous and phosphatic manures reduce the silica content of barley straw; on the other hand, the lime and magnesia content is only influenced to a negligible extent by nitrogenous, potassic or phosphatic manures; the atmospheric conditions of the year have so intense an influence on the growth of barley that its nitrogen, potash and phosphoric acid content does not allow of any certain conclusion being drawn so far as the needs of fertilisers for a soil are concerned. However, the nitrogen content of barley is slightly reduced by potash and very much reduced by phosphoric acid; all this confirms the fact that barley is not a plant which should be used in these experiments; the ratio of nitrogen to potash or phosphoric acid gives no certain indication of the fertility of a soil.

b) The yield in root of beet in good years, but in determined conditions that are unfavourable to the assimilation of phosphoric acid, is influenced by nitrogen, and slightly by potash. In any case the epigeal production depends considerably on the nitrogenous manuring. The lime and magnesia content of the roots is only influenced in an accessory manner by the manuring; in straw, on the other hand, the lime and magnesia content is increased by potassic fertilisers and decreased by phosphatic manuring; the effect of nitrogen is variable. If 50 kg. of nitrogen is not removed per hectare in the leaves and a total of 100 kg. in the roots + leaves of beet, it signifies that there is insufficiency of this element: the potash of beets being less influenced, there is nothing to indicate the quantity of potash required for this plant; when less than 14 kg. of phosphoric acid is taken out in the roots of sugar beet, it is a sign that this substance is present in small quantity in the soil; for the green parts there are no precise indications. But the meteorological conditions also exert such an influence on beet that the percentages of nitrogen and potash can give no indication regarding the corresponding requirements of the soil for phosphoric acid, however, the minima limits of 0.18 % in the roots and 0.40 % in the epigeal portions can be established.

c) When, to ascertain the requirements of a soil in fertilising material, 2 plots are taken, one manured with nitrogen and the other with phosphoric acid and potash, the following rules can be used for estimation, according to the methods previously proposed by the author regarding winter wheat:— 1) If a soil lacks potash in the plots manured with nitrogen, the percentage of potash in the plants remains less than that of nitrogen, made equal to 100 ; if it is phosphoric acid which is lacking the ratio $\frac{\text{nitrogen}}{\text{phosphoric acid}}$ in the plots manured with nitrogen is more than 100 ; if this ratio in the plots manured with phosphates and potash is less than 100, the soil lacks nitrogen.

2) The conclusions are more certain when the ratios $\frac{\text{nitrogen}}{\text{potash}}$ or $\frac{\text{nitrogen}}{\text{phosphoric acid}}$ are equal to 100 on the plots with both phosphatic and potassic manure, because the meteorological factor is thus, as far as possible, eliminated ; then, on the plots manured with nitrogen, a ratio $\frac{\text{nitrogen}}{\text{potash}}$ less than 60 indicates a lack of potash ; if, on the other hand, this ratio exceeds 60 it indicates that there is sufficient potash; a similar ratio of less than 40 for phosphoric acid indicates that it is insufficient and above 40, that it is sufficient.

The indications would be clearer if, instead of 2 plots, 3 were taken (manured with nitrogen, potassic and phosphatic fertilisers); the percentages noted for different cultivated plants would thus enable the state of fertility of a soil to be estimated.

Whether a general value can be attributed to such observations further experiments alone can decide ; until this method has been perfected, accurate manuring experiments still remain the normal procedure for determining the fertiliser requirements of a soil.

604 - **A Critical Study of Pot Fertiliser Experiments.** — LIPMAN C. B., and LINHART, G. A. (Proceedings of the National Academy, of Sciences of U. S. A., November 1920), in *the Chemical News and Journal of Physical Science*, Vol. 122, No. 3180, pp. 137-138, London, March 24, 1921.

WAYNICK, SHARP and LIPMAN had already demonstrated that owing to the great variability of soils and of plants, fertilising experiments of long duration cannot be of much practical value, if the factors of variation and probable error are ignored.

For this reason, LIPMAN and WAYNICK began, in January 1919, a systematic study by statistical methods of the results of the pot fertiliser experiments carried out at the Ohio and the Pennsylvania Agricultural Experiment Stations.

Since the work would possibly be some time in the press, the authors deemed it wise to present a few of their most important conclusions. They draw attention to the fact, that the originators of the experiments saw the value of replicating check pots, but did not recognise the importance of such replication for the fertilised pots, which renders it difficult to subject their data to statistical treatment. Fortunately, however, the long series of years during which the pots were studied gives a replication of each kind.

The authors arranged the data respecting the experiment pots into 8 groups according to the fertiliser ; then they studied the effect of the fertiliser on each crop in the rotation, although they consider that the rotation study included in these experiments, which were themselves expensive, inadequate, and fallacious, only served to complicate a situation which was already sufficiently difficult.

The data from the pot experiments at the Ohio Station, when worked out according to the statistical method showed that:

1) The " one-element " fertilisers produced no significant increases in yield over the yields obtained from the check plots. All statements to the contrary must be regarded as erroneous.

2) The " two-element " fertilisers gave definite increases in yield over the check plots; but whether the increases are profit-yielding still remains to be determined.

3) The same may be said for the " three element " fertilisers.

4) Different combinations of the same fertilising element seem to have produced no differences in the results.

5) The amount of fertiliser used seems likewise to have been without significance.

6) Even when fertiliser experiments are properly planned, and the results adequately studied by statistical methods, our present knowledge of the enormous variability of all soils and plants renders the data from any given fertiliser plot of value only on that plot. This important consideration renders it highly probable that no fertiliser experiment as ordinarily conducted is possessed of sufficient practical vaue to justify the large expenditure of money, time and energy involved.

Having delivered themselves of this very severe criticism, the author declare, that they are not desirous of making a fetish ôf the application of statistical study to fertiliser experiments, but wish to show, that if statistical methods are not applicable to the evaluation of fertiliser experiments, the latter must be accounted of even less value and significance than the authors have accorded to them.

605 - **The Effect of Manure-Sulphur Composts upon the Solubility of the Potassium of Greensand.** — MAC CALL, A. G. (Agricultural Experiment Station, College Park Md), in *Journal of the Association of Official Agricultural Chemists*, Vol. IV, No. 3, pp. 374-376, Washington, February 15, 1921.

The recent work directed to increasing the availability of the phosphorus in floats by the solvent action of composts of manure and sulphur (1) suggested the idea of studying the effect of the said composts in rendering more assimilable the potassium present in greensand (2). Two series of composts were prepared for the purpose, with greensand containing 5.9 % and 1.4 % of potassium respectively. For each series, in addition to the control, the composts consisted respectively of: flowers of sulphur — sulphur and half-decomposed manure — sulphur, manure and sandy-clay soil — sulphur, soil, traces of sulphate of aluminium and of ferrous sulphate — sulphur, manure, soil and a small quantity of calcium carbonate. Each test was carried out in a glazed pot kept in the greenhouse (water being added to one-half the water-holding capacity), and the soil was aerated every week. Water extractions with samples of 75 gr. were employed for the determinations; the extractions were made at the beginning of the experiment, and once a week during the 23 weeks the experiment lasted.

---

(1) See *R.* 1919, Nos. 24 and 603.

(2) A more or less ferruginous hydrated silicate of potassium. (*Ed.*)

In the case of the composts consisting of greensand, manure, and soil in different proportions, a perceptible amount of the potassium of the greensand was rendered soluble in water through the process of "sulphofication" (oxidation of sulphur), the most efficacious being the compost of equal parts of sulphur and manure On the other hand, in those composts where part of the manure was replaced by soil, the acidity and the amount of sulphur oxidised, and consequently also the potassium dissolved, were decreased. When soil was entirely substituted for the manure, the sulphofication proceeded so slowly, that only a minimum amount of potassium was found in the water extract The addition of sulphate of aluminium and of ferrous sulphate in no way stimulated sulphofication, whereas calcium carbonate exerted a stimulating effect at first, but it did not succeed in increasing the acidity and the soluble potassium beyond the maximum attained by the corresponding composts containing no calcium carbonate. A much larger *total* quantity of soluble potassium was obtained from composts containing greensand with a high potassium content, although a larger *percentage* of potassium was yielded by green ands with little potassium In composts containing manure, the amount of potassium recovered in the water extracts varied from 9.1 % to 41.3 % of the initial content.

In conclusion, the accumulation of soluble sulphates closely paralleled the development of acidity, and in every case, with the increase in acidity and the accumulation of sulphates, there was a corresponding increase in the amount of potassium in the water extract. The potassium, however, continued to increase for some weeks after the acidity and sulphates had attained their maximum.

606 – **The Variability of Plants Grown in Water Cultures.** — DAVIS, A R (College of Agriculture, University of California), in *Soil Science*, Vol XI, No 1, pp 1-31, 12 figs. Bibliography of 15 works Baltimore, January, 1921.

Much emphasis has, of late years, been placed upon the water-culture method as a means of determining the influence of salt upon plant-growth. The differences in the salt content being relatively small, the question arises whether fixed values can be assigned to differences of such degree when the material being compared shows extensive variation, more especially as usually the number of plants used in water-culture experiments is very small: from to 1 to 6.

For these reasons, the author has taken as his basis SHIVES extensive work (*Physiol Res.*, I, 327-397, 1915) on the physiological balance in nutrient media. SHIVE used a three-salt solution in three different concentrations having the osmotic pressure of 0.1, 1.75 and 4 atmospheres. In these the partial molecular concentration of salts was varied in increments of one-tenth, 36 different combinations resulting. As the author wished to make a statistical experimental study based on the frequency distribution of certain data, it was desirable to have a sufficient number of variants to permit of an approximately normal distribution about the mean. For this purpose, it was enough to consider a few well-chosen combinations of the 36 1.75 atmosphere solutions, which were called provisionally, following SHIVE's example, optimum, average and minimum solution respectively according to their growth efficacy. They had the following partial molecular concentrations.

Solution	Monopotassium phosphate	Calcium nitrate	Magnesium sulphate
Optimum	0.0180	0.0052	0.0150
Average	0.0036	0.0026	0.0400
Minimum	0.0072	0.0130	0.0150

A sufficient number of replicate cultures are also necessary: two series were set up for each concentration, one of 33 cultures of 5 plants each, and the other of 50 cultures of 6 plants each. In these cultures, wheat of high germination was grown and after 7 weeks the dry weight of the epigean parts was determined in the ordinary way.

The variations exhibited by plants of both series was of considerable magnitude, being approximately 20 % on either side of the mean for culture weights, and about 50 %, when individual plants were compared. When results were plotted in the form of frequency curves, the variation was of such extent, as to show considerable overlapping for the three solutions in question. Further, the arithmetic means of the optimum and medium solutions of the first series were practically the same, thus showing no significant difference in the growth efficiency of the two solutions; in the second series, an apparent difference was shown, but always within the limits of the probable error, which made it of no importance. The total and partial means of one series also varied to a noticeable extent.

It is seen from what has been hitherto said, that plants grown in culture solutions exhibit considerable variability. Indeed, this is of such magnitude, as to cast serious doubts upon the practice of drawing conclusions from the means of relatively few cultures. Since it is a question of living organisms, which are of a very varying nature, it is necessary not only to ascertain the degree of variation from a sufficient number of data, but also to determine the probable error; only thus is it possible to compare and estimate the effect of differing environments, or external agents, upon plant development.

In comparing the relative growth efficiency of different culture solutions, the probable errors of the means compared must be fixed, and as the mean of few cultures can have but little accuracy, a large series must be used, unless large differences are being compared. Moreover it could hardly be said that there is an optimum of culture in the actual conditions of experiment, for the limits within which are found conditions favourable to growth efficiency are relatively wide.

Finally, it is most important in the comparison of culture solutions, that seed of known parentage should always be employed.

607 - **The Hydrogen-Ion Concentration of Certain Three-salt Nutrient Solutions for Plants.** — MC CALL A. G. and J. R. HAAG (Department of Soil Investigations, Maryland Agricultural Experiment Station), in *Soil Science*, Vol X, No. 6, pp 481-483. Bibliography of 5 works, figs. 1. Baltimore, December 1920.

Until quite recently, practically all of the nutrient solutions used in the study of plant-nutrition problems have contained four, or more, salts in addition to a trace of iron. But in 1915 (1) SHIVE showed, that it was possible to make a satisfactory nutrient solution in which all of the essential ions, except iron, were derived from the 3 salts, calcium nitrate, magnesium sulphate, and monopotassium phosphate. Later, LIVINGSTON and TOTTINGHAM suggested 6 possible combinations of 3 salts which would give the 6 essential ions.

Type I	*Type II*	*Type III*
Calcium nitrate	Calcium nitrate	Monocalcic phosphate
Phosphate monopotassium	Potassium sulphate	Potassium nitrate
Magnesium sulphate	Monomagnesium phosphate	Magnesium sulphate

Type IV	*Type V*	*Type VI*
Monocalcic phosphate	Calcium sulphate	Calcium sulphate
Potassium sulphate	Potassium nitrate	Monopotassium phosphate
Magnesium nitrate	Monomagnesium phosphate	Magnesium nitrate

The Division of Biology and Agriculture of the National Research Council (United States) appointed a special Committee to organise a movement for the cooperative study of plant nutrition problems. In order better to correlate the work of the co-operating scientists, this committee formulated standardised methods to be adopted, and provided each cooperator with a printed copy of directions in which the preparation of the 6 type solutions is given in detail. In connection with this work, the authors have been using (in sand culture studies), solutions of types I, III and V, and it occurred to them to correlate the relative growth rates of the plants with the hydrogen-ion concentration of the nutrient solutions.

It was found by the determinations made, that in general within any one type of solution, the hydrogen-ion concentration is a function of the volume-molecular proportion of the di-hydrogen phosphate salt present, the types containing monopotassium phosphate having a lower hydrogen-ion concentration than those containing either monomagnesium or monocalcium phosphate. It further appears, that the sulphate and nitrates play only a minor part in determining the reaction of the nutrient solution. The variations in plant growth, within any one type of solution, cannot be correlated with differences in the hydrogen-ion concentrations of the solutions.

608 - **Are Vitamines Necessary for the Growth of plants?** (1). — LUMIÈRE, A., in the *Comptes rendus de l'Académie des Sciences*, Vol. 171, No. 4, pp. 271-273. Paris, July, 26, 1920.

Certain biologists have maintained that vitamines are necessary for the growth of plants (BOTTOMLEY, *Proceedings of the Royal Society of London, Biological Science*, 1914, p. 237; MOCTHERIDGE, *Ibid.*, 1917, p. 508; AGULHON and LEGROUX, *Comptes rendus de l'Académie des Sciences*, vol. 167, 1918, p. 597; LINOSSIER, *Comptes rendus de la Société de Biologie*, April, 1919 and March, 1920) and this opinion, generally admitted moreover, is derived from experiments of which the author by no means contests the results, but the interpretation of which docs not seem to agree either with other facts or with the numerous tests made by him personally in this field.

Not only can certain micro-organisms and fungi be cultivated in chemically definite media without any trace of vitamines, but it is also possible to ensure the growth and complete development of higher plants with nutrient solutions which are purely inorganic.

MAZÉ (*Annales de l'Institut Pasteur*, March, 1919, p. 139) has shown that maize can accomplish its complete evolution in a liquid containing 15 elements, all organic matter bring excluded. It is hardly conceivable that certain plants, ranging from micro-organisms up to the most complex plants, can live and grow in mineral media, while others require vitamines for their development. The idea of the utility of vitamines in the cultivation of mushrooms is due to the fact that the authors who have upheld that thesis have used very poor, insufficient media, such as a mixture of ammonium tartrate and glycerine the addition to which of a few drops of an infusion of raisins will considerably improve the nutritive value of the broth.

If the minute quantity of material thus added includes vitamines, it also contains salts, proteins and carbohydrates, and it seems improper to conclude, *a priori*, that the effect noted is due to one rather than to others of these substances. The author has stated that a great number of definite chemical products, inorganic and organic used in minute proportions, would give the same results as those obtained by the addition of the infusion of raisins, and sometimes they even gave better results; all these substances cannot be considered as vitamines.

Beer yeast heated to 135° C. for one hour, that is to say, which has lost all its antiscorbutic properties, can be used to prepare broths which favour considerably the growth of mushrooms grown in poor solutions having for basis ammonium tartrate and glycerine.

---

(1) See No. 593 of this *Review*.

By methodically exhausting the yeast with alcohol, or by precipitating its extracts with phosphotungstic acid, the isolation of the vitaminic principles can be arrived at and it is thus possible to obtain, on the one hand, the exhausted yeast having no longer any curative effect on avitaminosis and, on the other hand, an extract containing the active vitamines; the latter, evaporated and then mixed with water does not improve the nutritive properties of suitable artificial media; it is sometimes rather injurious to growth, whilst the decoction of the residual yeast heated to 135° C. and deprived of its vitamines by this treatment can confer qualities which allow of a slightly more abundant growth.

By filtering organic liquids through fullers' earth to remove the vitamines, it is found that the filtrate deprived of these substances is more favourable to the growth of mildews than the liquid before its filtration.

Finally the author satisfied himself that organic extracts also, heated to about 250° C. up to the point of carbonisation, preserved their fertilising properties when they were added to a tartro-glycerine medium, and it is difficult to admit, in this case also, that the vitamines were able to withstand this temperature.

Vitamines are substances indispensable to life, which cannot be replaced by definite chemical compounds, precipitable by phosphotungstic acid and the reagents of the alkaloids; they are retained by filtration through fullers' earth and are destroyed by heat. Now, none of these properties is found in the substances which are capable of improving the nutritive qualities of poor media for plants. Therefore it does not seem proper to compare these substances with vitamines of which they do not possess any of the characteristic properties.

609 – **Reduced Acidity in Oranges Caused by Certain Sprays.** — GRAY G. P., and RYAN, H. J., in *Monthly Bulletin of the Department of Agriculture, State of California, Chemistry Number* Vol. X, No. 1, pp. 11-33, tables 29. Sacramento, California, Jan. 1921.

Report of experiments carried out with fruit picked from sprayed and unsprayed orchards. Laboratory tests were made on single fruits to show the extent of variation of individual oranges from the same tree or orchard.

The results of these tests were both surprising and convincing. No consistent difference was noted in the sugar content of sprayed and unsprayed fruits, but a remarkable difference was noted in the acid content. A discussion of the preliminary tests made at Berkeley is presented first, followed by that of the large scale sampling and testing carried out in Los Angelos County.

The data recorded at Berkeley on Valencia oranges, over ripe, indicate a distinct difference in the acidity of the comparative lots and the highest acidity of any sprayed orange is considerably less than the lowest of the unsprayed fruits.

The unusual ratios shown in the table follow as a natural sequence of practically unchanged Brix readings, but reduced acid percentage, the latter being on an average 0.32 % for sprayed and 0.76 unsprayed. The results of the tests on Valencias taken in March, before the groves had fully ripened, did not show such a remarkable reduction in acidity of the sprayed fruits as that of the previous season's crop which had hung on the trees many months after becoming fully ripe but nevertheless there is a striking contrast' (average:— 0.67 % sprayed to 1.06 % unsprayed).

With Early Navels, there appears to be no indication of any effect on acid content early in the season The average of all sprayed fruits tested is, in fact, about $^1/_5$ of 1 % higher than that of the unsprayed lots. Later on, however, the acid content of navels is reduced, as shown by tests taken in May and June (Average for sprayed 0.375 %; for unsprayed 0.871 %, etc.).

The results of the large scale tests confirmed without exception those obtained at Berkeley, and proved that certain sprays composed of lead arsenate, sulphur, and soap powder (soap and sodium carbonate) appear to be in unstable equilibrium, that is, changes in chemical composition may take place depending upon various conditions and when applied to orange trees, even for one season only, produce a marked, and in many cases a startling decrease in the acid content of the fruit, although no consistent change in sugar content.

The results obtained, including the percentage of anhydrous citric acid, and official ratio, are tabulated, comparing samples from sprayed orchards with samples from previously fumigated orchards. The juice obtained from each fruit was also measured.

The effect on lemons appears to be similar to that on oranges, although insufficient data were obtained to warrant a positive statement. Specimens of lemons from 8 groves were examined, 4 from sprayed and 4 from unsprayed groves.

Subsequent to the co-operative experiments with the Fruit Growers Supply Company, two lots of Valencia oranges were received for analysis, one sprayed with acid lead arsenate *only*, and one sprayed with basic lead arsenate and lime sulphur. An unsprayed lot was also analysed for comparison purposes: The average acidity % in fruit from the first mentioned was 0.72; from the second 0.90 and from the unsprayed 0.94.

This reduction in acidity amounts therefore to approximately 50 % of the normal acidity of fully-ripe oranges, but in many cases is much more, especially when left on the trees beyond the usual cropping time.

610 - Line Selection of Wheat at the Phytotechnological Station "La Moncloa," Madrid.

— *Estación Central de Ensayo de Semillas, Boletín trimestral,* Year I, No 1, pp 2-7, figs. 24 Madrid, March, 1921.

The phytotechnological Station "La Moncloa" commenced its work of improvement of cultivated plants by following the methods and technique of the phytotechnical Station of Svalöf.

A beginning was made with wheat and with a series of investigations with the object of facilitating the selection of local kinds by isolating and propagating the best pure lines. On account of the very great number of local varieties and also the desirability of dealing only with the zone where the physical conditions (of soil and more especially of climate) of the environment are similar to those found at the Station, the work was restricted to a small number of indigenous wheats, mostly from the two Castiles. These were the following varieties: — " Candeal de regadío " of Alfaro (Logroño), " Candeal de secáno " of Alfaro (Longroño), " Candeal de la Sagra " (Toledo), " Toledo sin barbas " (Toledo), " Toledo con barbas " (Toledo), " Candeal de Guadalajara," " Sagreño " (Guadalajara), " Candeal blanco de Zamora," " Candeal de gluma blanca" (Badajoz), and " Candeal fino " (Ciudad Real).

Each variety was sown in a special plot and, at harvest time, 25 ears were selected in each plot, establishing for each the density calculated according to the formula $D = 10 \frac{a}{l}$ where a is the number of grains in the ear and l is the length of the rachis in cm.

Table I contains the biometric data relating to the variety " Toledo con barbas " (awned Toledo).

TABLE I — *Data relating to the wheat " Toledo con barbas."*

Serial number of the ears	Length of the rachis in cm.	Number of grains in the ear	Density	Serial number of the ears	Length of the rachis in cm.	Number of grains in the ear	Density
1	12.50	41	33	14	14.00	40	29
2	14.40	57	40	15	14.00	53	36
3	13.00	48	37	16	14.50	48	33
4	13.00	47	36	17	13.00	47	36
5	13 70	53	39	18	13.00	55	42
6	12.70	54	43	19	12.50	51	41
7	14.00	48	34	20	13.70	47	34
8	13.50	54	40	21	14.50	55	38
9	14.00	60	43	22	15.00	53	35
10	14 00	50	36	23	14 00	42	30
11	14.50	47	32	24	13 00	54	42
12	14.50	53	37	25	13.60	55	40
13	14.50	55	38				

As can be seen in Table I, 15 density values (29 to 43) were obtained for the 25 ears examined. If " Toledo con barbas " represented a homogeneous group of individuals (elementary species of JORDAN, pure line of JOHANSSEN), the ears of average density (D = 36) ought to be most numerous and those of extreme density (D = 29 and D = 43) ought to be the least numerous. Representing diagramatically the values of density and of frequency, a simple curve is obtained with a single apex. On the other hand, if the varieties examined are not pure lines but populations, that is to say, mixtures of pure lines, instead of a single maximum frequency there would be more then one maximum. The curve of the diagram, instead of showing a single apex, would be broken and show separate apices increasingly numerous in proportion as the population is more heterogeneous. This is exactly the case with "Toledo con barbas" (see Table I)· There are two well defined maxima corresponding with densities 36 and 40 which, if reference is made to the law of GALTON, should be considered as the average density values of two *good* elementary species. The ears with a density of 36 and 40 (seven in all) were selected as founders of new pure lines of "Toledo con barbas."

So far as the distribution in frequency of the character "density of ear" is concerned in the other wheats, we have:—

TABLE II. — *Characters of the pure lines.*

Candeal fino (Ciudad Real)	Moncloa No. 27	35

"Trigo candeal de regadio," 4 maxima corresponding to densities 33, 35, 39 and 40.

"Candeal de secáno," 3 maxima :— 32, 35, 37.

"Candeal de la Sagra," 2 maxima :— 35 and 40.

"Toledo sin barbas," 3 maxima :— 26, 28 and 33.

"Candeal de Guadalajara," 2 maxima : — 22 and 24.

"Sagreño," 1 maximum :— 35 (this is therefore a very homogeneous variety).

"Candeal de Arévalo," 2 maxima :— 32 and 36.

"Candeal de Soria," 3 maxima :— 28, 29 and 36.

"Candeal blanco," 2 maxima :— 37 and 40.

"Candeal de gluma blanca," 2 maxima :— 81 and 92.

"Candeal fino," 1 maximum .— 35.

The ears corresponding to the maxima values are set apart for sowing separately in plots so as to constitute, as noted above, the founders of other pure lines.

The results of selection are given in Table II.

The author intends to continue the work of line selection and to extend it to other indigenous varieties, which will contribute in a large measure to the improvement of Spanish wheats by rendering them more homogeneous and heavier producers.

611 - **The Improvement of Wheat and Oats by Selection, and by Crossing Combined with Selection, in the United States.** — HAYES, H K. and GARBER, R J, in *The University of Minnesota, Agricultural Experiment Station, Bulletin* 182, pp. 1-44, 10 figs. St. Paul, Minn. March 1919.

The work carried out at the Minnesota Experiment Station with a view to improving agricultural plants may be divided under 3 heads:

1) Introduction of new varieties and types.
2) Pure line selection, or mass selection.
3) Crossing followed by selection.

INTRODUCTION OF NEW VARIETIES AND TYPES. — New introductions are essential, in order to obtain the best material for experiments, further, the time and trouble necessary to the production of a new variety adapted to a certain locality is wasted, if the same result can be obtained through introductions.

The head selection method is used, from 50 to 200 heads being selected the first year. Non-promising sorts are eliminated in the field. The next year, three systematically distributed plots of a single 18-foot row are each grown for selection, one foot being removed from each end before harvest. Those that are not eliminated, are tested the third year in three plots of three 18-foot rows each, the central row only of each plot being used for the yield test. Border rows are grown to obtain more accurate data on lodging and to overcome competition between other sorts grown near.

Selection was begun with the F_2 of a cross The seed of each plant selected in F_2 is planted in a separate plot in F_3. Some plots are homozygous for all characters, some are heterozygous for some characters and homozygous for others, while some show segregation as in F_2.

Selection by the individual plant method is continued until many homozygous forms are obtained. These are isolated and treated afterwards as selections, all rogues or inferior individuals being weeded out.

SELECTION AND CROSSING — WINTER WHEAT. — There are three main reasons why it is preferred to spring wheat:

1) It allows for a better distribution ot labour on the farm.
2) It matures earlier, which serves to protect it from rust and drought.
3) It yields more grain per acre

On the other hand, winter wheat suffers much from the cold, which kills many of the young plants, leaving gaps in the fields, so the acreage is small.

Many new varieties have been introduced and tested, as for instance, those chosen by LEIGHTY which had proved very resistant to cold in the Eastern States, but in Minnesota were only equal, or inferior, in this respect to Turkey wheat, a variety that is not noted for winter hardiness.

In short, the experiments proved that the various introductions were less hardy than the selection and crosses made at the Minnesota Experiment Station many years ago.

Of the pure lines that excelled in hardiness mention should be made of Odessa I-01-3, Big Frame I-06-6, and two semi-hardy types, Turkey I-03-120 and Padui I-03-229 (the latter is a selection from a winter wheat introduced from Russia). Crimean (Minnesota 845) has also given a good record as a hardy variety.

As regards other characters, the four (semi-hardy) Odessa selections Odessa I-01-3, I-15-179, I-15-177 and I-15-190 deserve special mention for their resistance to lodging.

The Odessa × Turkey crosses gave excellent results. They showed all sorts of recombinations of the characters of the parents, some being very hardy, others intermediate, while others again were very susceptible to cold. Data ot this sort corroborate the observations of NILSSON-EHLE and show that winter wheat hardiness is due to the interaction of numerous inherited factors.

The following Table gives the summarised data:

Variety	Nursery Series No.	Minnesota No.	Average yield bushels per acre	Average winter injury
Odessa	I-01-3	1471	2 089	38 %
Turkey	I-03-120	1481	2 471	40
Turkey × Odessa	II-02-195	1505	2 627	29
Turkey × Odessa	II-02-280	1507	2 344	42
(?) × Turkey	II-02-519	—	2 600	—
Crimean	—	845	2 056	37
Turkey	check	1487	1 549	73

Some of these hardy hybrids were also very productive, indeed tests proved that types excelling in hardiness generally excel in yield. Lower temperature appears to be the chief exterior factor affecting the yield of winter wheat.

Spring Wheat. — Rust-resistance is the most important character of spring wheat. The object of selection is to combine in the highest possible proportions the two characters of high specific yield, and resistance to rust.

Recent studies of the biology of *Puccinia graminis Tritici* have revealed the existence of several biologic forms of the parasite which can only be differentiated by their reaction to pure lines of wheat. This fact makes it difficult to obtain rust-resistant varieties by means of selection and crossing, until further investigations have been made as to the life-history of the parasite.

It is therefore best for the present to give the preference to early maturing wheats which escape the attacks of the cryptogam.

As regards selection by pure lines Marquis occupied the first place.

Several crosses made in 1908 between Turkey Winter and Wellman's Fife are better than Haynes Bluestem, and Minnesota 169; none however seem of more value than Marquis. Minden, a selection belonging to the Arnautka group, has given evidence of being a valuable sort for Minnesota.

In 1916, the following yields were obtained:

Variety	Average yield bushels
Mindum	16.6
Kubanka, Minn. n° 990	11.0
Marquis	12.7
Preston	6.2
Minnesota n° 169	5.8

Oats. — Selection by pure lines has shown that it is possible by this means to get really valuable commercial varieties. Excellent results were obtained with Sixty Day: one pure line I-17-72 was more productive than the original variety and resisted lodging better.

Selections of the following varieties deserve further testing: Minota, Garton 473, Garton 784, Scottish Chief, Irish Victor, Lincoln and Kherson.

612 - **The Improvement of Barley by Pure Line Breeding, and Crossing Combined with Selection, in Minnesota, United States.** — HARLAN, H. V. and HAYES, H. K., in *The University of Minnesota, Agricultural Experiment Station, Bulletin* 152, pp. 1-44, 10 figs., St. Paul, Minnesota, March 1919.

PURE LINE BREEDING. — Especially interesting results were obtained with the Manchuria variety: of the many lines selected, I-16-2, has given a low yield during the years that it has been tested, while the yield of

I-15-2 has always been very high. Nearly as wide variations are found within a variety as are obtained by comparing different varieties. This shows what can be attained by means of pure-line breeding alone.

Crosses Manchuria × Lion. — Lion is a smooth-awned, black barley, the former character is very important. The hybrids also are smooth-awned, and though they do not generally give as high a yield as Lion, yet as a rule, the crops are satisfactory. Several of these crosses, when compared with Manchuria No. 105 and No. 154, seemed very promising as they combined the good qualities of the latter with the character of smooth awns.

Two crosses between Lion and Mariout were tried in 1917 and 1918. Both gave high yields, but lodged rather badly; they have however the dense heads of Mariout and the smooth awns of Lion. Thus, smooth-awned barley of any head type can be produced by crossing and subsequent selection

Cross between South African and Manchuria — South African is a dense-headed type resistant to lodging, but with a very small yield. Table I gives the comparative results for the South African parent and Minnesota No. 154 (a pure-line Manchuria selection).

TABLE I. — *Comparison of yielding capacity of South African and one of the best selections of Manchuria.*

Variety	Minn. N°	Nursery series number	Year	Yield
				gm
Manchuria	184	I-01-67	1902	471.7
»	184	I-01-67	1903	621.0
»	184	I-01-67	1904	465.3
Average . . .	—	—	—	**519.3**
South African	99	I-97-3	1902	306.0
»	99	I-97-3	1903	241.9
»	99	I-97-3	1904	304.5
Average . . .	—	—	—	**284.1**

These figures show that South African is a poor yielding variety. In spite of the manifest inferiority of one of the parents, characters of some value are found in the hybrids. Thus, II-16-47 and II-16-77 are not only much more resistant to lodging than Manchuria but also excel the latter in yield (from 1916-1917, the two hybrids produced respectively 56.3 bushels and 51.1 bushels per acre).

ELIMINATION OF INFERIOR MATERIAL. — The 63 selections studied at the Minnesota Agricultural Station, together with the numerous crosses and introduction of new varieties, provided ample material for selection, and increased the possibility of fresh combinations, but in the end, this enormous accumulation of material hindered the work of definitively isolating the best types. It was therefore necessary gradually to discard all types, sorts and groups of interior quality, or that had already served their turn, and were of no further use.

After a series of severe comparative tests made for the purpose of overcoming, as far as possible, all discrepancies arising from soil heterogeneity, the series that survived was as given in Table II.

The last of these selections, Highland Chief, has been discarded as it lodges badly. This leaves 7 varieties, all six-rowed sorts, that will be further tested in field plots. All the two-rowed varieties gave less satisfactory results; but the hybrids Bohemian × Manchuria II-16-78, and 456 × Svanhals II-16-37 deserve further trial.

PRELIMINARY TEST AT SUBSTATIONS. — In 1918, several of the more promising sorts were grown in rod-row tests at the University Farm, and also at the three sub-stations of Waseca, Morris and Crookston. The averages obtained are given in Table III.

613 – **A New Means of Obtaining Types of Maize with a High Gluten Content.** — EAST, E. M., and JONES D. F., in *Genetics*, Vol. 5, No. 6, pp. 543-610, 8 figs. Baltimore, November 9, 1920.

Although the protein content may vary very greatly owing to climatic conditions and cultural operations, it is nevertheless sure that it is controlled by a certain number of genetic factors which, however, it has hitherto not been possible to discover The existence of genetic factors, or determinants, proves that there is every hope of obtaining by means of selection, or of crossing combined with selection, new lines, or types, possessing a larger number of factors and in such proportions, that an abundant supply of gluten may be insured.

Work in this direction has been rendered extremely difficult by double fertilisation, which takes place in maize, as in all other cereals, but with even more important consequences. The zygote is formed by the union of two gametes, ♀ and ♂, but the endosperm results from the fusion of three gametes ♀ + ♀ + ♂ which takes place at the same time. The grain is formed by successive cell division: 20 % of the protein of the maize grain is therefore found in the embryo which only transmits the inherited characters, whereas 50 % is in the endosperm which latter has no influence upon character inheritance. Let us suppose, that the differential factors of two plants, one rich and one poor in gluten, are 4 in number: A, B, C, D The formula of the plant with the high gluten content will be AA BB CC DD, and that of the one with the low gluten content will be, aa bb cc dd. The results of reciprocal crosses will be as follows. Except for a slight decrease in the amount of protein due to heterosis, the grains of the F_1 are of the maternal characters, and though they have the same formula, Aa, Bb, Cc, Dd, there will be among them some seeds that are rich in gluten, and others that are poor in gluten, according to whether the gluten content of the female parent was high or low.

On the other hand, there will be, as regards the successive generations, a very large number of possible re-combinations, which will still further complicate the work of isolating, creating, and fixing lines with a high protein content. This explains the failures that have occurred in the experiments hitherto carried out.

In the article analysed, the author gives the results obtained in the required direction by the application of a new method, viz., the artificial pollination of the greatest possible number of plants — the careful testing of the grain produced by each individual by means of the progeny-plot system — the continuation of the self-fertilisation work until the largest number of homozygote plants with gluten-containing seeds have been obtained, and the inter-crossing of these plants, for some of the hybrid, thus obtained would inherit the capacity of producing a large amount of gluten. The 4 following varieties were used: Stadtmüller's Leaming Burwells' Flint, Illinois High Protein, and Illinois Iron Protein.

Table I gives the data referring to a family of Stadtmüller's Leaming.

The examination of 27 ears (obtained by self-pollination from plant No. 14 in 1912) gave protein percentages varying from a minimum of 8.11 to a maximum of 17.86, with an average of 12.03. In 1914, the ear richest in gluten (No. 6) always produced, by self-pollination, progeny with 4 ears giving percentage ranging from 9.57 to 16.21, with an average of 13.04. The progeny of the ear which was freely exposed to cross-pollination produced an average of 11.61 % of gluten. The best ear was always chosen, and an uninterrupted series of self-fertilisations carried out until 1918, in which year the family 14-6-20-10-15 produced as a result of unrestricted pollination an average of 17.07 %.

TABLE II — *Gluten content of 7 First Generation Crosses (Stadtmüller's Leaming × Illinois High Protein).*

	Offspring										Average	Parent-Ear
A	15.86 %	14.81 %	14.36 %	14.26 %	14.22 %	14.17 %	13.71 %	13.45 %	12.81 %	12.46 %	**14.01 %**	17.98 %

G	15.55	14.57	14.54	14.52	13.96	13.55	13.52	13.28	12.42	12.20	**12.81**	10.71

TABLE I. — *Data Referring to a Family of Stadtmüller's Leaming.*

	1912	1914	1915	1916	1917	1919
Mother ear ♀	14	14–6	14–6–20	14–20–10	14–10–3	14–10–15
Protein in mother ear ♀	—	17.86 %	16.21 %	15.92 %	17.30 %	16.59 %
Extreme values of the protein in the self fertilised population	8.21–17.86	9.87–16.21	11.82–15.92	13.47–17.30	—	—
Number of ears examined	27	4	11	10	—	—
Average protein of self fertilised population	12.03 %	13.01 %	14.09 %	15.93 %	—	—
Average protein of the population exposed to cross-pollination . . .	—	11.61 %	12.69 %	15.09 %	16.75 %	17.07 %

The highest value observed was obtained in 1912, when one ear contained 17.86 % of gluten ; if however a larger number of ears had been examined, perhaps a higher figure might have been recorded. It is evident, that the commercial varieties of maize include plants with ears that are very rich in gluten and possess genetic factors which, when brought together in a homozygous condition, would give ears with a high gluten content like those obtained by mass selection at the Illinois Agricultural Station during a period lasting about 25 years. The highest percentage registered at that Station was indeed 15.66, in 1916, whereas, as has shown above, the Stadtmüller's Leaming family gave good results, as did also Burwell's Flint. On the other hand, less success was attained by selection in the case of the two Illinois varieties, which after being subjected to selection for 16 successive generations, are still in a homozygotous condition as regards most of their factors, and are hence less susceptible to modification.

One of the chief difficulties encountered in the production of lines rich in gluten by means of continued self-fertilisation is the lack of a practical method of carrying out the necessary selection operations on a large number of individuals. Theoretically all the individuals presenting extreme characters in a population should be tested, but this is practically impossible.

The author has tried to obtain at least a partial solution of the problem by crossing the types richest in gluten that had been obtained by selection combined with continued self-fertilisation. The plants of the F_1 thus obtained were self-fertilised and the progeny subjected to successive selection.

There were 37 crosses made between the families of Stadtmüller's Leaming (No. 14) and Illinois High Protein (No. 20), the gluten content of the ears thus obtained varied from 18.48 to 9.08 %. Seven of these ears (A—G) were sown in 1915. Ten ears taken from the most vigorous plants of the progeny of each of these ears were examined. The results are given in Table II.

Groups G and D gave an average even higher than that of the mother ear, but showed great individual variations. The best result was obtained from group C, which although inferior by 1 % to the female parent, manifested but slight variations ranging from 16.32 to 13.99 %. The ear with the highest protein content was chosen from each of the 7 groups and the seeds were sown in 1916. The plants thus obtained were again freely intercrossed; by this means 2 ears with 18 % of protein, and a large number with over 17 % were obtained (F_2).

Ten carefully-chosen ears were sown in 1919, and some of these were self-fertilised. The analytic data referring to these self-fertilised ears show such a high correlation between parents and progeny, that it is impossible to entertain any doubt as to the influence of heredity (see Table III).

TABLE III. — *Comparison between gluten content of parents* (1916) *and of their offspring* (1917)

	C 23 × *B* 20	*A* 26 × *B* 2	*A* 22 × *B* 2	*D* 27 × *A* 15	*B* 20 × *D* 15
Average for 2 parents in 1916 .	18.26 %	17.39 %	16.90 %	16.89 %	16.82
Average for offspring in 1917 . .	**16.31**	13.43	14.12	11.65	**15.42**
	B 2 × *A* 4	*A* 36 × *D* 10	*A* 20 × *D* 21	*A* 10 × *D* 2	*B* 41 × *A* 26
Average for 2 parents in 1916 .	16.67 %	16.53 %	6.04 %	15.98 %	15.93 %
Average for offspring in 1917 .	13.09	12.86	**15.05**	12.83	12.37

After 7 years of work, 3 types of maize were obtained with respectively 16.31, 15.42, and 15.05 % of gluten, which were also vigorous and gave fair yields of grain.

Further, each of these types still possess a reserve of variability, which renders possible further improvements. The two ears highest in gluten content from family C 23 × B 20 were planted in 1918. From the offspring of one of these plants, the 15 selfed ears obtained averaged 17.68 % gluten, and one reached 20.14 %.

Gluten content is due to a large number of inherited factors; and various strains having the same percentage composition probably differ in respect to their genetic composition, so that it is possible to obtain a number of genetic factors that are superior to those of its parents, and hence a still higher gluten content.

614 - **The Explanation of Heterosis in Maize.** — COLLINS G. N., in *The American Naturalist*, Vol. IV, No. 637, pp. 116-133. Lancaster Pa., March-April 1921.

A stimulation of growth has come to be recognised as one of the results of hybridisation. This phenomenon is of so much importance both practically and theoretically, that it has been given a special designation, *heterosis*.

TABLE I — *Number of F_2 individuals necessary to provide an even chance of obtaining at least one individual homozygous for the number of dominant characters indicated in Column I.*

Number of dominant homozygous characters	Number of characters involved													
	2	3	4	5	6	7	8	9	10	11	12	13	14	15
2	11	5	3	2	2	1	1	1	1	1	1	1	1	1
3	—	45	14	7	4	3	2	2	2	2	2	2	1	1
4	—	—	178	45	19	16	6	4	3	3	2	2	2	2
5	—	—	—	710	150	54	26	14	9	6	5	4	3	3
6	—	—	—	—	2 480	516	165	70	35	20	13	9	7	5
7	—	—	—	—	—	11 400	1 820	516	199	94	49	29	19	13
8	—	—	—	—	—	—	44 900	6 520	1 760	584	246	123	68	41
9	—	—	—	—	—	—	—	182 000	23 400	5 500	1 770	700	322	165
10	—	—	—	—	—	—	—	—	726 000	85 400	18 400	5 490	2 030	870
11	—	—	—	—	—	—	—	—	—	2 900 000	313 000	62 600	17 400	6 000
12	—	—	—	—	—	—	—	—	—	—	11 600 000	1 160 000	215 000	56 000
13	—	—	—	—	—	—	—	—	—	—	—	46 500 000	4 320 000	750 000
14	—	—	—	—	—	—	—	—	—	—	—	—	186 000 000	16 150 000
15	—	—	—	—	—	—	—	—	—	—	—	—	—	744 000 000

Heterosis is shown to a special extent in maize , in nearly all the commercial varieties of the latter, individuals manifesting this abnormality are to be found, and these abnormal plants are almost always deficient in vigour and yield. Heterotic variations are recessive, but when the dominant character is eliminated by continued self-pollination, these anomalies show themselves, and influence the development and yield of the plant.

Different varieties possess different groups of recessive lethal, or semilethal, characters In a cross between two varieties, the negative characters common to one parent are brought into combination with, and suppressed by, the dominant allelomorphs in the other parent. Freed from the depressing effects of these recessive characters, the first generation of a hybrid is usually more vigorous and productive than either parent; this explains the phenomenon of heterosis.

One of the objections to this hypothesis is that; if this explanation is correct, it should be possible to obtain an occasional F_2 individual homozygous for all dominant allelomorphs, the progeny of which should be uniformly as vigorous as the F_1 and so far, this individual has not been found.

The probability of finding such an individual is indeed very small, as can be seen by referring to Table I (page)

On the other hand, an examination of the maize literature, and the biometric data directly obtained by the author, in no wise exclude the possible existence in the F_3, and even in the F_2, of hybrids with vigorous growth.

Height is probably the most satisfactory character to use as a measure of heterosis. There are 29 comparisons of F_1 and F_2 populations (23 made by Emerson and East, and 6 by the author) : in these 29 cases, the mean of the F_2 was below that of the F_1 in every instance, but in 10 of the 29 cases, the largest of the F_2 plants equalled, or exceeded, the largest of the F_1 plants.

Similar observations were made respecting length and diameter of ear and length of internode : as regards the last character, 5 of the F_3 individuals were superior to the F_1, whereas none of the F_2 equalled the F_1

The second objection brought forward was ; that a series of independent dominant characters influencing size would bring about an asymmetrical (skew) distribution of the F_2 individuals.

All the cases observed have, on the contrary, shown perfectly symmetrical distribution, but it should be noted that the number of individuals used in the construction of a diagram would have to be very large in order to make departures from a normal frequency distribution apparent.

In fact, with 20 pairs of characters (giving 21 classses), 514 627 776 individuals would be required to obtain a representative population; 99.91 % of this population would fall into the 12 classes with the largest number of dominant characters. Therefore, in order to obtain any individuals smaller than those represented in these 12 classes, populations of over 700 would have to be grown. With ordinary-sized populations, the distribution would be fairly represented by these 12 classes (see Table II).

TABLE II. — *Distribution of* F_2 *individuals, classed according to size.*

Number of dominant allelomorphs	Proportion of individuals
9	0.3
10	1 0
11	2.7
12	6.1
13	11.2
14	16.9
15	20.2
16	19.0
17	13.4
18	6.7
19	2.1
20	0.3

A distribution of this nature, with populations of approximately 500 individuals representing the highest classes (9-20) conforms to the normal frequency curve as closely as would be expected.

The asymmetry would appear if the first 8 classes were considered, but these are so little represented, that in order to determine their presence, an enormous number of individuals have to be examined.

Thus the two chief objections made against the hypothesis which has been employed to account for heterosis fall to the ground, and in no way affect the truth of the explanation.

615 - **The Improvement of Tobacco by Hybridisation and Selection in Sumatra.** — JOCHEMS, S. C. J., in the *Mededeelingen van het Deli Proefstation te Medan*, 2nd Series, No. XIX, pp. 1-25. Medan, 1921.

Results of work on the improvement of tobacco, carried out at the Medan Station (Sumatra), in two ways, viz., hybridisation followed by selection, and selection by pure lines.

HYBRIDISATION. — Study of descendants of the cross *light line* No. 1 × *dark line* No. 72 in order to individualise and isolate a hybrid with constant characters. The results have again been negative; the descendants were never homogeneous and intermediate gradations were met with.

The data collected lead to the following conclusions :—

1) The percentage of dark leaves is higher in most of the hybrids than in *line* I, and the percentage of light leaves is less than in *line* 1.

2) The percentages observed in the hybrids differed very slightly from those of *line* 72.

3) Among the few hybrids which can be considered as superior, the *line* No. 2155, which furnished a tobacco superior to *line* 1 (Consortium of Deli), should be noted.

Data relating to the F_2 *and* F_3.

Line	Cross	Generation	Dark leaves per cent	Light leaves per cent	Intermediate leavesper cent.
2184	72 × 1	F_2	58.4	18.7	22.5
2144	»	F_3	30.9	45.3	23.4
2223	»	F_3	41.6	27.9	30.1
2174	»	F_3	33.5	37.0	29.1
2267	1 × 72	F_3	37.0	31.5	31.0
2229	»	F_3	31.4	46.7	21.5
2231	»	F_3	30.5	31.1	38.0
2233	»	F_3	38.1	37.3	24.1

4) In the Soenger Bahasa plantations, the *hybrid* 2225 proved superior to *line* 72 · in the Goenoeng Rinteh plantation No. 2229 stands first.

5) It has not so far been possible to isolate a hybrid with really constant characters.

Crosses between the lines 1 and 774 (many leaved) are also under study; the data collected so far do not yet allow conclusions or forecasts to be formulated.

PURE LINES. — The study of these continues, with favourable results in the case of lines 774, 976, 542 and 553.

616 – **The French National Wheat Committee.** — HITIER, H, in the *Comptes rendus de l'Académie d'Agriculture de France*, Vol. VII, No. 4, pp. 77-83. Paris, Jan 26, 1921.

In April, 1920, M. J. H. RICARD, the French Minister for Agriculture, instituted the National Wheat Committee with the general object of examining all means tending to increase the production of wheat and proposing all measures likely to ensure their application.

The author reviews the results obtained in 1920 by the National Wheat Committee, through the work of its sections dealing with:— *Technique, competitions, corporate action, and propaganda.* Departmental Committees, in collaboration with Directors of the Agricultural Services, Offices and Agricultural Associations, organised seed fairs, sorting sheds, wheat growing competitions, etc. Up to the present, the results satisfy the object aimed at by the creation of the National Committee and there is every reason to predict that its scope will be still further widened during 1921.

To this end, M. RABATÉ (General Secretary of the Committee) presented to the Committee, on December 18, 1920, a programme of work which was approved and, among other things, has in view the following measures:—

A general inquiry regarding the present adaptation of various varieties of wheat to the geological, agricultural and climatic conditions of various parts of France. Study of the tillage of fields under wheat and subjecting to regular controlled experiments the operations at present recommended, not always with sufficient discernment and knowledge of the very varied conditions of agriculture in France Cultivation of wheat in spaced lines with second ploughing, earthing-up, etc. Multiplication of wheat competitions in the different Departments. Development of co-operative societies for agricultural tools, apparatus for threshing and sorting seeds, and more specially a new form of association, namely, co-operative seed production, grouping 10, 20, 30 of the leading farmers of each canton, having at its disposal a genealogical selection farm and a central depot for sorting and despatch. By means of control over standing wheat crops and over threshing it would be possible to deliver one or two varieties with a maximum guarantee.

M. CHASLES, President of the French National Association of millers, has initiated an organisation of this kind in the Seine-et-Marne district.

In all parts of France progress in the cultivation of wheat can be made, but to obtain results quickly, efforts must be brought to bear on those parts which cultivate the largest areas under wheat, because they possess land suitable for the crop ; and it is necessary, in the whole of those regions, to endeavour especially to improve the cultivation in those which give the smallest yields. M. RABATÉ has compiled an interesting table dealing with this point. After having determined the average figures of areas in hectares and of yields in quintals for the period 1905-1914, he calculated for each Department the coefficient obtained by dividing the number of thousands of hectares sown with wheat, by the yield per hectare. The higher the coefficient so obtained, the greater is the relative effort of improvement required.

By perusing this table both the efforts to be made and the results which may be hoped for can be ascertained, in regions such as that of the west (Maine-et-Loire, Vendée, Loire-Inférieure, Ille-et-Vilaine) sowing over 140 000 ha. of wheat in each of these Departments without obtaining an average yield of 14 quintals per hectare ; and such as that of the south-west (Lot-et-Garonne, Dordogne, Gers, Haute-Garonne, Charente, Charente-Inférieure, etc.) sowing over 110 000 ha. of wheat and obtaining a yield of less than 12 quintals per hectare.

617 - **Experiments with Wheats from the Swiss Jura at the School of Agriculture at Cibeins (Ain, France).**— SCHRIBAUX, in the *Comptes rendus de l'Académie d'Agriculture de France*, Vol VII, No. 13, pp. 330-332 Paris, Apr 1921.

Since 1918 the author has repeatedly induced farmers in regions in France where the winter is severe and where the high yielding wheats recommended do not stand the hard frosts, to sow the varieties of Swiss Jura wheat selected by M. MARTINET, Director of the Seed Testing Station at Lausanne (Switzerland). In the note reviewed he brings to notice the good results obtained by M. BLÉRIOT, Deputy-Director of the École Municipale lyonnaise d'Agriculture at Cibeins (Ain), with the two varieties " Bretonnières " and " Vuitebœuf " which confirm results previously obtained by other experimenters.

On poor soil, sown as late as November 26, 1919, the following yields were obtained :—

Vuiteboeuf	1568 kg. of grain per hectare
Bon Fermier	1328 » »
Carre Vaudois	1300 » »
Montcalme	1187 » »
Mottet de Savoie	1110 » »

Bretonnières was, by mistake, threshed with another variety, so it is not possible to give the yield; but from the look of the crop on the field it must have been equal, if not superior, to the Vuitebœuf wheat.

In 1919 and in 1920 the author found at the "Ferme des Colonies étrangères" at Champagne and at the Experimental Farm of Noisy that Vuitebœuf and Bretonnières compared favourably with Japhet, Gros-bleu, Bordeaux, and Noë for yield, quality of grain and earliness, and that they had a great advantage over the last two varieties in being resistant to rust.

The author considers that the Swiss Jura wheats improved by M. MARTINET can be tried with good prospects of success throughout the whole of France, excluding the zone of the olive where they would be liable to scorching.

618 – **Notes on the Cultivation of Oats in France.** — VILCOQ (Director of the School of Agriculture at Chesnoy, Loiret), in the *Comptes rendus de l'Académie d'Agriculture de France*, Vol. VII, No. 18, pp. 434-437. Paris, May 11, 1921.

The land, belonging to terrace sands and gravels and which had borne a crop of wheat in the previous year, was first ploughed to a depth of 15 cm. about February, followed at the time of sowing, by the application of 400 kg. of $^{13}/_{15}$ superphosphate per hectare, and scarifying and scutching. The seed was sown in lines 15 cm. apart, and each variety studied occupied a plot of one-fiftieth of an are.

The oats tried in the experimental crops of M. VILCOQ and the yields obtained, were as follows :—

	Yield per hectare in quintals
VILMORIN Hybrid	11
Victoire	18
SCHRIBAUX 1st hybrid (Ligowo × Brie) (1)	19
SCHRIBAUX 2nd hybrid	20
Grey oat of Houdan (or of Beauce)	21
Pluie d'or	22

The hybrid oat Ligowo × Brie gives a first class grain and very abundant straw. For light calcareous soils a hybrid of SCHRIBAUX, the grey oat of Houdan and the Pluie d'or have shown themselves superior to the other varieties for quality of grain, hardiness, and yield.

---

(1) See *R.*, May, 1920, No. 507 (*Ed.*)

The author has thought that, for the calcareous soils of Gâtinais, it would be interesting to cross the grey oat of Houdan with the Pluie d'or, so as to preserve the quality of grain of the former whilst improving considerably the proportion of straw. He has been working on this problem for two years. By cross-fertilisation he has obtained a new hybrid which he is at present studying.

619 – ***Zea Mays dentiformis* var. *leucoceras*, a New Variety of Maize from French Guinea.** — RAYBAUD, L., in the *Comptes rendus de la Société de Biologie*, Vol. LXXXIV, No 15, pp 796-797 Paris, April 30, 1921.

The author has received a new variety of maize from French Guinea, where it is called " niogoué, " and has tried to acclimatise it in Provence. It is characterised by its flattened grain pointed at the upper end and by its white colour. It corresponds to the *Zea Mays dentiformis* var. *crococeras* of KÖRNICKE, but is white instead of yellow and is intermediate between the maize with sweet wrinkled grain (*Zea Mays saccharata*) and the dent maize properly so-called (*Zea Mays dentiformis*). Grown in Provence, this variety formed ears that were more cylindrical than conical, 17-22 cm. long and 5 cm. broad, composed of a dozen rows of grains. Out of some fifty varieties studied by the author the characters " spacing of rows " and " compactness of ears " are more pronounced in this variety than in others. It is also remarkable on account of its very fusiform leaves.

Sown in Provence in April this variety was not harvested until November.

620 – **Results of Experimental Cultivation of " Reggiano " Maize (Early Dwarf)** (1).— SUCCI, A., in the *Giornale di Agricoltura della Domenica*, Year XXXI, No. 13, p. 99, figs 3. Piacenza, March 27, 1921, and the *Gazzetta agraria*, Vol X, No 7, p. 1, 2 figs Alessandria, Apr. 15, 1921.

Experimental cultivation which has been carried out all over Italy has brought to notice that the " reggiano " maize of Reggio Emilia is the earliest and most dwarfed of all, and that, of equally early kinds, it is the most productive. The data contained in the two following Tables show the results of experiments made in 1920 at Parma by the Technical Office for the Production and Selection of Seeds and at Forli by the Agricultural Office of the Royal Laboratory of Agricultural Chemistry.

Results of the cultivation of maize at Parma.

621 – **Types of Maize with a High Gluten Content.** — See No 613 of this *Review*

622 – **Cultivation of Rice in Ceylon.** — I Summers, E, The Tillering of Ceylon Rices — *The Tropical Agriculturist*, Vol LVI, No 2, pp 57-86, pl. 6 + Tables 19 — II Bamber, M K., Paddy Manuring Experiments with Yala Crop, 1920 *Ibid*, pp 87-90 Peradeniya Ceylon, Feb 1921.

The observations here described are intended to throw light upon the question of the average number of ears per acre to be expected in the following 3 cases — 1) when the seed paddy is broadcasted in the ordinary ways; 2) when single plants are transplanted at intervals of 6 × 6 in.; 3) when the seeds are sown at intervals of 12 × 6 in.

The data given refer to various varieties grown at the Experiment Station, Peradeniya in 1920.

I. Broadcasted Paddy. — Results indicate that in a paddy crop broadcasted, weeded and thinned out by the methods normally employed by the Ceylon cultivator: 1) most of the plants in the crop will have either one or two good ears; 2) if more than 2 ears are borne on a plant the chances are that one of these will be immature and worthless; 3) the average number of ears per plant to be expected from the crop is 1.9; 4) if the plants are separated on an average by a distance of 22 in., each square yard will contain 220 plants, and should therefore produce about 418 good ears. These results have been checked in the field, chiefly with Central Province fields of Hatiel, Heenati and Mawi. These were found to be conformed to in all cases.

II. Transplanted Paddy. — By transplanting the seedlings at intervals of 6 × 6 in., a square yard contains $^{1}/_{9}$ of the number found when the crop is broadcasted.. It follows therefore that on an average, the plants must produce, if there is no increase in the average size of the ears, 9 times as many ears as the broadcasted plants, if the yield is to be maintained. The varieties used were a series of 3 months paddies grown in the experimental plots at the Dry Zone Experiment Station at Anuradhapura. The series comprised 90 varieties of which 52 were exactly duplicated at the Peradeniya Experiment Station. The seed samples were collected from all parts of the Island about the middle of 1919. A striking feature of all plots was the almost entire absence of weeds so that no weeding was necessary from start to finish. Progress was excellent at Anuradhapura, many of the varieties being harvested within 76 days from the time of transplanting or within 110 days from the time of sowing. The results obtained in the case of 44 Ceylon varieties are tabulated in full, with a view to serving as a guide to cultivators in the future in connection with what results may be expected with a particular variety as regards the number of tillers when transplanted alike. It is concluded thereby that the increased yields obtained by transplanting are not entirely due to increased tillering on the part of the seedlings.

A comparison of results at Anuradhapura and Peradeniya is rather surprising in view of the fact that the fields at the former station are only 3 years old, the drainage is good and the mud not at all clayey. On the contrary the fields at the latter station are old, clayey and the drainage inferior. The view is generally held that in the case of dry cultivated cereals, a sandy soil encourages tillering, while a soil rich in clay has the reverse effect. In these experiments there was not the slightest evidence that this is true for the rice plant, so that evidently caution should be taken before attempting to apply to paddy, the results obtained with dry cultivated cereals.

During the Yala season of 1920, in an attempt to elaborate a system of field technique for pure line work at Anuradhapura, the plan was tried of sowing the individual seeds by hand directly upon the paddy field. In all, 69 pure lines were thus sown, but the results have not yet been worked out in every case. Sowing took place on June 2 and 3, 1920, with varieties varying from 6 to 4 months old.

Most of the plants appeared to possess tiller numbers lying between 5 and 15, although a fair number had from 16 to 20 tillers. There was no more variation of the tillering mean between the different varieties than there was amongst the means of the lines of any single variety, nor was anything in the nature of a specific tillering capacity observed.

As regards the yield and development, the following general comparison may be made between broadcasted and transplanted paddy :

Broadcasted	Transplanted
1) Number of ears produced is a minimum.	Number of ears produced is greater.
2) Tillering is irregular	Tillering is more regular and can be expressed by a definite tiller mean.
3) Development of the aerial portion of the plant is small.	Aerial portion develops vigorously.
4) Root development is greatly restricted.	Root development is very great compared with broadcasted plants.

It appears as though it is necessary to furnish adequate space to the plant during the first two months of its growth, if root development is to be maximum.

II. Owing to the urgent necessity of increasing food production, several paddy manuring experiments were arranged by the Agricultural Society for the Yala crop in 1920. The chief objects were to ascertain :—

1) Whether Ephos phosphate could be usefully employed to replace bone meal, the common paddy manure, as at that time the latter was very scarce and very expensive; there was a possibility of the export of bone meal from India being stopped altogether;

2) to try the effect of Nitrolim as a source of nitrogen for paddy.

The following mixtures were employed:

No I	Fish Guano	70 lb.	containing nitrogen	8 8 lb.
	Ephos Phosphate	80 »	and phosphoric acid	29 6 »
	Nitrolim	18 »		
No. II	Bone meal	120 lb.	containing nitrogen	6.16 lb.
	Nitrolim	25 »	and phosphoric acid	24.64 »
No III	Ephos phosphate	100 lb	containing nitrogen	4.0 lb.
	Nitrate of potash	40 »	phosphoric acid	30 0 »
			and potash	13.2 »

The manures were to be well mixed with their bulk of soil and applied broadcast after the second ploughing, and before mudding and levelling. No change was to be made in the method of cultivation adopted in each district. It was proposed to cover the cost of the manures from the crop after harvest.

The following is a summary of the results of the manuring received up to the present time:—

	Yield per acre			
	Mixture I	Mixture II	Mixture III	Control
	bus.	bus.	bus.	bus.
Kandy District	30	$28^{2}/_{5}$	25	25
Udispattu, H. B. Rambukwella	22	19 (+2 light)	20 (+2 light)	
Girihagama	23	20	24	
Dunuwila Fields	32	—	—	24
Mavilmada	24	20	15	20
Colombo	28	30	25	12
Ratnapura	26 (also 28)	32	—	

Before the Maha crop which is grown between October and February, a new series of plots was arranged in different parts of Ceylon, some 45 in all. The general plan was to have 4 plots of approximately 1 acre each to be cultivated by the usual methods, but thoroughly, and treated as follows:—

1) Green manure at 2 000 lb. per acre and 1 cwt. Ephos phosphate; 2) fish guano 84 lb.+ Ephos phosphate 100 lb. + nitrolim 40 lb.+ (13.5 lb. nitrogen + 37.14 lb. phosphoric acid; 3) control; 4) sterilised animal

meal 112 lb. + sterilised bone meal 56 lb. nitrogen 10.1 lb. + phosphoric acid 19.8 + potash 6.3 lb..

Most of these plots are now under cultivation but several were started very late owing to the lateness of the N. E. rains in the districts concerned and in a few cases the plots have been partly ruined by heavy floods.

The harvest will be made between February and April.

623 - **Mechanical Cultivation of Rice Fields** (1). — RINGELMANN, M., in the *Journal d'Agriculture pratique*, Year 84, No. 31, pp. 94-95, figs. 1 Paris, July 29, 1920.

In Louisiana, U. S. A., rice has been harvested since 1884 with binders constructed for harvesting cereals (wheat, oats, barley, rye) except that the driving wheel is wider and its rim furnished with angle pieces projecting 8 to 10 cm. so as to enable the wheel to grip soil which is still moist at the time of reaping, although the rice fields are drained some days before the machine is taken in. This practice, which exists in Burma where reaping is done by hand, apparently gives better results than those obtained when the rice is reaped in water as is the practice in Indo-China. The object of the great width of the driving wheel is to prevent the machine from sinking far into the soil. In Italy the ordinary wheel of the binder has been replaced by a sleigh bearing a small internal-combustion engine which actuates the mechanism of the machine which is drawn by a team, (*Journal d'Agriculture pratique*, 1912, vol. 1, No. 26, p. 814).

In 1893 in Louisiana the binders were usually drawn by 4 oxen yoked in pairs and 2 mules in front; threshing was done with heavy traction engines and threshing machines as used for wheat.

The use of this machinery, which made possible an increase in the area under rice with the same available labour force, had the following results reported in 1893:— The first binder was employed in Southern Louisiana in 1884; in 1885 there were 5 machines and the number was increasing; 50 binders were in use in 1886, 200 in 1887, 400 in 1888, 1500 in 1890, 2000 in 1891, and 3000 in 1892. These figures show the extension of rice cultivation in Louisiana due to the use of machinery and are verified by the following figures:— The Southern Pacific Railway Co. transported in 1886 one thousand metric tons of rice; this special traffic increased regularly and reached 150 000 tons of rice in 1892.

This and further information, expounded by the author in his special lectures on Farm Engineering applied to Colonial needs, given at the Ecole nationale supérieure d'Agriculture coloniale at Nogent, induced some of his former pupils to study the modifications required in rice cultivation in the French Colonies.

M. ALAZARD made conclusive tests in Indo-China for the Indo-Chinese Rice-growers' Association; after his experiments on the mechanical cultivation of rice fields, he harvested with an ordinary binder without any modification; at the time of reaping, the ground was fairly dry, so that there was no fear of the machine sinking in the field, and he considered that even a heavy tractor (4 to 5 metric tons) could draw the binder.

---

(1) See *R.* June 1920, No. 680, *R.* Oct. 1920; *R.* May 1921, No. 491 (*Ed*)

Official tests of mechanical ploughing were made in Cochin-China in 1917; the results were unfortunate owing to the poor choice of the apparatus used, to its mechanical build, and its great power to which much importance was attached under the pretext of being able to work on a wide track, whereas it is preferable to use a light tractor, to decrease the width of the tract, and to increase the pace.

For the mechanical ploughing of rice fields, the author believes that a tractor of the GRAY type should be tested but with a 20-25 HP engine, with front wheels having rims 30 cm. wide and providing these wheels with iron discs so as to transform them into drums, which in soft soil, cause less resistance than when the spokes of the wheels are uncovered.

624 - **Mechanical Sowing and Weeding of Rice by the Cabrini-Mocchi Method** (1). — TARCHETTI, A. and CHIAPPELLI, R., in *Il Giornale di Risicoltura*, Vol. XI, No. 2, pp. 21-26. Vercelli, Feb 28, 1921.

The method invented by CABRINI and which he improved in collaboration with MOCCI, both of Pavia, has spread at the present time over a large area of the provinces of Pavia and Milan The Royal Lombardy Institute of Science and Literature awarded him the prize offered " to the person who should invent or introduce in Lombardy a new machine, any industrial process or any other improvement from which the inhabitants obtain real and proved benefit ».

The " R. Stazione di Risicoltura " at Vercelli tested the CABRINI-MOCCHI method in 1920.

Eighty-five ares of old rice field were divided into 4 equal plots, two of which were sown broadcast on May 15 (one with " Originario " seed and the other with " Onsen ") and the other two, on May 17, with the seeder (with the same two kinds of seed respectively). Medium sized machines were used, namely, a seeder and an 8-row weeder, 2.40 metres long. From the first period of growth onwards the rice sown with the seeder was seen to have more uniform growth, fewer blanks, and especially a much smaller and less vigorous growth of weeds.

On June 15, the first cleaning and weeding was made. It was not possible to carry out the second cleaning with the machine; it had to be done by hand. In spite of this there was a saving of about one-third in the labour employed in cleaning, and cleaning required only 200 hours work per hectare as against 293 hours per hectare for cultivation in the ordinary manner. The saving would have been much greater had it been possible to execute the second cleaning also with the machine. In the plots cultivated according to the CABRINI-MOCCHI method there was scarcely any lodging, whereas it was very considerable in the control plots. In the former the crop was finer and probably superior by about 30 %.

The authors recommend that the labour up to the present employed on weeding the rice should be transferred to transplanting, and that the rice fields should partly be cultivated in the CABRINI-MOCCHI method and partly by transplanting. This is possible as the operations of cleaning and transplanting take place at the same season.

---

(1) See *R.* Apr. 1919, No 457. For further details see the *Giornale di Risicoltura*, 1915, No. 12; 1916, No 6 - 1918, Nos. 10 and 11; 1920, Nos. 2, 3, 4, 5, 6, and 7. (*Ed.*)

CABRINI and MOCCHI offer their help to farmers who wish to experiment with their method. They also offer the use of their machines and accept as their fee half the increase in yield obtained with their method.

625 - **Notes on Adlay (*Coix Lacryma-jobi* var. *mayuen*) in the Philippines.** — WESIER, P. G. Agricultural Advisor, Bureau of Agriculture) in *The Philippine Agricultural Review*, Vol. XIII, No 3, pp. 217-222, pl 4 Manila, 1920.

One of the most interesting economic plants once important, but now allowed to fall into the background is the adlay, *Coix lacryma-jobi* L. var. *mayuen* Stapf., a form with soft hulls and very distinct from the ordinary *C. lacryma-jobi* with hard, bead-like shining grains.

The author gives a brief outline of the distribution of adlay in India, China and the Philippines and, with reference to the last mentioned, he reports the results obtained in Zamboanga from seed obtained in Bukidnon. In 1918 a small plot 5 × 6 metres was sown with adlay in the early part of July and harvested in the new year. After an allowance of 10 % was made for possible errors due to the small area, the yield was calculated at the rate of 3625 kilos per hectare of which 2610 kilos was hulled, clean grain, or 72 % of the total weight. In 1919, 257 sq. metres were sown at the Lamao Experiment Station. This plot yielded at the rate of 1634 kilos of grain and 4319 kilos of air dried straw per hectare. This low yield is, however, believed to be due to the fact that the seed was not sown until early August, and not transplanted until September.

The analysis of adlay from Bukidnon made by the Bureau of Science is shown in the following Table, which for comparison shows the analysis of various grains and pulses.

Samples	Moisture	Protein	Fat	Ash	Crude fibre	Carbohydrate starch etc.
	%	%	%	%	%	%
Edible adlay (whole grain)	10.02	8.23	8.87	8.94	14.08	49.86
Hulled adlay .	10.91	11.27	6.65	1.89	0.45	68 83
Wheat. .	10.62	12.23	1 75	1.81	2.36	71.18
Maize	10 93	9 88	4 17	1.36	1.71	71.95
Oats. . .	10.06	12.15	4 33	3.46	12.07	58.75
Rice. . .	11.88	8.02	1.96	1.15	0.93	76.05
Millet .	11.66	9.25	3 50	2 35	7.29	65 95
Pea	12.40	20 68	1.31	2.88	4.21	58.52
Beans .	15.25	19 63	1.72	3.29	3.54	46.57
Mungo . .	9.21	18.30	0.88	4.23	4.89	62.49

For comparison with the Philippine adlay, the following analysis of hulled adlay grown in India is given: moisture 13.2 %; albumen 18.7 %; starch 58.3 %; oil 5.2 %; fibre 1.5 %; ash 2.1 %.

According to the observations made in the Philippines adlay grows well at sea level up to an elevation of at least 1000 metres (in India it is grown up to an altitude of 1500 metres). The plant requires a moderate rainfall during the growing period but is not injured by heavy rains, provided the land is well drained It does best on a somewhat friable, loose, fairly rich loam, and should not be planted on heavy, clay soil.

From the preliminary experiments made in the aforementioned districts, it would appear that in field culture, adlay should be sown in June, July and early August, so that the plants have the benefit of the rainy season, and can be harvested during the dry period Four to 5 seeds should be planted per hillock, the hillocks being 40 to 60 cm. apart in rows 70 to 80 cm apart.

After germination the field should be cultivated and hoed as for maize. Later further cultivation is found to be unnecessary.

When the grain is ripe, the stalks should be cut from 60 to 75 cm. from the top, tied in bundles, dried, and subsequently threshed and cleaned like other grains. The tender plants make good forage for cattle and horses, and for this purpose, the seed should be sown in drills and not on hillocks as in the former case.

In a broad sense, adlay cannot hope to supplant rice and maize in the dietary of the people in the Archipelago, but the author considers it a feasible proposition to use it to take the place of the said grains partly as stock feed and for poultry. Considering its reputed breadmaking qualities, the possibilities of native grown adlay as a wheat substitute is worthy of careful study, especially taking into account the fact that the value of wheat flour imports exceeded the imports of rice which in 1919 amounted to 8 817 362 pesos (1).

Owing to its cultural adaptability to a wide region of the Philippines, and the many and varied uses to which the grain may be put, and its apparent productiveness, which, however, requires verification, adlay should certainly not be disregarded, and deserves a thorough investigation.

The plates illustrate the variability in construction and yield.

626 - **Adaptation of the Cultivation of Cotton on Sandy Soils in Egypt** (2). — MARGOS, D. P., on the *Bulletin de l'Institut d'Égypte*, Vol II, Session 1919-1920, pp 1-8. Cairo, 1920.

The author states that in sandy soil on the border of the Egyptian desert he has succeeded, by annual pruning and by grafting Egyptian varieties on American arborescent cotton plants *Gossypium barbadense* L. in obtaining shrubs which live for some fifteen years and produce a cotton comparable with that of the best native kinds (Sakellaridis).

This process of cotton cultivation has the following advantages: — 1) Utilisation of sandy soils of small value; 2) heavy yield and early harvesting; 3) rational and effective remedy against cotton pests (*Gelechia gossypiella*); 4) invariable preservation of the qualities of the fibre; 5) facility in producing the varieties desired; 6) no difficulty in preventive treatment against any eventual attack of parasites (winter treatments); 7) resistance to drought; 8) economical plantation and upkeep, since the work is done mechanically and the cost of plantation does not recur for 10 to 15 years; 9) reduction in the cost of production per unit owing to increase in the yield (10 to 15 quintals of raw cotton per hectare from the second year with a maximum of 35 quintals towards the 8th year with subsequent insignificant variations).

---

(1) 1 peso = 50 c (U.S.)

(2) See *R.* Apr. 1921, No. 328. (*Ed.*)

The rotation for such a method of cultivation would be:— one third of the property under cotton, one third under permanent irrigated pasturage and one third under various crops (groundnuts, lupins, chick-peas, sesamum, potato, barley, millet, etc.).

627 - **Curua Palm Oil from *Attalea spectabilis* in Brazil.** — *Bulletin of the Imperial Institute*, Vol. XVIII, No. 2, pp. 172-174. London, April-June 1920.

The fruits forwarded to the Imperial Institute from Brazil for analysis, averaged 2.5 in. in length, 1.5 in. in diameter and had an average weight of 35 gm They bore at the apex a spike about ½ in. long and at the base papery leaf-like bracts. The husk or pericarp which was brown and fairly smooth on the outside enclosed a light brown nut with a very hard shell about ¼ in. thick. The kernels averaged 1 in. in length, 0.8 in. in breadth and 4.8 gm. in weight.

The fruits were identified at Kew as those of *Attalea spectabilis* Mart. They closely resemble cohune fruits (*A. Cohune*), except that the kernels of the latter are blunt at both ends.

The analyses showed that the pericarp contained % moisture 11.1; fat 2.9; fat (expressed on dry pericarp) 3.3, and the kernel, 4.3 moisture, 62.5,fat and 65.3 fat (expressed on dry kernels).

A comparison is made with the respective contents of cohune, oil palm fruits, and the coconut.

The kernel fat when refined would be suitable for edible purposes, and the kernels yield a considerably higher percentage of fat than palm kernels, and if available in commercial quantities should realise a higher price than the latter.

The residual meal when analysed gave the following results: % moisture 8.9; crude proteins 16.8; fat 0.1; carbohydrates 52.8; fibre 15.1; ash 6.3; and the nutrient ratio was 1 : 3.2 and food units 95. Judging from these results it is evident that curua meal is fairly rich in proteins, and should be nearly equal in value as a feeding stuff to palm kernel meal Practical trials would, however, be necessary before the kernel meal or cake could be safely recommended for general use as a feeding stuff.

628 - **The Oil of the Prickly Pear Seed.** — LOMANITZ, S. (College Station, Texas, in *The Journal of Industrial and Engineering Chemistry*, Vol. XII, No. 12, p. 1175. Easton, Pa., December, 1920.

In Mexico, an excellent hardened jelly is made from the fruit of the prickly pear. The pulp alone is employed for this purpose, the seeds being removed. The analysis of the seeds of a more or less cultivated white variety known as the orchard prickly pear gave the following results: moisture 7.68 % — ash 2.96 % — oil 10.89 %. The oil, which was obtained by extracting the seed with petroleum ether, was greenish yellow in colour, odourless and somewhat viscous at ordinary temperatures.

From the constants determined, this oil apparently belongs to semi-drying group, and if produced in sufficient quantities, might be used in some of the oil-products industries.

629 - **Seed Oil Production in Egypt.** — See No. 671 of this *Review*.

630 - **"Gonaké" (*Acacia arabica*) an African Substitute for Quebracho** (1). — VUILLET J. (Chef du Service d'Agriculture in Haut-Senegal-Niger), in *La Nature*, No. 3444, pp. 92-93, figs. 2. Paris, Feb 5, 1921.

A still little known African tanning product is "gonaké ' or "gonakie" of Senegal, "bagana" of the Bambara country, "sant" pods of the Egyptian Sudan, the pod of one of the arborescent Mimoseae (*Acacia arabica* Wildenow), whose habitat extends over the basins of the Senegal, the Gambia, the Niger and the Nile and over a considerable part of British India, where it is known as "babul".

In West Africa there are at least 2 varieties of this acacia, one wild, common on the flood zone of the rivers where it forms forests in certain places (notably the forest of Gorgol in the Senegal basin), the other propagated by the natives, a few trees being frequently met with in the interior or in the neighbourhood of villages (variety *Adansoniana* of DUBARD). The former is distinguished by its taller habit (some trees are 12 m. in height) and especially by its pods being very much constricted between the seeds. The village variety bears flattened pods, more or less curved and twisted, 6 to 15 cm. long, 1.7 to 2 cm. broad, with undulating edges, at first covered with a short whitish velvety down, becoming greyish and wrinkled when dry. This variety is seldom more than 4 to 8 m. high when full grown.

In both varieties the bark, which contains 20 to 30 % of tannin, is dark coloured and fibrous in structure.

According to numerous analyses carried out by P. AMMANN, chemist employed on industrial investigations by the Government of French West Africa, the pods of the wild variety, collected before they become dry, contain from 35 to 41 % of tannin (estimated with permanganate) Pods of the cultivated variety were found by the same chemist to contain 45 % of tannin on dry material.

Before the war, England occasionally imported from West Africa, pods of *Acacia arabica* under the designation « Gambia pods ".

Lately various experiments have been made with this product on the continent, in France, Belgium, and Italy, with satisfactory results.

Gonaké pods, used by native tanners, are sold in certain markets in the vallies of the Senegal and Niger, but only in small quantities. The author has seen them sold before the war at 0.10 fr per kg. at Nyamina, 0.05 fr. at Barouéli and 0.03 fr. at San. The trade in Senegal might form important stocks by organising the collection in wild stands, especially in the districts of Kaédi and Matam (1). Also, experiments made in the valley of the Niger, at the Agronomic Station of Koulikoro, with the *Adansoniana* variety, have shown that the tree is well suited to cultivation. It is easily propagated from seed and can be transplanted when a year old without any difficulty. It grows fairly quickly and does not require a rich soil. It seems to thrive best on clay-loam soils. Experiments made with the Indian variety on the Golconda coast, showed that salt water in the sub-soil does not impede its growth, so it could be advantageously used for reafforestation in Lower-Senegal in places where "Filao" (*Casuarina* spp.) does not succeed (2).

---

(1) See *R*, Feb 1913, No 137 (*Ed.*)

In good conditions of growth, a 4-year old tree has already produced several kg. of pods; commencing from the 5th year, the average yield of a compact plantation, 6 m. by 6 m., is at least 5 kg, or a yield per hectare of 1387 kg. of pods collected before drying, but weighed dry (in drying the pods lose about 50 % of their weight).

An isolated full-grown tree, well grown, produces annually from 25 to 40 kg. of dry pods.

P. AMMAM, who has analysed the pods collected in the experimental plantation at Koulikoro, found that they contained 45 parts of tannin per 100 of dry pods and gave a light yellow solution in water and a blue black precipitate with iron salts. He is of opinion that they are an excellent substitute for sumac,

It was suggested that the cost of transport could be decreased by separating the pods from the seeds, which contain no tannin and form 32 to 35 % of the total weight of ripe pods. It is therefore usefal to note that two samples of powdered pods from Sant, containing respectively 60.9 and 54.5 % of tannin were sent for examination to the Imperial Institute in London in 1910 ("New colonial and other tanning materials", in the *Bulletin of the Imperial Institute*, 1913, No. 3) and submitted to tanners and manufacturers of extracts. The experts considered that the product would be difficult to sell in that form which is not suitable for the extraction of tannin, and the tanners prefer to use a solid or liquid extract, soluble in water. On the other hand, whole pods were considered interesting and it was stated that they might be disposed of in England at 200 fr. per metric ton.

The pods of the Indian Babal, although rich in tannin, are not generally used on the spot for tanning, as the tanning liquid prepared from them is rapidly fermented by a *Mucor*. Experiments made at the technical Laboratory of the Department of Industry of the United Provinces in India showed that fermentation could be arrested by boiling the liquid, by keeping it at low temperature, or by treating it with an antiseptic. The feeble activity of the *Mucor* in a temperate climate explains why fermentation does not prevent the use of the pods of *Acacia arabica* in Europe (*Bulletin of the Imperial Institute*, 1916, No. 4). A product rich in tannin would be obtained by collecting the pods before the seeds are formed as the latter which constitute 32 to 35 % of the total weight of ripe pods contain no tannin. Is is particularly desirable not to let the pods dry on the tree. Collected at such a time they stain the leather more or less strongly and contain a relatively small proportion of tannin.

631 – **The Production of Tea and the Tea Trade throughout the World, the Improvement of Old Tea Estates and Soil Treatment on Plantations.** — I. JUDGE, A S., The Production of Tea in the Empire and its Relation to the Tea Trade of the World, *Bulletin of the Imperial Institute*, vol XVIII, No 4, pp. 490-523. London, Oct -Dec. 1920. II MCKAY, J. M., Improvement of old Tea Estates, in *Tropical Life*, Vol XVII, No. 4, pp. 57-59, London, April, 1921. III. HOPE G. D, Notice sur la préparation du sol pour la culture du the, *Bulletin Economique de l'Indochine*, Year 23, No. 145, pp. 814-820, Hanoi-Haiphong, Nov.-Dec. 1920.

I. As it is of great importance at the present time that the position of the tea trade in the world should be stated and explained, the author, lately Chief Collector of Customs in Burma, here gives a summary of the prevailing conditions in each country concerned with the production of tea.

In the first place, the origin of tea is discussed and the gradual spread of tea drinking from China, where it has been a recognised beverage since the early years of the Christian era. It is interesting to note that the Japanese acquired the tea habit about the Xth century, but that it was only in the XVIIth century that it was first introduced into Europe. The author traces the spread in the United Kingdom, the British Empire, the United States, South America, Russia, Europe in general. In addition to this, Persia, Asia Minor, Arabia, Afghanistan, Morocco and North Africa are apparently now also acquiring the habit, green teas being most in demand.

TEA-PRODUCING COUNTRIES. — The following countries supply the world with tea : China, Japan, Formosa, Indo-China, India, Ceylon, Java and Sumatra in Asia, and Natal and Nyasaland in Africa. In the Caucasus, near Batoum (1), a small tea industry is in existence; it was started some 30 or 40 years ago, but has made little progress. In the United States, exhaustive experiments were made by the Agricultural Department; it was proved, however, that without plentiful and cheap labour the tea industry could not be made a paying proposition. The supply of labour is the most important question in regard to the cultivation of tea, more than twice the number of coolies being required to work a tea estate than would be necessary to work the same acreage under coffee or rubber. A large proportion of the labour should consist also of women and children for leaf-plucking. If all the leaf is not taken off when ready to be plucked, the shoots get ahead, especially in the centre of the bush, and not only is the plucking surface reduced, but the bush will not continue to " flush " so freely, and the yield is diminished.

---

(1) See *R* Jan. 1912, No. 118; Dec. 1913, No. 1343; Jan 1916, No. 54, March 1919 No 323. Dec. 1919, No. 602. (*Ed.*)

As the labour question is a cause of anxiety to planters in all parts ot India, Ceylon and the Dutch Indies, the aim of the planter is to obtain the best results from the area already planted: this can be effected by improved methods of cultivation and pruning, and by gradually replacing plants of inferior " jât » (variety or strain) by those which will give the highest yield of leaf.

CHINA. — The region of greatest production lies in the coastal and interior provinces bordering and immediately south of the Yangtze-Kiang; it is in this region that the black and green teas of international commerce are produced. In Yunnan also there is considerable cultivation, but the plant grown is the large-leafed indigenous variety, and the tea produced is usely only in Western China and Tibet. In China, tea is grown in small patches, large plantations being practically unknown The finest teas are produced in April, when the young leaves and buds are covered with a white down. Only 3 or 4 pickings can be made between April and October, owing to the severity of the winter climate together with the somewhat scanty rainfall.

The leaves are picked and partially cured by members of the grower's family; they are then collected by a middleman, who subjects them to a process of firing betore sending the product in bulk to one of the large centres, where factories have been established for refiring, sorting and packing The chief centres of the tea trade are Hankow for brick and black tea, Kiukiang, Santuao and Foochow for black and green tea, and Hangchow and Ningpo for green tea. Yachan is the centre for the trade with Tibet.

In 1919 the aggregate exports from China were about 92 000 000 lb., — an improvement on the trade of 1918 which amounted to only 54,000,000 lb. The decline, as compared with pre-war exports was mainly due to the uncertain Russian market, and also to the unfavourable exchange. In 1919, over 27 000 000 lb., were sent to London, which was more than twice the average quantity shipped during pre-war years. In an effort to encourage the tea trade, the Chinese Government, in October 1919, abolished the export duty levied on all teas shipped abroad

INDO CHINA (1). — Tea has been exported in small quantities, mainly to France since 1900. In recent years the exports have amounted to nearly 2 000 000 lb. The China variety has been cultivated and the tea produced has been of poor quality. Is is stated that, in Tonkin and Central Annam, Europeans are growing tea, and as the climate is suitable and the labour should be cheap and plentiful, it will be interesting to watch the development of this industry. The large-leafed tea-plant is said to be indigenous in the hills of Tonkin.

---

(1) See *R.* Nov. 1918, No 1243; April 1919, No 467, May 1919, No 601 (*Ed*)

JAPAN. — Green teas are mainly manufactured and for many years Japan has supplied America with tea; in recent years, this trade has amounted to about 35 000 000 lb.

The competition of British and Dutch grown teas in the United States is now very keen and Japanese merchants are making great efforts to retain, and if possible to extend their trade.

FORMOSA. The tea plant was introduced into Formosa from China more than 100 years ago. The cultivation is carried on, as in China and Japan, by peasant proprietors, who also manufacture the tea and sell it to central factories. The Japanese authorities have encouraged the industry and there is now a considerable export trade, which does not, however, appear to increase. Formosa Oolong teas are said to have a distinctive flavour and are very popular in the United States, where they obtain good prices. The annual exports amount to about 25 000 000 lb.

INDIA. The first sample of tea made in India was prepared in 1837 from old plants found growing on a tract of land in Lakhimpur, Assam, which had been cleared for cultivation. The tea plants and other trees on the land had been cut down and the land cultivated with rice and after the paddy had been harvested, the tea plants had thrown out young shoots and leaves. This discovery led to the cutting down of plants regularly in order to improve the quality of the foliage that was obtained for the manufacture of tea; of which about 500 lb. were shipped to England in 1838.

The principal tea districts are situated in North Eastern India, in the provinces of Assam and Bengal, and contain 84.5 % of the aggregate tea acreage in India. Tea is grown to perfection in Assam, the natural home of the plant, not only as regards quantity but also as to quality. The China plant formerly cultivated and bringing in an average yield per acre of 290 lb. has been replaced by the finest varieties of the indigenous plant raised in various seed gardens in Assam. These gardens have supplied nearly all the seed used in recent years in India, Ceylon and the Dutch Indies. The yield has been enormously increased, and the average per acre from 23 600 acres plucked in 1918 was 725 lb. There are also many estates producing over 800 lb. of fine tea per acre. Two companies, Budla Beta and Pabbojan, famed for the high quality of their produce, had in 1919 an average yield of over 900 lb, of tea per acre from a planted area of 4656 acres. There are large areas of waste land suitable for tea in Upper Assam, but future extensions must depend on the available labour supply.

In Cachar and Sylhet, excellent yields have been obtained from some of the "bheel" gardens (swamps or bog land composed often of true peat, very rich though with shallow surface soil, and an impervious subsoil) It seems, however, doubtful whether the tea plant, with stunted root developments, will have a long life in shallow soils. Tea has also been extensively planted in the plateau lands; the soils are not equal to those of Assam, and the quantity and quality of the crops are inferior to those obtained in Assam or the Dooars.

In Darjeeling, the teas are famous for their flavour All the land suitable and available in the hills has been used and no further extensions can be made. By improved cultivation, the average yield per acre is being steadily raised, and many estates produce over 500 lb. of fine tea per acre.

In Terai, tea can be produced at a fairly low cost, but the quality is not high. Mosquito blight, combined with an unhealthy climate have been the most serious drawback.

In the Dooars in the west, very high yields up to 1000 lb. per acre are obtained, and the average quality of the tea is good. There are large areas of excellent tea land available which will be brought into cultivation as the occasion presents itself.

In Southern India, China seed was planted in the Nilgiris in 1834, and for many years the cultivation on a small scale was confined to the highlands. During the present century about 30 000 acres have been planted in the said district and in the adjacent districts and about the same acreage in Travancore State The climate differs very largely from that of N. E. India, and corresponds with the conditions prevailing in Ceylon. Good yields are obtained and the quality of tea is being improved. The industry has been a success, and can be extended. Labour is not difficult to obtain.

General. The average annual production of tea in India as a whole for the 6 years 1915-19, was 375 000 000 lb., an increase of about 85 000 000. lb., over the average crops of the preceding 5 years. The crop of 1920 was a short one, owing to unfavourable climatic conditions, especially in Terai and the Dooars where the output in many Estates was from 25 to 40 % less than in 1919.

CEYLON. Tea planting was taken up only about 1875, when *Hemileia vastatrix* in an epidemic form had attacked the coffee plant. The following figures show how rapidly the industry was developed: — In 1875, The acres planted numbered 1080; in 1885, 152 000; in 1895 305 000; in 1905, 390 000 and in 1915, 409 000.

About 1904, rubber planting was taken up, and in the low country tea eventually disappeared. At the same time, however, tea continued to be planted in the highlands and during 1906-17 over 15 000 cwt. of tea seed were imported from India, sufficient to plant out 45 000 acres. In 1920 it was estimated that there were 395 187 acres under tea of which 366 678 acres were in bearing. The production was estimated at 192 500 000 lb., which works out at 525 lb., per acre. The output from the native-owned gardens was estimated at 7 818 000 lb. Dr. BERNARD who was deputed in 1912 by the Government of Java to study the conditions of the tea industries of India and Ceylon, stated in his report that the absence of terraces on the Ceylon tea estates had resulted in a serious loss of soil so that on many estates more manure had to be used than would otherwise have been necessary in order to obtain a satisfactory crop.

There is no cold weather season, the leaf is therefore plucked throughout the year, and the bushes pruned at intervals.

The following statement shows the exports of tea from Ceylon 1917 to 1920

1917 lb.	1918 lb	1919 lb.	1920 lb.
193 030 000	180 639 000	208 438 000	184 847 000

NATAL. — The restrictions placed on Indian immigrations into Natal in 1911 seriously hampered the industry, which has contracted and is being replaced by the cultivation of the sugar cane. The production of tea in 1918-19 was 1 410 000 lb. from 4136 acres, compared with an output of 2 681 000 lb. from about 4000 acres in bearing in 1903.

NYASALAND. — Tea is grown only in the Mlanje district where the soil and climate are well suited to the plant. In 1919 about 4500 acres had been planted and about 700 000 lb. of tea were exported. The tea comes into profitable bearing in the 5th year, and can be produced at a cheaper rate than in India or Ceylon.

JAVA (1). — Tea is grown mostly in the mountainous districts on the western side of the island; a large proportion of the area is cultivated by native proprietors and consists of small gardens of a few acres in extent, usually found in the vicinity of European plantations where the green leaf is sold.

Dr. G. D. HOPE, scientific officer of the Indian Tea Association, who visited Java in 1916, has written a very instructive account of the Java tea industry. He speaks in the highest terms of the excellent manner in which the Dutch planters have laid out their estates on the sides of the hills, and by terracing and planting along contour lines of the slopes, have prevented loss of surface soil by wash. He also refers to the general superiority, from an agricultural standpoint of the soils of Java, over those of N. E. India; they are richer in organic matter and nitrogen, but contain considerably less potash than Indian soils in the tea districts, which would account for the fact that the greater proportion of Java teas are of common medium description. They are, however, carefully manufactured, evenly sorted in lots or " breaks ", and put down at low cost, which appeal to the blender.

The bushes are plucked all the year round, and, as there is no fixed time for pruning, if the bushes are not regularly plucked, they get out of hand, and the yield is lowered in quantify.

It seems improbable that any large extensions will be made in Java for some time to come, but the general tendency will be to attract labour to the existing estates, and by this means obtain larger crops. Java can produce tea more cheaply than either India or Ceylon. The Chairman of the Anglo-Dutch Plantations estimated the present cost of production at 5d. per lb. The gradual rise in export trade is shown as follows: 1913, 64 703 000 lb., 1917, 80 236 000 lb., 1918, 61 853 000 lb., 1919, 110 772 000 lb. The exports to Holland were larger than the quantity required for home consumption; it is not known whether markets were found for the surplus. Java is seriously competing with Ceylon in the Australian market where tea is admitted free of duty; Java tea can be sold at from 2d. to 3d. per lb. cheaper than Ceylon teas.

---

(1) See *R.* June 1917, Nos. 549 and 595; *R.* Oct. 1917, No 955; *R.* Jan. 1919, No. 17. (*Ed*)

SUMATRA (1). — Tea cultivation was introduced in Sumatra in 1910, and at the present time it is estimated that there are 20 000 acres under cultivation. The root growth of tea bushes is shallow owing to the impervious nature of the subsoil, and roots do not penetrate more than 1ft. deep. MANN in a report on the tea soils of Cachar and Sylhet remarks: .. "though the plant may be exceedingly luxuriant so long as the superabundant tertility of the surface soil lasts, it becomes after this, exceedingly subject to drought, and the quality during its whole life reveals the unnatural conditions under which it is grown".

As much as 1200 lb. of tea per acre has been produced in the 4th year after planting. The actual production of tea, however, in 1919 was 8 818 500 lb. from 13 500 acres in bearing (equal to 670 lb. per acre). Compared with Upper Assam, this is comparatively low in spite of the fact that the best yielding Assam varieties are grown and plucked all the year round and that the growth is luxuriant. It can only be attributed to shortage of labour.

The quality of the tea produced corresponds to ordinary Java teas. The export trade has increased as follows: 1917, 3 949 000 lb., 1918, 5 266 000 lb., 1919, 9 368 000 lb.

PRODUCTION AND CONSUMPTION AND THE INTERNATIONAL TRADE IN TEA. — Fifty years ago China and Japan produced practically all the tea consumed in the world. The author traces the gradual spread and quotes reliable data indicating the world's trade in 1890, 1900, 1913, and 1919, and it is interesting to compare the gradual rise and fall in the export trade and the same with the total consumption in the various countries.

Country	Exports	% of Total trade	Exports	% of Total trade	Exports	% of Total trade	Exports	% of Total trade
	1890	1890	1900	1900	1913	1913	1919	1919

The author closes by giving a general idea of the present condition of affairs with regard to British grown teas from the commercial standpoint.

II. — McKay who is one the most experienced of agricultural authorities in India considers that the present time is opportune to consider many aspects of the tea industry, and presents in his article a series of facts and recommendations worthy of attention.

The deciding factors as to whether or not an area ot old tea is worth renovating, or even retaining in cultivation are first, the number of bushes per acre, next the "jât" of these bushes and their condition of health. If on exhausted soil, old and sickly tea bushes are struggling to grow, and if the number of such bushes is less than 1000 per acre, the author considers it advisable to abandon the area. If the soil is moderately good and the bushes healthy, it may be wise to fill up vacancies or even to interplant between the existing lines of tea bushes. For this purpose strong 2-year old plants will be required, which should be manured the following year after planting, or preferably for 2 years.

In undertaking the renovation of old tea, the first point is to stop all further soil wastage and the only effective system is by terracing (see Java). In some cases the cost of making terraces is prohibitive, but a cheap effective means of arriving at the same result is to sow seed of a leguminous crop e. g. *Tephrosia candida* along the contour lines, and allow the plants to remain for several years in this position An appreciable terrace will gradually be formed and when the shrubs are eventually cut away, a small drain can be made at the underside of the terrace, the excavated earth thrown up, and a fresh supply of seed sown. In flat lands there is less likelihood of serious injury from soil wash, but as clayey and retentive soils are frequently met with in such situations, adequate drainage is essential. A good supply of organic matter will tend to keep these soils open and friable and green crops should be grown for this purpose. Bone dust applied at the rate of 200 to 250 lb. per acre usually will be found to encourage development of green crops.

Trenching can be adopted with advantage on old tea lands. Small drains are cut out to a depth of 18 in, and 6 to 9 in. wide and filled with prunings etc. and then the earth levelled in. The value of the work will depend on 2 main factors:

1) the length of time the trench can be left open to the ameliorating influences of the atmosphere;

2) the amount of vegetable matter that is available for burying on the trenches.

Collar pruning has often given good results but the bushes may ultimately be found to deteriorate unless this operation is accompanied by manuring and other ameliorative soil treatment.

Shade is an important factor in the health of the tea bushes. *Dalbergia* spp. and *Albizzia* spp. are suitable leguminous trees for planting among tea; these not only produce a good shade but the leaf fall has a beneficial manurial effect (1).

To bring back deteriorated tea estates to a profitable cropping condition, adequate manuring will be necessary where the bark on the branches is dry and hidebound, and where few or no young shoots are coming from below or from the collar of the bush, nitrate of soda or sulphate of ammonia applied at the rate of 100 to 150 lb. per acre will prove useful. If the soil is acid, as many tea soils are, the former is to be preferred. These manures should be applied early in the season before the heavy rains are due. (The Scientific Department of the Indian Tea Association have reported very good results in recent experiments with nitrate of soda). Phosphoric acid can be supplied by a cheap dressing of bone dust which will assist the growth of green crops and help the development of the tea bush. Potash is not much required for Indian tea soils; endless new mixtures have been recommended by various specialists, but the following is typical of many of those which have found considerable favour during the last few years:

		Nitrogen	Phos. acid	Potash
200 lb.	Fish guano.	15 lb.	17 kg	—
200	Nitrate of soda	30	—	—
100	Ephos phosphate	—	30	—
50	Muriate of potash	—	—	20 lb.

Application 550 to 750 lb. per acre.

This application refers however to tea manuring in Ceylon, but a smaller quantity of the same mixture can probably be relied upon to give profitable results in India, thus involving less expense.

---

(1) Full details of the various green manures and the special advantages of each will be found in "Green Manures and Manuring in the Tropics" by P. DE SORNAY (Tropical Life Publishing Dept. 83-91. Gt. Tichfield St. Oxford st. London). (*Author's Note*).

III. — A review of the latest scientific investigations carried out as regards the proper treatment of soil relative to the cultivation of tea. From the results obtained, the author draws the following conclusions:

1) Light and sandy soils can be improved by the application of organic manure or of soil of a heavier texture. Trenching and terracing is sometimes advisable Heavy soil should be well worked, but not when in a very humid and sticky condition; improvement is effected by the addition of sandy soil.

2) The surface soil should be kept loose and friable to prevent evaporation of moisture during the cold season; for this two things are advised:— *a*) pinching off the adventitious shoots which prevent loss of water by transpiration; *b*) mulching (tea leaves are apt to transpire to a considerable extent).

As the sun's rays probably play an important part in actuating soil fertility, during the cold weather, the surface soil exposed to the sun should be kept well cleaned.

632 - **Aromatic and Medicinal Plants of Sardinia.** — MICHELETTI, G., in I. *Rivista Italiana delle essenze e profumi*, Milan, March 1921. — II. *Bollettino della Associazione Italiana pro piante medicinali, aromatiche ed altre utili*, Year IV, No. 3, pp 42-43. Milan, March, 1921.

The Sardinian flora is very rich in wild aromatic and medicinal plants, originating perhaps from species formerly cultivated as medicaments and now become wild. Among these plants may be cited: — Marsh mallow, arnica, borage, camomile, lesser centaury, hemlock, foxglove, eucalyptus, gentian, henbane, laurel, mallow, oleander, rue, elder, datura, squill, mullein, etc.

The southern coasts of Sardinia are rich in the Lycian juniper (*Juniperus phoenicea*) which yields 2 % of an essence, not comparable, it is true, with that of *Juniperus officinalis*, but nevertheless sufficiently appreciated. The island could furnish 5000 tons of the berries of this species for distillation.

On the coasts and mountains, rosemary abounds and 15 000 tons of fresh leaves could be collected yielding from 0.25 to 0.35 % of essence, as against 1 to 1.5 % for dried leaves. Myrtle is very abundant, and 30 000 tons of its leaves could be collected, which, when fresh, contain from 0.200 to 0.225 % of essence and as much as 0.35 % when dry.

The stoechas lavender (*Lavandula Stoechas* L.) is widely distributed, especially on poor soils, little suited for cultivation both in mountain and plain. It can furnish several tons of flower heads, which yield, in a fresh state, 0.2 % of essence. Wormwood is fairly wide spread throughout Sardinia, but especially in the province of Sassari.

Water-mint and penny-royal, very common along the streams and in damp places, could provide 20 000 tons of raw material for distillation with a yield in essence of 0.2 %.

Thyme is abundant in the zone of Mount Gennargentu; it yields about 3 % of essence.

Some experiments in cultivating roses for essence have given very satisfactory results.

At Cagliari there is a company (" Società Sardo-Lombarda SUBINAGHI & Co. ") which collects and manipulates Sardinian aromatic and medicinal plants, but there is still much room for similar undertakings.

633 - **Market Gardening in Italy.** — SCANO, C., in *Il Coltivatore*, Year 66, No. 36, pp. 980-983. Casale Monferrato, Dec. 1920

The author, continuing his notes on the situation of market-gardening in Italy (1) gives the following information.

ONIONS AND GARLIC. — This crop is cultivated over 6000 hectares and produces 657 500 quintals. The cultivation of onions and garlics is very evenly divided between the districts of North and Central Italy and those of the South and the islands. The largest areas are in Venice and Campania and the smallest in Emilia. The greatest production occurs in Campania and Venice and the least in Sardinia and Tuscany. The average production for the whole Kingdom is 109 quintals per hectare, with a maximum of 268 in Emilia and a minimum of 77 quintals in Venice.

ARTICHOKES. — These cover 5775 hectares and the total production in 511 000 quintals. This crop also is equally divided as regards area between the north and south of the peninsula and the production is almost equal in each. The largest areas under artichokes are in Tuscany and Sicily, the smallest in Venice and in Apulia. Tuscany has the greatest production and Apulia has the least. The average production is 88 quintals per hectare for the whole peninsula, with a maximum of 134 quintals in Tuscany and 127 quintals in Apulia, and a minimum of 57 quintals in Liguria.

CARDOONS, CELERY AND FENNEL. — The area devoted to the cultivation of these plants for the market in Italy is only 2025 hectares, and the production is 335 500 quintals. The cultivation of these pot-herbs is more extensive in the southern districts than in the north (where only 915 hectares are under these plants) but the quantity produced is about the same in the north and south. The largest areas on which they are cultivated are in Campania and in Apulia whilst the smallest area is in Sicily. Campania and Liguria give the highest production. The average production for the Kingdom is 166 quintals per hectare; the highest average production is in Liguria with 310 quintals, and the smallest in the Abruzzi, 111 quintals, and Latium, 109 quintals per hectare.

ASPARAGUS. — This occupies the smallest area of all market garden crops; the cultivation of asparagus is limited to 4 districts, 3 of which (Piedmont, Liguria and Venice) are in Northern Italy and 1 (Latium) in the Centre. Only 792 hectares are under asparagus and the production is barely 25 900 quintals.

The average production is 33 quintals per hectare; the highest average is 45 quintals in Venice and the smallest is 24 quintals in Latium.

634 - **Suggestions for the Right Selection of Apple and Pear Stocks.** — HATTON, R. B. (Wye College Fruit Experiment Station, East Malling) in *the Journal of the Royal Horticultural Society*, Vol. XLV, Pts. 2 and 3, pp. 257-277, pl. 23. London, July, 1920.

I. APPLE STOKS. — Investigations have been made at Wye College Fruit Experiment Station, East Malling with regard to the relative vigour of Free, (dwarf stocks both fibrous and stump-rooted as well as vigorous ones resulting from a well-balanced root system) Crab and Paradise stocks, and the range of growth and root system included in each class.

Selected types of Paradise, ranging from the dwarf to the very vigorous type, all raised vegetatively from layers, were planted out on their own roots to demonstrate their relative vigour. A selection was also made of crab-stock seedlings obtained from a foreign source through an English nurseryman in 1912. It was noted that when these seedlings, mostly 2 years old, were planted out, they appeared to be very even, and the majority exhibited a tap-rooting tendency. (The taproots were, of course, trimmed back at the time of planting).

At the first inspection a year after planting, the plants appeared to be very free growing and clean-stemmed at the base, and only a few were stunted and spiny. It is interesting to note that in the normal course of events at this point such a bed of stocks would have been " worked " before anything more was known about it, — hence the common impression among many tree-raisers that free and crab stocks vary little.

Certain typical plants were selected and were planted out in Feb. 1914 to grow on their own roots, which they were allowed to do until March, 1919, when they were lifted, in order to obtain a series of photographs of their relative growth and rooting characters. This series, included in this article, is a striking illustration and proof of the immense variation in vigour amongst so-called free or crab stocks.

A similar close examination was made of a collection of free stocks raised from the Pomace from an orchard in the west of England, and results were similar.

With regard to the desirability for working purposes and the possible means of overcoming this variability habit, the author awaits the results of the selected types upon different soils, before making any further statements concerning soil solubility, but confines his remarks to certain outstanding points.

A very complete series of Paradise would be made up by the selection of: —

Type I. — Broad-leaf for permanent bush trees and weak-growing sorts.

Type II. — Doucin or English Paradise — for bush fillers and general commercial dwarfing trees.

Type V. — Amélioré or Improved Doucin — for cordons and garden trees.

Type IX. — Jaune de Metz or Yellow Paradise, for extra precocity, probably useful on which to work new seedlings, pot trees, etc., to induce rapid maturity.

These are the most marked and constant indications on the soil under consideration with regard to definitely dwarfing types of stock.

There is apparently no distinct line betwixt free and Paradise stocks, each contains dwarfing and free-growing stocks, both capable of vegetative propagation. There are 3 possible lines along which a standardisation of free stock may proceed: 1) if seedling stocks are to be used, they should be graded at an early stage *i e.* at the time of planting out; 2) the stronger types of so-called Paradise should be selected, with free-rooting and growth habit, and deep anchorage, which appear identical with free stocks. Any of these types can be raised quickly by layers, wood and root cuttings, and could be used for standard purposes with comparative safety; 3) reproduction of the most promising sorts from root cuttings. When these better trees are lifted and their roots trimmed, these root cuttings should be preserved and kept separate from the inferior ones. Very good stocks can quickly be obtained by this method

II. Pears. — The object of the author is to place on record a summary of the commercially used dwarfing stocks for pears at the present time, different forms of quince being used almost exclusively for this purpose, though trees worked upon the white thorn (*Crataegus Oxyacantha*) and upon the Mountain Ash (*Pyrus aucuparia*) are occasionally to be found.

A collection of quince stocks from various nurseries was made, and it was evident that many and various varieties were in common use, but differing in vegetative characteristics, that several varieties had got mixed together, and that the variety of quince most recommended as a stock by the older writers namely the Portugal Quince — had practically gone out of use as a stock.

The author proceeded to a classification of the types, and gives a table showing the characters useful for identification in the growing season, and the average leaf measurements (on one-year bedded stocks) worked as follows:

	Breadth	Length	Leaf stalk
Tipe *A* (Angers)	4 6	5 64	0 66
» *B* (Common)	3 97	5.06	0.62
» *C* ?	4 16	4.77	0.64
» *D* (Paris or De Fontenay)	3 84	5.09	0.59
» *E* (Portugal)	5 47	6.82	1.09

Type A; undoubtedly the one in most common use to-day. It appears to be both a grower's and nurseryman's stock; it layers very readily, is vigorous and healthy in the nursery, and ultimately develops a very fine fibrous root system.

Type B; less vigorous and can be distinguished by the smaller acutely-tipped leaf; comes readily from wood cuttings; fruit small, hard and downy

Type C; very erect yet dwarf growth; small circular, yellowish crinkled leaves; soon lacks vigour and tips of shoots often die, roots well from wood cuttings.

Type D, exaggerated drooping habit and dark green elongated leaf; less fibrous and more coarse-rooted than other types; long weak lateral roots.

Type E; very large downy leaf, and stout vigorous growth; rarely roots in a single season; layering appeared to be more effective than the stool method employed for the others.

The average height measurement of bedded stocks (once transplanted) was as follows: A, 3 ft.; B, 2 ft. 4 in.; C, 1 ft. 11 in.; D, 1 ft. 10 in.; E, 3 ft. 5 in., and the spread for these 5 types respectively was 2 ft. 7 in. 1 ft. 10 in., 11 in., 2 ft. 9 in, 2 ft. 11 in.

Now that the period of classification is practically complete, the authors proposes to undertake a series of experiments with a fairly wide range of pears, as the whole question of pear growing commercially in Great Britain, and of double working varieties in general opens up a wide field for advance through careful research.

635 - **Restoration of Peach Trees Growing in Open Air.** — LAMPROY E., in the *Revue Horticole,* year 92, No. 2, pp. 32-34, 2 figs. Paris, Feb. 16, 1920

Cutting back with the object of restoring vigour is little practised with peach trees, because it is generally agreed that the old wood, in this case, does not produce branches or does so with difficulty. However, the operation may be suitable in *certain cases,* as was noted by NAUDIN and DECAISNE in the middle of the XIX century (*Manuel de l'amateur des jardins* Vol. IV, p. 423) and also by ALLEMAND, Director of the « Jardin des plantes » at Grenoble, who brought it to the notice of the Pomological Congress at Metz in the autumn of 1919 He described the very succesful experiment carried out over the whole of his peach orchard by COMPTE of Bernin near Grenoble Having been obliged to leave his property for three and a half years, COMPTE, on his return, found his peach trees growing in the open air destitute of small fruiting branches at the normal height, with their trunks excessively lengthened and their growth sickly. He cut back the branches well below all fresh growth. Vigorous branches sprung from the trunk and, in the following year, gave a finer crop than the trees of which he had simply pruned the ends of the branches.

The operation should be done with care; the branches should be cut with a sharp fine saw; each cut should then be smoothed with a pruning knife and covered with grafting mastic

From the discussion which took place at the Congress after ALLEMAND's communication, it would appear that the cutting back of peach trees in exposed conditions, gives variable results according to the environment. The author remarks that it would be useful to study the causes which influence the success of the operation.

636 - **The Oignies Peach, Belgium.** — DACHY, A., in the *Revue Horticole Belge*, Year II No. 4, p. 53, Huy, Apr. 1, 1921.

There are not many peach trees suited to northern climates; a good kind which is so suited is the Oignies peach which originated at Hainaut. Although not very robust in appearance the Oignies peach is very fertile, propagates itself by seed, can be grown either as bushes or in the open. The fruit is medium sized or very large according to the quantity; its skin is very downy, greenish yellow, and more or less red on the sunny side; the flesh is easily separated from the stone. It ripens at the end of September. This peach ripens perfectly on isolated trees if grown on a tree raised from seed, or on a grafted tree In other cases it is always much less sweet and notably so when the tree is grafted on a plum tree.

For successful growth of this peach, a warm, healthy, sandy soil which is fairly deep and a very sunny situation are required.

637 - **The Preservation of Tropical Fruits.** — WESTER P. J. (Agricultural Advisor, Bureau of Agriculture) in *The Philippine Agricultural Review*, Vol. XIII, No. 3, pp. 173-185, pl. 4 Manila, 1920.

Amongst the more than 200 species of fruits that grow in the Philippines, the following are recommended as suitable for the manufacture of preserves on a fairly large scale, and a description is given of each, combined with recipes suitable in each case:— Banana (*Musa sapientium* L.); Carambola (*Averrhoa Carambola* L.); chico (*Achras Sapota* L.); Condol (*Benincasa hispida* Cogn.); custardapple (*Anona reticulata* L.); ginger (*Zinziber officinale* Rosc); guanabano, (*Anona muricata* L.); guava (*Psidium Guajava* L.); jujube (*Ziziphus Jujuba* L.); kamia (*Averrhoa Bilimbi* L.); lanzón (*Lansium domesticum* Jack.); makopa (*Eugenia javanica*); mango (*Mangifera indica*); mangosteen (*Garcinia Mangostana* L.) nipa (*Nypa fruticans* Wurmb.); papaya (*Carica Papaya* L.); pineapple (*Ananas sativa* Schult.); santol (*Sandoricum Koetjape* Merr.) and tamarind (*Tamarindus indica* L.).

The mango is at present the only fruit produced in sufficient quantity to keep even a small factory running at full capacity during the mango season. The next largest supply is the santol.

638 - **The Breadfruit (Artocarpus communis L.) in the Philippines.** — WESTER, P. J. (Agricultural Advisor, Bureau of Agriculture) in *The Philippine Agricultural Review*, Vol. XIII, No. 3, pp. 223-229, pl. 4, Manila, 1920.

The cultivated, seedless form of breadfruit here discussed, rarely growing more than 15 m. high in the Philippines, originated in one of the Polynesian archipelagos, whence it has spread to a large part of the tropics elsewhere. While the tree does best with a rainfall of fairly equal distribution it is quite tolerant of short dry periods, and it also flourishes under irrigation.

The observation of the formation of adventitious buds on injured roots of the breadfruit tree led the author to conduct a series of experiments with root cuttings. The cuttings were inserted at Lamao from the latter part of May through June to July, i.e the close of a long dry season and the beginning of the rainy period. With proper treatment up to 80 % of the cuttings taken during this period showed promise of making healthy plants, but at any other time of year, very few cuttings will strike.

In nursery practice it has been found best to dig out the soil to a depth of 20 cm., and fill it with clean, medium coarse sand. The sand should be levelled, saturated with water and beaten hard The roots of the tree can then be dug up with care, and should not be allowed to become dry while they are exposed to the air, and should never be left exposed to the sun. The author considers it better to use many of the smaller roots for cuttings than to cut one or two large ones near the trunk of the tree. The small wounds are more quickly healed, and there is less danger of the tree being uprooted by typhoons. Cuttings should be 20 to 25 cm. in length, and it is advisable to paint the wound on the thickest end of the cutting with coal tar or white lead. The cuttings should then be inserted diagonally 12 cm. apart, in a trench with the thickest end from 3-6 cm. above the ground level.

After insertion of the cuttings, the sand should not be kept saturated by daily applications of water, and watering should be limited to once every 5 to 7 days. Occasional spraying is however beneficial or damp sacking spread over the cuttings during the hot part of the day and removed at night.

Some cuttings will be ready for removal 2 months after insertion, whilst others take 5 months. The majority will be large enough for transplanting to the nursery at the age of 7-8 months, and into the field, 6-7 months later. When transplanting, about $^3/_4$ of the leaves should be cut off. In the orchard, plants should be spaced from 10-14 m. apart.

The advantages attached to the cultivation of *Artocarpus communis* L. are evident: the trees are unaffected by locusts and other plant pests; even in the regions where the dry season is exceptionally long, if properly mulched, they would require very little water. The extended planting of breadfruit trees is therefore strongly recommended.

As regards the food value, it is interesting to note that the breadfruit comes next to the banana amongst the tropical fruits. The high food value may be noted from the following analysis adapted from the Report of the Hawaii Agricultural Experiment Station, 1914.

Fruit	Edible portion	Total solids	Edible portion						
			Ash	Sulphuric acid	Protein	Sugar	Fat	Fibre	Carbohydrates other than sugar
Bread fruit (Hawaiian)	77.75 %	41.82 %	0.952 %	0.049 %	1.575 %	9 49 %	0 190 %	1.204 %	27.89 %
Bread fruit (Samoan).	83 44	26.89	1.152	0.078	1.575	14.60	0.517	0.978	9.21
Banana (Chinese) . .	70 00	21.28	0 995	0.245	1.788	16.66	0 180	0.253	—
Mango (Curabao) .	73.00	17.02	0.450	0.140	0.220	13.-4	—	—	—

639 – **Re-afforestation in Mountainous Regions without Temporary Nurseries.** — DESCOMBES, P. and DEVAUX, H., in the *Journal d' Agriculture pratique*, New Series, Vol 35, 1921, Vol I, No 6, pp 118-119 Paris, Feb. 12, 1921

One of the difficulties of re-afforestation in mountainous regions is that the period of the year favourable for vegetation varies according to the altitude. Transplanting trees from a nursery at a lower altitude than the land to be re-afforested is generally impracticable in spring, because the trees commence growth in the nursery before the thaw in the land to be planted, and in autumn, because their growth has not stopped by the time the first falls of snow take place there. The French Forest Administration meets this difficulty by establishing temporary nurseries at the altitude of the land to be planted ; but their remoteness from inhabited places and the scarcity of labour makes the upkeep of such nurseries very difficult. The authors have therefore recommended a new method of re-afforesting mountains based on the use, in spring, of plants taken out of nurseries situated in the plains and kept in the cold up to the time when the thaw enables them to be planted.

This method has been tested by several experiments undertaken by the Central Society for forest management in mountains.

The Vignec territory (Hautes-Pyrénées), which covers an area of 30 ha. in the valley of the Aure, varying in altitude between 580 and 1120 metres, has been entirely re-afforested in this manner by a plantation of pines mixed with silver firs, made in 1908 and 1909, and in which broad-leaved trees have since been planted.

A plantation of acacias was made in 1908, by the same method, in the Testes du Plan territory, commune of Aragnouet (Hautes-Pyrénées) at an altitude of 1700 m.

This method has also been applied by the mountain dwellers of the Commune of Estensan (Hautes-Pyrénées), where the municipality has re-afforested two plots, one on a plateau and the other on the steep banks of a torrent.

All the plants used in these experiments were sent by passenger train, during March, to Vaux near Ferté-Imbault (Loir-et-Cher), taken quickly from the railway station to a place higher than the land selected for plantation, where they were stored in bundles separated from the ground by a wooden platform and covered with planks supporting a thick layer of snow, and, later, planted out as soon as the thaw had taken place on the area to be planted. Although the advantages of putting the plants in tubs during the interval between their arrival and planting out were known, it was thought preferable to avoid the injuries to which they would have been liable in unpacking and repacking for inevitable transport on mules over the paths connecting the depot with the area to be planted.

All these plantations have succeeded remarkably well. They withstood successfully the exceptional droughts of 1911 and 1918. Quick transport is an indispensable condition for success.

[639]

640 – **Tractors on Fire-Lines in the Landes, France.** — GREILSAMMER, R., in the *Journal d'Agriculture Pratique*, Year 84, No. 37, pp. 216-218, figs. 2. Paris, Sept. 9, 1920.

Description of trials organised by the Gironde Society of Agriculture on June 20 and 21 and on July 3 and 4, 1920, near Bordeaux in forests at Ychoux (Landes), with the object of solving, by means of tractors, the problem of clearance and upkeep of firelines by a mechanical process. Two firms took part in the tests, the " American Tractor Co. " (Colombes works, 33, Rue du Louvre, Paris, 2^e) entering a 36 H.P. GRAY tractor with one driving wheel. The RENAULT firm of Billancourt (Seine) entered a 20 H.P. RENAULT chain-track tractor. The upkeep of firelines in the Landes has become very difficult owing to the scarcity and high cost of labour. The work however, has considerable economic importance because fires destroy several thousand hectares of pine forest every year in that region and the damage caused ran to millions of francs.

In consequence of the abandoned state in which the firelines in the Landes have been left for several years they have become overgrown with very abundant vegetation composed of heaths of the genus *Erica* (forming what is known locally as " la brande "), gorse, broom, and even young pines. All this shrubby growth forms impenetrable thickets attaining a height of up to 2 or 3 metres in places. The destruction of this vegetation really constitutes a regular clearing and not merely a work of maintenance. The Renault tractor was attached to a kind of triangular extirpator made on the spot with a wooden frame very near the ground and working parts in the form of curved knives arranged to cut layers horizontally. When the tractor attached to this instrument had passed, the " brande " had been pulled up, but the work seemed very slow, and therefore not economical, on account of the constant clogging of the instrument which necessitated frequent clearances. This tractor is easily handled and requires small space for turning ; but rapid wear of the chain-tracks is to be feared in the very sandy soils of the Landes.

With the GRAY tractor the crushing of the woody growth by the weight of the machine was tried. This crushing was effected by the large driving wheel of the tractor armed with angle pieces which could even be sharpened for this work. The highest heaths and gorse were completely laid and even to a great extent broken ; this in itself is an interesting result as fires spread chiefly by the thickets at some height above the ground.

As the GRAY tractor travelled at 4 km. per hour and worked on an effective width of 1.60 metres, the work of crushing was very rapid, representing about 5 hectares a day.

The author thinks that by making several passages one after another using an extirpator with rigid teeth the vegetation would be completely eradicated. It would then be possible to collect the plants so uprooted into swaths by means of a special machine similar to the CASANOVA stone clearer formed with several strong rake teeth followed by a scoop for collecting the stones or uprooted stumps.

Only after clearing away the swaths formed by the debris of plants collected by the stone clearer could ploughing be done without excessive clogging.

After this ploughing the clearing of the fireline would be complete, and then only periodical work of upkeep with machines used in ordinary cultivation (pulveriser, cultivator, plough, etc.) would be required.

LIVESTOCK AND BREEDING

641 - **On Lathyrism or Poisoning Caused by Vetch Seed.** — MIRANDE, M., in the *Comptes rendus de l'Academie des Sciences*, Vol. 172, No. 18, pp 1142-1143 Paris, May 2, 1921.

After CANTANI, the term lathyrism has been given to the specific poisoning of man and animals caused by ingesting the seeds of certain vetches, especially those of *Lathyrus sativus* and *L. Cicera*.

Several cases of poisoning in horses fed with vetch having recently been reported from various places in France, the author investigated the seeds of *L. sativus* and *L. Cicera*, and obtained the following results:— The seeds crushed, ground or reduced to coarse flour and moistened with water, placed in a glass receptacle, at a temperature of 35° to 40° C., after some hours begin an auto-fermentation and evolve a fairly large amount of carbon dioxide and sulphuretted hydrogen.

The substance which decomposes and gives off sulphuretted hydrogen, is contained in the cotyledons and not in the tegument of the seed. The finer the grinding of the seed, the quicker this fermentation takes place; a medium fine flour gives off H_2S in 6 or 8 hours. If the ground seeds are macerated in water, the substance from which H_2S is generated is contained in the water; careful washing is however necessary to extract it totally.

The seed, decorticated or not, but left whole and placed in a small quantity of water does not give off sulphuretted hydrogen; if then dried, ground and moistened it does not give off sulphuretted hydrogen either. The simple commencement of germination in the unbroken seed has transformed the substance which generated H_2S.

The spontaneous fermentation which sets free H_2S hardly commences below 35° C.; it is very active between 35° and 40° C., the temperature of most warm blooded animals; it is produced also up to about 60° C., that is to say up to the average coagulation temperature of albuminoids. Above this coagulation temperature spontaneous fermentation does not take place, but, by boiling or in a digester (from 110° to 120° C.), direct but only partial decomposition of the substance generating H_2S is obtained. This partial decomposition is increased by the action of dilute acids.

The spontaneous sulphuretted-hydrogen fermentation is caused by the slow action of water; it does not appear to be influenced by any phenomenon of oxidation or of reduction.

The author succeeded in extracting from these seeds a substance which by heat alone, or still better with dilute acids, gives off sulphuretted hydrogen.

CORNEVIN (*Des plantes vénéneuses et des empoisonnements qu'elles* *déterminent*, Paris, 1887. Lib. Firmin-Didot) and other writers have observed that if the vetches are given to horses after soaking, the soak water being rejected, they are harmless. CORNEVIN states also that, if the vetch-seeds crushed or reduced to flour, are fed to animals the symptoms of illness appear more rapidly than if they are given whole and without having been crushed or ground. The author's experiments explain these facts. The poisoning seems to be really caused by the sulphuretted hydrogen which is set free in the stomach of the animal as *in vitro*. The great toxicity of sulphuretted hydrogen gas, which attacks the blood corpuscles, takes oxygen from them and causes the formation of iron sulphide in them, is known. Animals die from asphyxia, sometimes very quickly, sometimes after a more or less long period. In the latter case they perhaps die from slow injuries of the blood corpuscles.

642 - The Value of Arsenical Dips as Remedies against Scab in Domestic Animals in the Colonies.

— VELU, H. (vétérinaire de première classe), in *La Colonisation Française au Maroc*, Year II, No 15, pp. 4-5. Casablanca, Jan. 8, 1921.

The author states that no simple and practical treatment of scab capable of application on a large scale in the Colonies, requiring neither expensive plant such as sulphur fumigating chambers or dipping tanks (1), nor considerable manual labour under careful supervision, by a staff without any technical knowledge as has yet been devised.

The foreign literature, however, is very rich in publications on sulphur and arsenical dips and numerous formulæ have been recommended. In 1915, in South Africa, BEDFORD (2) tested 18 dips prepared extemporaneously (formulæ or specialities) against scab in sheep: all except one proved efficacious and cured the scab by two minute immersions repeated at intervals of 9 days.

The author tested one of these specifics, probably an arsenical cresyl, "Cooper's Fluid," well known to breeders in South Africa, Australia, and even in Madagascar. The results obtained with this product in the treatment of scab in pigs were perfect: four dippings of about 2 minutes, repeated at intervals of 7 days, sufficed to cure the diseased animals; "Cooper's Fluid" also proved a quick and easy remedy against sarcoptic scab of horses imported into Morocco after the war.

The method was as follows: — When the 150 sick horses arrived at the hospital a small tank was made in 24 hours by building a cement wall 20 cm. in height; 200 litres of antiseptic solution were got ready of a strength of 15 %. The horses were led into the tank and douched by means of a spraying pump furnished with a long tube and a VERMOREL jet-nozzle; a spraying nozzle was too easily obstructed and the liquid did not penetrate sufficiently. Each day the liquid which had been used was put back, filtered through gauze. To prevent the dip getting too weak and to replace loss, 100 litres of freshly prepared solution were added each morning. In this way 25 horses were treated a day (a number which might easily have been doubled), the douche was repeated once a week and the total number of douches was 3 or 4. Although this process only permits of a restricted number of animals being treated daily it is, however, very simple, the cost is very small and it can be employed anywhere, being sufficient for the treatment of sick horses in a military post of several hundreds of horses or in breeding farms, where the stock never exceeds 1000 head.

(2) BEDFORD G. A. H., in *Union of South Africa Dep. of Agr. 3rd and 4th Reports of the Director of Veterinary Research*, 1915, pp. 163-172. (*A.*)

The author also explains that this process has the great merit of avoiding the usual disadvantages of dips for destroying parasites, such as variations in the concentration of the dip, errors in strength and above all the decomposition of sodium arsenite. Most of the dips used in South Africa, including Cooper's Fluid, contain sodium arsenite and not arsenious acid or arseniate of soda as do the French dips and it is, perhaps, to this fact that they owe their destructive power on parasites and their being less poisonous: the efficiency of these dips is further increased by the addition of an emulsion to wet the tissues.

The author further explains the composition and preparation of two other dips used in English-speaking countries and which have been employed up to date only as remedies againsts ectoparasites in cattle, namely CHAPLIN's sulphur solution recommended by the Bureau of Animal Industry Washington, and WATKINS-PITCHFORD's arsenical solution, which ought to be tried in the treatment of scab in horses. These solutions are composed and prepared as follows:—

I. — CHAPLIN'S SULPHUR SOLUTION. — Take 8 lb. of quick lime or 10 ½ lb. of slaked lime, 18 lb. of sublimed or powdered sulphur, 10 gallons of water. Stir and keep boiling for one hour. Then add water to bring the volume up to 10 gallons. Dilute when required for use in the proportion of 1 volume of concentrated solution to 9 or 10 volumes of water for sheep and to 7 or 8 volumes of water for horned cattle.

II. WATKINS-PITCHFORD'S ARSENICAL SOLUTION:—

Sodium arsenite (80 % arsenic)	4 lb.
Soft soap	3 »
Vaseline oil	1 gallon
Water	100 gallons

Dissolve 4 lb. of sodium arsenite in about 1 gallon of hot water; when the solution is cold, add cold water to make the volume up to 88 gallons; then add the emulsion stirring constantly and make up with water to a volume of 100 gallons.

According to the author these dips, including Cooper's Fluid, have some drawbacks. The sodium arsenite may cause more of less serious inflammation of the skin, which becomes covered with cracks, and diarrhoea, or it may become inactive by changing into arseniate. However, these occurrences will always be of slight importance, and should not prevent the adoption of this method of treatment of scab in domestic animals.

[642]

643 - Experiments on the Value of Intratracheal Injection for Creating Active and Passive Immunity. — PFENNINGER, W., in the *Annales de l'Institut Pasteur*, Year 35, Vol. XXXV, No. 4, pp. 237-260, tables 14, figs. 5. Paris, Apr. 1921.

With the object of finding a solution of the questions which resulted from the researches of BESREDKA (1) who was the first to record that, compared with intraperitoneal and intravenous channels, the respiratory channel is equally accessible if not more so, to injections of serum, the author investigated the production of anti-bodies (agglutinins, precipitins, bacteriolysins and bactericidins) by making intratracheal injections of antigens; the production of active and passive immunity; and the therapeutic value of serums injected into the trachea.

Notably in the researches on immunity, the animals inoculated by peritoneal (control animals) and intratracheal injections were tested with one or more lethal doses.

One series of experiments was made with rabbits and guinea pigs immunised against paratyphus virus B., another series of experiments was made with guinea pigs which had previously been used for the production of anticholera serum. In order to verify the transmission of passive immunity, experiments were made on guinea pigs by giving them injections of anticholera serum. The results of these experiments, the details of which are recorded in numerous tables and graphic figures, are as follows: —

1) By means of intratracheal injection of paratyphus virus B it was possible to give rabbits active immunity enabling them to resist three times the lethal dose.

Comparative researches regarding the immunity obtained by respiratory and peritoneal channels in guinea pigs, showed that intratracheal injection produced greater immunity against paratyphus virus B than intraperitoneal injection, and further that intratracheal injections are better endured. Comparative researches on guinea pigs immunised against cholera vibrio gave similar results.

2) The protective power of anticholera serum proved greater in intratracheal than in peritoneal injection.

PRACTICAL CONCLUSIONS. — According to the author the results of these experiments on active immunity, combined with those which BESREDKA obtained in experimental tuberculosis of the rabbit appear to justify the hope that the method of intratracheal injection possibly offers a prospect of obtaining active immunity in bovine tuberculosis. At any rate, in the case of many contagious diseases, the injection of serum might be attempted through the respiratory channel.

644 - Bovine Foot and Mouth Disease (2) is not Transmissible to Man; Human Aphthic Stomatitis is not Transmissible to Cattle. — LEBAILLY, C., in the *Comptes rendus de l'Académie des Sciences*, Vol. 172, No. 18, pp. 1140-1141. Paris, May 2, 1921.

Classic treatises on human medicine and on veterinary medicine, teach, on the strength of experiments made in Germany in 1834, that foot and mouth disease (aphthic fever) is transmissible from animals to man through milk. Periodically, observations are published which seem to confirm this. But the author having carried out an inquiry which he details in this note, thinks it justifiable to conclude from his observations and experiments that bovine foot and mouth disease and human aphthic stomatitis are absolutely distinct diseases, since the former cannot be transmitted experimentally to man nor the latter to cattle.

645 – ***Cysticercus cameli*, a New Hydatid Found in the Heart and Diaphragm of the Egyptian Camel.** — Abdel Aziz Eff Nomani, in *The Agricultural Journal of Egypt*, Vol X, p 69, 1 fig Cairo, 1920

During the course of a meat inspection at the Cairo abattoir, the author met with a heart of an Egyptian camel invaded with a bladder-worm having the general appearance of *Cysticercus bovis* which, as is known, is occasionally found in camels. No parasites were found in the skeletal muscles, but the diaphragm, as well as the heart, contained them in small numbers.

Careful examination of the camel hyatid showed that it was neither *Cysticercus bovis*, nor *Cysticercus cellulosae*. The cysticercus itself is oval, or elliptical in shape, and varies in size from 8 to 10 mm in length, and from 3 to 4 mm. in breadth. Each cysticercus possesses a white spherical head (*scolex*) about 2 mm. in diameter. The head is armed with a double row of hooks varying in number from 43 to 45, and possesses 4 oval suckers, one at each corner of the head. The neck contains calcareous granules.

The hooks are somewhat longer and thicker than those of *Cysticercus cellulosae*. Those of the outer row are smaller than the hooks forming the inner row, which are longer and more slender.

The author proposes giving the parasite the name of *Cysticercus cameli*.

646 – **Poisoning of Geese by the Nut of the Cabbage Palm (*Areca oleracea*) Given as a Remedy against Tape-worms, in Germany.** — Heidrich, in the *Berliner Tierärztliche Wochenschrift*, Year XXIII, No 9, p 102 Berlin, March, 1921; extract from *Bericht uber das Veterinarwesen in Sachsen fur das Jahr*, 1918, p 100. Dresden, 1921

A large number of geese affected with *Taenia lanceolata* and *Taenia fasciata* were treated, through the mouth, with powdered cabbage-palm nut. The medicine was given in mouthfuls with bread and butter. Geese that were obviously ill were only given half the prescribed dose. A few minutes after administration the geese vomited the mouthfuls, struggling and salivating. One strong goose fell down with its neck and legs rigid and had to be killed. According to Zurn cabbage-palm nut is the best remedy for tape-worms for poultry. The dose recommended, 3 gm., appears to be decidedly too great.

647 – **The Crevat Method of Rational Feeding for Cattle.** — Censi Mancia, G B, in *La Riforma agraria*, Vol II, No 2, pp 84-88 Parma, Feb, 1921.

According to the author, Crevat's book on the rational feeding of cattle, a work which gained a prize from the Société des Agriculteurs de France in 1885, has not yet been thoroughly discussed.

Crevat wished to dispute the classic method, according to which the ration is proportional to the live weight of the animal, and he based his work on the "law of rations of proportional intensity." This law is supported by the fact that small animals have, relatively to their weight, a greater muco-cutaneous area than that of large animals; it is therefore logical to suppose that they ought to have, proportionally, greater food requirements.

With the help of numerous references to the literature, the author criticises the hypotheses of CREVAT according to which: — 1) The muco-cutaneous area is proportional to the square of the thoracic perimeter; 2) the live weight of various animals is proportional to the cube of the thoracic perimeter; 3) the rations (R) are proportional to the cube roots of the squares of the weights (P). But, while the last rule speaks of proportionality, CREVAT expresses it by an equality: $R = \sqrt[3]{P^2}$. The author points out the necessity of introducing an average coefficient of proportionality (K) which varies according to the species and breeds and he calculated this coefficient from the average daily amount of good natural meadow hay consumed by 6 sheep and 3 head of cattle fed *ad lib.* for 10 consecutive days. For the sheep, he obtained K = 0 56, for the cattle K = 0.89 and, respectively: —

$$R = 0.56 \sqrt[3]{P^2}; \qquad R = 0.89 \sqrt[3]{P^2}$$

The data used in the estimation of these coefficients are shown in the appended Table, which shows that the two species considered are by no means constructed on similar models. In cattle the thoracic perimeter is about two and a half times greater than in sheep, whilst the cutaneous area is about 6 times greater and the food requirements are 10 times greater,

According to the data given in the Table, the author calculates that, per unit of skin area, large animals need a larger food ration than small animals. Thus, for sheep the quantity (in kg.) of grass required is about $^1/_{13}$ of the thoracic perimeter expressed in cm.; for cattle it is about $^1/_3$; the corresponding requirements of hay are about $^1/_{54}$ and $^1/_{13}$. Now, if the percentage ratios between the live weights of the animals are worked out the same results are arrived at. The ratio between the live weight and the cutaneous area $\frac{P}{S}$ shows that, in the cattle used in the experiment, the cutaneous area in square dcm corresponds approximately to the live weight in kg. while in the sheep it is about 4 times greater.

A coefficient of proportionality should therefore be introduced into the formula used for calculating the nutritive activity A, which CREVAT considers proportional to the ratio between the ration R and the live weight of the animal P $\left(A = \frac{R}{P}\right)$.

The formula of equality $A = \frac{\sqrt[3]{P^2}}{P} = \sqrt[3]{P^2 : P^3}$ assuming that

[647]

$R = K\sqrt[3]{P^2}$, ought to be corrected as follows:

$$A = \frac{K\sqrt[3]{P^2}}{P} = K\sqrt{\frac{P^2}{P^3}} = \sqrt{}\ P$$

that is to say, that the activity would be inversely proportional to the cuberoot of the weight.

In the case of the animals used in the author's experiments, the food requirement per 100 kg live weight was 17 2 kg. of grass, corresponding to 4.3 kg. of hay, for the sheep ; 10 9 kg. of grass, corresponding to 2.7 kg of hay for the cattle; whereas **Crevat** obtained the following figures. for sheep 30.7 kg of grass = 7.65 kg. of hay; for cattle 12.2 kg. of grass = 3 5 kg. of hay. The theory of the ration proportional to live weight, fixing the necessary quantity of hay at 3 33 kg per 100 kg. live weight, gives the large animals too much and the small animals too little , **Crevat**, by confusing proportionality with equality erred, according to the author, in the opposite direction.

The practical formula of **Crevat**, $R = C^2 \times 5$, signifying that the ration is equal to the square of the thoracic perimeter in cm. multiplied by 5, would give sheep a ration more than double that consumed in the experiments and to cattle an excess of 4 kg of grass per day.

Finally the author criticises **Crevat**'s law on the early maturity of breeds of animals and the deductions that have been made from it, and concludes that " there is no reason to contest the old classic method which makes the rations proportional to live weight, but it is very necessary to ascertain the precise food requirements for each species of animals "

Number	Animal	Live weight	Thoracic perimeter	Average daily ration of grass	Average daily ration of hay	Average coefficient K for calculating the ration	Cutaneous area	Coefficient K for the calculation of the area	Ratio between the area and the grass ration	Ratio between the thoracic perimeter and the ration	Ratio between the live weight and the area	Nutritive activity $\frac{R}{P}$ Requirement for 100 kg of live weight	
		kg	cm	R=kg	$\frac{R}{4}$ = kg		dm²		$\frac{S}{R}$	$\frac{Pt}{R}$	$\frac{P}{S}$	Grass	Hay

648 - **Study on Inbreeding, Especially as Regards its Supposed Relation to Mendelian Laws.** — HENSELER, H., in the *Zeitschrift fur Gestutkunde und Pferdezucht*, Year XV, Part 7, pp. 137-143. Hanover, July, 1920.

The author, in his study on consanguinity as a method of breeding, broaches the question of the supposed relation of inbreeding and the Mendelian laws, objecting that this idea has been rather hastily introduced into German text books and manuals of zootechnology.

He deals notably with the results of FRÖHLICH'S researches in PUSCH HANSEN, *Allgemeine Tierzucht*, new edition, p. 275, which attempt to prove how the probability of the appearance of homozygous and heterozygous descendants should develop among 64 animals of different degrees of consanguinity which consequently ought to lead to the combining of methods of experimental research in heredity with the methods of genealogical research based on Mendelian laws. The results of these researches are indicated in Table I.

TABLE I. — *Results of* FRÖHLICH'S *researches.*

Degrees of consanguinity Remove (1)	Dominant Homozygotes (out of 64 animals)	Heterozygote (out of 64 animals)	Recessive Homozygotes (out of 64 animals)
I-II	48	16	0
II-II.	36	24	4
II-III	30	28	6
III-III	25	30	9
III-IV	22.5	31	10.5
IV-IV	20	32	12
IV-V	19	32	13
V-V	18	32	14
II-II	17	32	15
II, III-III	36	24	4
II, IV-IV	33	26	5
III, III-III	30	28	6
III, III-IV	27.5	29	7.5
III, IV-IV	25	30	9

(1) Remove = Ligne ancestrale (Vendi) = Ahnenreihe (German) (*Ed.*)

Assuming that a founder is homozygous at least in respect of one character, the author obtains the same figures by the following calculation :—

TABLE II. — *Consanguinity with removes II-II.*

● AA	A a	● AA	A a
The sexual cells contain :-			
100 % A	50 % A 50 % a	100 % A	50 % A 50 % a

According to the calculated estimate, the progeny would have the following hereditary tendency as regards the character AA:—

Homozygote AA 50 % and	Homozygote AA 50 % and
Heterozygote Aa 50 %	Heterozygote Aa 50 %

The sexual cells consequently contain:—

75 % A and 25 % a, that is to say in 75 % A and 25 % a = 3 A: 1 a in the proportion 3 A : 1 a

The composition of the hereditary mass of the descendants can be calculated as follows:—

3 A : 3 A = 9 AA
3 A : 1 a = 3 A a
1 a : 3 A = 3 a A
1 a : 1 a = 1 a a

or 9 AA : 6 A a : 1 a a. Consequently, for 64 decendants: 36 AA. 24 A a: 4 a a

TABLE III. — *Consanguinity with removes IV-IV.*

● AA	A a	A a	A a	A a	A a	A a	A a	● AA	A a	A a	A a	A a	A a
100 % A	50 % A 50 % a	50 % A 50 % a	50 % A 50 % a	50 % A 50 % a	50 % A 50 % a	50 % A 50 % a	50 % A 50 % a						

50 % A A
50 % A a

25 % AA
50 % A a
25 % a a

3 A: 1 a   1 A: 1 a   1 A: 1 a   1 A: 1 a

3 AA: 4 A a: 1 a a
62 $^1/_2$ % A and 37 $^1/_2$ % a
5 A: 3 a

1 A: 1 a

The right half of the genealogical table corresponds to the left half

5 A A: 8 A a: 3 a a
56 $^1/_4$ % A and 43 $^3/_4$ % a
9 A: 7 a

81 AA : 126 Aa : 49 aa = total 256.

Consequently, for 64 descendants (divide by 4):—

20.25 AA : 31 5 Aa : 12.25 aa

Making the same calculation for the degrees of consanguinity with removes II-II and V-V, the following composition of the hereditary formula of the descendants is obtained:—

Removes II-II 25 AA : 30 Aa : 9 aa.
» V-V 18.0625 AA : 31.875 Aa : 14 0625 aa.

The following series results:—

1st	generation	the ratio in	the	sexual	cells is	3 A : 1 a
2nd	»	»	»	»	»	5 A : 3 a
3rd	»	»	»	»	»	9 A : 7 a
4th	»	»	»	»	»	17 A : 15 a
nth	generation	»	»	»	»	$2n-1 : 2n'-1$

Now, the author observes that this same calculation and the same reasoning hold good when the AA animals are not the same, that is to say, when no consanguinity or relationship exists. On the other hand, it would be possible, inversely, to proceed to in-breeding when the founder, with regard to its hereditary characters, is not homozygous but heterozygous and consequently to prove the reverse by this method of calculation. The author further remarks that by examining the degree of consanguinity with removes IV-IV, a degree of consanguinity by which practically the best results are obtained, it can be shown that as many homozygous descendants as heterozygous are probable, and that further, with relatively close degrees of consanguinity, with removes II-III and III-IV, even more heterozygous than homozygous descendants are probable.

According to the author, these facts show that there is no direct relation between consanguinity and the Mendelian laws. In his opinion the very fact of the reduction of ancestors or, which comes to the same thing, the accumulation of ancestors, proves sufficiently that the value of consanguinity has a biological basis and that the Mendelian laws and consanguinity are not inconsistent with each other.

649 - **Horse-Breeding in Brazil.** — I. SILVA, H., As raças equinas no Brasil, in the *Rivista de Commercio e Industria*, Vol. VII, No. 73-74, p. 16. Rio de Janeiro, Feb 1921. — II. RIET, M., O cavallo nacional. *Ibid.*, p. 15.

I. — After a stationary and almost regressive period, horse breeding in Brazil has made a great advance during the last few years. In the States of Rio Grande do Sul, São Paulo, Paranà, and Minas Geraes, a large number of horses of selected breeds (Arabs, English thoroughbreds, Anglo-Norman, etc.) have been imported and bred.

The predominant breed in Brazil is an Arab or one of its varieties, degenerated.

Assis BRASIL has imported for his stables in the commune of S. Gabriel (Rio Grande do Sul) valuable thoroughbred English and Arab stallions which have produced very fine results with native mares. English and Arab half-breds are now numerous in the plains of the Rio Grande and especially in the communes of Uruguayana, Rosario, Tangussú, Cacimbinhas, Caçapava, and D. Pedrito.

At São Paulo, a Government Stud Station attached to the " Posto zootechnico " is in full activity. In that State, the production of 3 types of horse :— 1) Military ; 2) agricultural ; 3) of high commercial value ; is aimed at. Another Station provided with stallions purchased in Europe is found at the " Posto zootechnico " of Moóka.

In some localities in the State of S. Paulo there are some fine riding and driving mares, Anglo-Norman thoroughbred and half-bred, Orloff thorough bred and halfbred, and fine specimens of the native breed. In the State of Minas Geraes, which also has some fine riding and driving horses, the " Real Candelaria de Campo " was founded in 1819, with the object of improving horse breeding. Arab stallions being used. When the Imperial form of government fell, the establishment remained the private property of the ex-emperor, and it now belongs to the Salesian Fathers.

Among the most celebrated breeds of horses in the State of Minas Geraes may be mentioned the " sublimes," " monarchas," " manga largas," and " pampas."

In Paranà, good horses are also found, particularly in the communes of Ponta Grossa, Castro,and Guarapuava. A pre-eminently national type of horse is the " curraleiro," which is also called " cavallo sertanejo " in the State of Goyaz. The best horses of this breed are bred in the Vão do Paranan, a zone on the borders of the States of Minas and Bahia ; but this breed extends all over the north of the State of Goyaz. " Curraleiros " are not remarkable for speed, but they excel in standing hard work and by their hardiness. This breed is of medium height at most, but its muscles are firm and stand any test ; it is well shaped, very agile and its coat is fine and glossy ; by selection a valuable breed might be created. " Curraleiros " stallions put to half-bred Argentine mares have given fine produce of a greater height, which is very important as the regular type of horse for the Brazilian army must be 1.48 m. in height.

II. — The author regrets that the English thorough bred has been chosen for the improvement of Brazilian horses and that the method of crossing with European breeds, which are produced in a very different environment from that of Brazil, has been generally adopted He insists that, on the contrary, recourse should be had to selection of the native horse, which is valuable on account of its reliability, resistance, and hardiness.

650 – **The Creation of an American Utility Horse.** — WILLIAMS, J O , in *U. S. Department of Agriculture, Department Circular*, 153, 22 pp , figs 17. Washington, March, 1921.

American light horses have long been world-famous in several highly specialised lines — for example, the trotting and saddle breeds.

The United States Department of Agriculture has recognised the need of developing a type of the native light horse suitable for general utility work on farm or ranch. Such a type would also supply desirable horses for the army. With this end in view, co-operative experimental breeding work has been carried on for many years by the Department of Agriculture and horse-breeders. The ideals sought in this new type of horse are a uniform combination of size, substance, soundness, endurance and a sufficiency of speed.

Although the motor-car, motor-truck, and tractor undoubtedly will displace some horses, nevertheless, the active, sizable, utility horse will be an increasingly important factor in American farming, especially in those sections where the heavy-draught breeds are not the most economical type to use.

The co-operative breeding work was begun in 1904, with several selected mares, and the standard-bred stallion "Carmon." This remarkable sire is still used in the development of the work. The Bulletin analysed describes the progress hitherto made at the United States Wyoming Horse-Breeding Station.

651 - **Cattle-Feeding Experiments at the Kansas State Agricultural College, U. S. in 1918-1919.**—McCampbell, C. W., Bell, F. W., and Winchester, H. B., in *Agricultural Experiment Station, Kansas State Agricultural College, Department of Animal Husbandry, Circular No.* 77, 11 pp., fig. 1 Manhattan, 1919.

In the first part of the Circular analysed, Messrs. Campbell and Winchester describe a feeding experiment, lasting 120 days, that was made with 39 two-year-old steers divided into 4 lots, with the object of ascertaining how far the maize grain ration could be reduced, in order to lessen the maintenance costs by the maximum use of lucerne hay and sorghum silage.

The course of the experiment and the chief results obtained are summarised in the following Table.

Substituting sorghum silage for maize grain in the ration of two-year-old steers.

Ration	Average initial weight	Feeds consumed per 100 lbs of increased weight: Ground maize	Linseed meal	Lucerne Hay	Sorghum Silage	Percentage of Shrinkage in marketing	Dressing percentage	Ranking of carcasses in cooler
	lb.	lb.	lb.	lb.	lb.	%	%	
I Ground maize 15.45 lb + linseed meal 2.74 lb lucerne-hay 13.14 lbs.	944.92	477.54	84.72	406.91	—	3.18	59.74	2
II Ground maize 15.11 lb + linseed meal 2.68 lb lucerne hay 2 94 lb + sorghum silage 25.26 lb.	949.60	492.34	87.36	95.68	822.74	3.11	61.05	1
III Ground maize 7.69 lb linseed meal 2.72 lb lucerne hay 2.97 lb. orghum silage 41.84 lb.	960.20	292.08	103.33	112.67	1589.00	3.54	60.37	3
IV Linseed meal 2.70 lb + lucerne hay 2.95 lb + sorghum silage 60.26 lb.	963.10	—	87.42	95.31	1949.51	5.40	56.80	4

Reckoning the food at the current prices at the time the experiment was made, all the lots were sold at a loss, but the latter was less in the case of lot IV (without maize) although these animals gave lower dressing results and lost much weight on the journey.

In the second part, Bell gives the results of comparative experiments between maize silage and sorghum silage in fattening baby beeves. The experiments lasted 90 days. Fifteen young steers and 15 heifers (weighing on an average about 459 lb.), were divided into 2 lots each of which were fed the same amount of ground maize, linseed meal and silage. The daily increase in live-weight per head of the lot given maize silage was 2.54 lbs; that of the lot fed sorghum silage attained 2 62 lbs. The latter animals made slightly larger and cheaper gains, dressed at a higher percentage and showed carcasses of better quality than the calves of lot 1. The year being a bad one for maize the sorghum made a yield of 9 tons of silage per acre as compared with 3.5 tons for the maize.

In the third part, a comparison is made between one lot of two-year-olds reported in Part I of the Circular (lot IV) fed on sorghum silage, and one lot of baby beeves reported in Part II. All the animals received as much maize, lucerne hay and sorghum silage as they could eat, and approximately 2.5 lbs of linseed meal daily per 1000 lb. live-weight.

The two lots were fattened to the end upon the same food that they were given at first. It required 150 days to make the calves as fat as the two-year-olds at the end of 120 days. In order to make 100 lb. gain, the baby-beeves consumed 367 76 lb. ground maize, 64.14 lb linseed meal, 117.51 lb. lucerne hay and 679.77 lb. sorghum silage, whereas the two-year-olds needed respectively 492.34 lb. (33 % more); 87.38 (36 % more); 95.68 lb. and 822.74 lb. (21 %) which shows that it pays better to feed baby-beeves than two-year-olds, if the animals are destined for beef-production.

652 - **Experiments in Feeding Beef Cattle in Nebraska, United States.** — Gramlich, H. J., in *Agricultural Experiment Station, the University of Nebraska, Lincoln, Bulletin* 174, 22 pp, figs. 6. Lincoln, September 1919

The feeding experiments began on November 22, 1917, and were carried on for 130 days with 5 lots of 10 cattle each. Three lots were used, in order to compare the results obtained with coarsely ground, or snapped maize, and whole maize. The supplementary protein food given consisted of cotton seed cake (broken into pieces of the size of a hazel nut): the only bulky feed was lucerne hay. Lot 4 received no supplementary food; lot 5 was given maize silage, instead of maize corn. The cattle were followed by pigs, and as the grain ration was increased, more pigs were added.

The Table on p. 747 gives the most important results.

The feeds are charged as follows:

	$	
Shelled corn	1.40	per bushel
Snapped corn	1.50	» cwt
Cottonseed nut cake	60.00	» ton
Lucerne hay	25.00	» »
Silage	10.00	» »
Grinding maize	04	» bushel
Grinding lucerne hay	3.00	» ton

The control lot (No. II) did not succeed at the beginning of the experiment.

The results obtained lead to the following conclusions:

1) The addition of 1.71 pounds of cottonseed nut cake to a maize and lucerne ration failed to increase the rate of daily gain, but increased the feed required per pound gain by 0.56 pound, and the cost of 100 pounds of gain by $2.16. It also decreased the profit $2.65 per steer (Lots I and II).

2) The grinding of maize and lucerne, when these are fed in conjunction with cottonseed cake, gave a 0.32 pounds per day larger gain at a materially reduced cost per 100 pounds gain, namely $2.08 and increased the profit per head from $5.56 to $11. It also reduced the pork produced per steer from 42.6 to 28.9 pounds (Lots II and III).

3) The feeding of snapped maize + cotton-seed nut cake + lucerne hay in comparison to shelled maize + cottonseed nut cake and lucerne hay gave a slightly greater daily gain, and a $5 cheaper cost per 100 pounds of gain. The feeding of snapped maize gave, exclusive of pork, a profit of $13.87, in comparison with $1.26 loss where shelled maize was fed; and inclusive of pork, a profit of $19.85 in comparison with $5.56 (lots II, and IV).

4) The feeding of a heavy silage ration did not produce as much fattening as the feeding of maize in conjunction with cottonseed nut cake and lucerne, but the animals put on a considerable amount of flesh, and the market price left a margin of profit. This amounted to $1.49 per steer, in spite of the fact that the sale price was $1 per 100 pounds less than when the steers received a heavy feed of maize (Lots II and V).

Comparison between the different ways of preparing maize for fattening cattle.

Lots	Maize modes of preparation	Average initial weight	Average daily gain	Feed required per lb. gain			Cost per 100 lb.-gain	Value per cwt.	Dressing percentage	Pounds pork per steer
				Maize grain or silage	Cotton seed nut cake	Lucerne hay				
		lb	lb.				$	$	$	$
I	Whole maize	835.5	2.77	6.54	—	4.24	21.65	14.50	60.69	38.9
II	Whole maize	837.7	2.56	6.47	0.67	4.50	23.81	14.50	57.29	42.6
III	Coarsely-ground maize . .	831.5	2.87	6.15	0.54	3.12 (2)	21.73	14.85	59.85	28.9
IV	Snapped maize (108 days) . .	825.0	2.64	1.34(1)	0.79	3.08	18.81	14.50	59.27	37.4
V	Maize silage . .	830.0	2.20	23.66	1.73	0.99	18.26	13.50	58.48	45.8

(1) Shelled maize substituted for snapped maize for the last 22 days since snapped maize was no longer available. — (2) Ground and fed, mixed with grain.

653 - **Experiments in Fattening Steers in Oregon, United States.**— POTTER E. L., and WITHYCOMBE, R., in *Station Bulletin* 174, *Oregon Agricultural College Experiment Station, Eastern Oregon Branch Station*, pp. 16, figs. 2 Corvallis, Oregon, August 1920.

A report of a series of experiments begun in 1913-1914 in the winter-fattening of cattle in the open. At the commencement of the tests, the weight of the animals was from 967.72 to 1066.13 pounds.

The first year's work was a comparison of three different kinds of hay, no other food being given. It was found that lucerne hay increased the live-weight twice as much as wild hay, and three times as much as awnless barley hay. The object of the further experiments was therefore to determine the best way of feeding lucerne hay.

When the steers (cross-bred Herefords 2 years of age) were given all the lucerne hay they could eat, and 5 lb. daily of rolled barley for the whole duration of the experiment (120 days), or 10 lbs of rolled barley for the last 60 days, the average daily gain in live-weight was 1.24 lb. and 1 17 respectively, while it was only 0.92 lb. when they were receiving hay alone.

When silage was added to the lucerne hay, the average gain in live-weight was 1.93 lb. as against 0.94 lb. when lucerne hay alone was fed. Chopping increased the nutritive value of lucerne hay 28 % when fed alone ; 14 % when barley was added, and 7 % when silage was also given. In most cases, however, the improvement was not equal to the cost of chopping.

The most satisfactory and economical of all the rations tried was hay and silage, therefore the authors advise its use in fattening cattle during the winter months.

The different animals which, at the end of the experiments, were in a half-fat condition were turned out to pasture in the following spring. Their average daily gain in live-weight was 1.00 lb. the first month; 2.39 lb. the second ; 2.31 lb. the third, and 0.70 lb. the fourth. The steers finished on pasture fetched the highest prices.

654 - **Relative Values of Feed Proteins for Dairy Cows.** — LARSEN, C., WRIGHT, T., JONES, H., HOOVER, H., and JOHNSON, B., in *Bulletin 188 of the Agricultural Experiment Station, South Dakota State College of Agriculture and the Mechanic Arts*, pp. 163-204. Brookings, South Dakota, 1920

The authors carried out 2 series of metabolism experiments on dairy cows with the object of comparing the availability of the proteins contained in linseed meal and gluten feed. Three cows were used in the first series which was continued in 1918 (though begun in 1917) ; it consisted of 6 periods of 10 days. The second series was begun late in 1918, and consisted of 4 periods : 4 cows were used. During the first series, the basal ration consisted of 30 lbs. of maize silage and from 11.59 to 16.65 lb. of prairie hay, and during the second series, of 20 lb. to 20.50 lb. of maize silage and 19.70 to 23.20 lb. of prairie hay. During the first period of each series, the basal ration consisted only of prairie hay and silage, and in every case, the nitrogen balance was negative. During the successive periods of series I, and in periods 2 and 3 of series II, linseed meal and gluten were in amounts which theoretically contained sufficient nitrogen to give the balance, but in no case was a positive nitrogen balance obtained.

The cows of the first series weighed respectively at the beginning of the first period 1153 — 1378 — 1040 lb., and those of the second series respectively 1043 — 830 — 936 — 864 lb. at the beginning of the first period. The results are set forth in 26 tables and are discussed; the literature referring to the subject is reviewed.

The percentage availability of the nitrogen has been calculated by 2 methods.

In the first, which is a modification of THOMAS's method, the increase in the amount of nitrogen assimilated during a period of feeding with concentrated food as compared with that digested when the basal ration alone was given, is expressed in % of the nitrogen available for accumulation in the organism and for catabolism. In the second, the increase of nitrogen used for milk production and for accumulation in the organism is expressed in % of the increase of the digested nitrogen. The following Table gives a summary of the data obtained by the second method; they agree very well with those supplied by the modified THOMAS method, according to the latter 52.4 % of linseed meal nitrogen and 76.4 % of gluten feed nitrogen were used on an average to establish nitrogen equilibrium.

The authors consider, that the fluctuations observed in the amount of nitrogen utilised are due to a great extent to fluctuations in the energy

Utilisation of the surplus nitrogen supplied for the formation of maintenance and milk production protein in relation to the concentrated feeds consumed and the energy afforded by the bulky feeds.

Concentrated feeds given during the successive periods (1)	In % of the necessary energy supplied by the bulky feeds					
	1917			1918		
	Cow No. 1	Cow No. 2	Cow No. 3	Cow No. 1	Cow No 2	Cow No. 3

» »	91.2	83.9	89.0	—	—	—

Concentrated feeds given during the successive periods (1)	In % of surplus of available nitrogen used					
	1917			1918		
	Cow No. 1	Cow No. 2	Cow No. 3	Cow No. 1	Cow No. 2	Cow No. 3
Linseed meal	43.1 %	35.7 %	42.7 %	99%	87%	106%
» »	53.2	49.6	52.8	—	—	—
» »	39.9	44.5	37.3	—	—	—
Gluten feed	70.9	62.9	47.7	119	115	74
» »	76.9	77.4	67.9	—	—	—

(1) In the case of cow No. 3 of the 1918 series, the gluten feed period preceded the linseed meal period.

of the food ingested. When the percentage of therms furnished by the hay and silage was low, the protein in the gluten feed or linseed meal was used principally as a source of energy and could not be employed to build up the body tissue, or furnish milk protein. Therefore the percentage availability of the food-nitrogen was extremely low in these cases.

The order in which the different rations are fed also seems to have an effect on availability Although no concentrated feeds were given during the last period of the second series, the 4 nitrogen balances were positive.

The authors give Tables showing the approximative amount of foods fed during each experimental period and the quantities of nitrogen, fat, crude fibre, N-free extract, and ash ingested and excreted.

655 - **Observations and Experiments on Calf-Feeding in Italy.**— BRENTANA, D, in the *Riforma Agraria*, Vol I, No 12, pp 491-497, figs. 2; Vol. II, No. 2, pp. 82-83, figs 2. Parma, December 1920, February 1921

Observations made by the author in 1917 and 1918, at the Central Cattle Depôt of the 4th Army, where most of the calves produced by the cows in calf that had been seized by the requisition Commissions were being reared.

The following foods were used :— Whole milk, skim milk, hay, wheat bran, and limited amounts of sesame cakes and spoilt wheat flour.

For the first 4 or 7 days, the calves were fed by their dams; later, they were bottle-fed twice aday. A very simple form of bottle was used, the milk being given as soon as it was taken from the cow.

The effect of very prolonged suckling and weaning, for 107 and 127 days respectively, was tried upon 3 calves (2 males and 1 female) of the brown Alpine breed.

When the animals were about 3 days old, they were given a little hay of excellent quality grown on a permanent pasture; from the 108th day, small but continually increasing, quantities of bran were fed.

The results are given in the two following Tables.

TABLE I. — *Calf-Feeding Experiment.*

	Periods	Duration (days)	Live weight		Increase in live weight		Whole milk consumed	Hay consumed	Bran consumed	Digestible nutrients consumed for an average increase of 1 kg. in live weight			
			initial	final	Total during the period (3 calves)	Average per day (3 calves)				Protein	Fats	Estimate	Starch value
			Kg.	Kg.	Kg.	Kg.	Kg.	Kg.	Kg.	Gm.	Gm	Gm.	Gm.
Suckling . .	I milk alone	34	115	219	104	3.058	811.30	—	—	257	266	359	1 148

TABLE II. — *Economic results (in lire)*

	Periods	Cost of milk	Cost of hay	Cost of bran	Cost	
					total	expressed per increase of 1 kg in live-weight
Suckling	I milk (alone)	811.30	—	—	811.30	7 80
	II milk + hay	2356.00	48.00	—	2464 00	10.49
Weaning . .	III	2271.00	376.70	270.12	2817.82	7 10
Totals . .	—	**5438.30**	**424.70**	**270.12**	**6033.12**	—

Cost of foods per quintal: Whole milk 100 fr.; hay 50 fr ; bran 80 fr

The cost of the food consumed to produce 1 kg. of live-weight was 8.26 fr., to this about 50 % must be added, in order to obtain the total cost of production. Under the conditions prevailing in the Parma market towards the end of 1920, the total cost amounted to 12.39 fr. per kg. of live-weight.

The milk represents 90 % of the cost of calf-rearing. Owing to the high cost of milk-production, the author advises that his rearing systems should not be adopted for butcher's animals, but only for breeding cattle.

Weaning should always be progressive, and ought to last at least 1 month. Good practical results have been obtained by allowing the suckling + weaning period to last 4 months The author obtained quite satisfactory results when it was reduced to 3 months In the first case, if the calves, after weaning, were chiefly given hay and bran, their usual live-weight on their reaching the age of 270 days, was over 2 quintals.

656 - **Plant Foods Rich in Protein Replaced by a Digestible Form of Animal Epithelial Products in Rations Fed to Wool-Producing Sheep; Experiments Carried out in Germany.** — ZUNTZ, N., in the *Biedermann s Zentralblatt*, Year XLIX, Part 5, pp 189-190. Leipzig, May 1920.

A means of increasing wool-development in sheep without the use of foods with a high protein content (1).

As is well-known, sulphur-containing cystine, an albuminoid derivative, is the substance chiefly concerned in the growth and development of wool. Only 0.3-2 5 % of it is to be found in the protein of nutrient liquids, and it sometimes occurs in even smaller quantities in protein food substances, whereas the cystine content of the horny constituent of wool is as much as 7.3 %. Thus, in order to obtain the necessary amount of cystine, considerable quantities of protein have to be ingested. Further, it has been found, that after the decomposition of the protein and the elimination of the cystine, all the other matters that make up food protein are lost, as regards the formation of animal albuminoids, which explains the relatively large quantities of protein required in the ration, in order to obtain a good wool-yield from sheep.

---

(1) See *R.*, Oct. 1920, No. 1015. (*Ed.*)

As foods rich in protein are lacking in Germany, the author, with a view to economising plant proteins, tried to give sheep all the nutrients required for inducing the growth and development of their wool by adding to their rations, hair and other epithelial products that had been rendered digestible by chemical action. The results of the experiment were satisfactory ; 4 sheep were given equal amounts of disintegrated straw and mangolds, the quantity being sufficient to maintain the weight of the animals.

Of the 4 sheep used in the experiment, 2 were given from 9-10 gm. of digestible horn in their rations per head per day.

After the experiment had lasted for four months, the fleeces, of these animals, were much finer than those of the sheep which had been given no horn, and microscopic examination showed that the diameter of the staple exceeded by one-third that of the wool produced by the control animals.

657 - **Compulsory Keeping of He-Goats by the Communes in Prussia.** — GERRIETS, J. (Regierungs und Landesökonomierat), in the *Deutsche Landwirtschaftliche Presse*, Year XLVIII, No 34, p 259 Berlin, 1921

Law of December 14, 1920 relating to the compulsory keeping of he-goats by Prussian Communes and the compulsory licensing of he-goats kept for public service (1). Goat-breeding in Prussia, on account of the altered economic conditions, has increased to such an extent of late years, that is has become an important industry. Whereas, in 1913 there were only 1 910 888 goats (2), the census of 1919 showed that there were 2 475 609. The milk-yield has, however, not increased, but rather diminished owing to the animals having been insufficiently fed, and to the use of unsuitable service goats.

On the other hand, the number of he-goats kept by private initiative and possessing any value for breeding purposes is very small, owing to the expense of purchasing and keeping them. Therefore, suitable male goats have to serve too many females, and frequently the latter are mated late or even not at all. The above-mentioned law regulating the keeping of he-goats in all the Prussian provinces is intended to remove these difficulties. The two main points insisted upon are as follows :—

1) Inasmuch as the number of he-goats kept in the commune by private persons is not sufficient to meet all requirements, the Commune is required to purchase and maintain as many of the said animals as are required to serve the female goats kept in the Commune. The law allows one male for the service of 80 female goats.

2) Any keeper of goats intended for public service is required to use licensed animals only.

---

(1) *Preussische Gesetzessammlung* 1920, p. 263. (*Author*)

(2) Reckoning according to the present area of Prussia. (*Author*)

The law contains no special provisions for the licensing of service goats; but leaves the matter to be settled by the Regierungspräsidenten after consulting the Chambers of Agriculture of the several districts.

As a considerable number of goats are kept in the towns, a special clause has been inserted in the law making this regulation apply also to town districts.

In South Germany, the keeping of he-goats has been regulated for some years by similar enactments. In the Prussian province of Hesse-Nassau, a similar law, which has produced excellent results has been in force since 1909 (1).

658 – **Pig-Breeding in the Marches, Italy** (2). — BARTOLUCCI, A., in the *Giornale di Agricoltura della Domenica*, Vol. XXXI, No 17, p 131, figs. 3. Piacenza, April 24, 1921.

The live-stock census taken in April, 1918, showed that there were then 2 388 926 pigs in Italy, as against 2 507 798 in April, 1907. Although the total for the whole country had decreased, the pigs in the Marches had slightly increased, the return for that district being 116 689 in 1918.

The native pig of the Marches is descended from the old Iberian breed, (which is the origin of all the Italian varieties and sub-varieties) and is the result of interbreeding local animals with those from Umbria, Tuscany, Romagna and Campania Of late years, in some districts, crosses have been made with the Yorkshire and Berkshire breeds. The indigenous variety is still found relatively pure in the mountainous part of the region and even more frequently in the Province of Macerata.

These animals have black coats shading off into slate-grey, the skin of the abdomen and of the interior of the thighs being reddish; they are frequently more or less spotted with red. Though this variety has rather long legs, a slightly elongated groin, and is laterally compressed, it is however very voracious and has great digestive capacity, matures remarkable early, is fairly and constantly prolific, and though their hygienic and food conditions often leave much to be desired, the sows have wonderful powers of suckling their young. The meat and fat of these pigs are much prized as was shown at the Pig Show held at Tolentino on March 17, 1921. The pig-breeders of the Marches therefore propose to preserve the native type and improve it by selection and better methods of breeding.

659 – **Effect of Age of Pigs on the Rate and Economy of Gains.** — ROBISON W L, in *Ohio Agricultural Experiment Station, Bulletin* 335, pp. 545-575, 12 figs. Wooster, 1919

Five experiments are here described In the 3 first, the author studied the development and food consumption, from their birth, of 3 lots of uniform pigs, with the object of determining the amount of feed consumed per unit of increase in weight until the weight of 500 lbs. was attained. Pure-bred Duroc-Jersey barrows were used shortly after weaning and were fed separately; in determining the feed per pig from farrowing to weaning, the average of the total feed consumed by sow and litter was taken. The pigs used in the first experiment were born in the spring, those of the other 2 experiments were born in the autumn. The pigs of the first experiment were given 10 parts of ground maize, 4 parts of middlings and 1 part of tankage by weight, from the time they were weaned (at the age of 3 weeks, that is to say, as soon as they could eat) until they were slaughtered. The ration of the pigs used in the second and third experiments consisted of maize and tankage, at first in the proportion of 8 :1, later, in the 24 following weeks, the maize was gradually increased to the proportion of 14 :1 at which it then remained.

---

(1) *Preussische Gesetzessammlung*, 1909, p. 675. (*Author*)

(2) See *R*, July-August, 1920, No 779. (*Ed.*)

As soon as the increase in weight attained 100 lbs., some pigs of each lot were killed, in order to ascertain the weight and quality of the carcasses. The following table gives the results for the first and second experiments.

Effect of weight on rate and economy of gains.

	Number % pigs	Average Number % days required	Initial weight per pig	Average daily gain	Average Daily feed		Feed per lb v ,		Average dressing per cent.
					Per pig	Per 100 lb weight.	maize	tankage	
			lb.	lb.	lb.	lb.	lb.	lb.	
From birth to 100 lb weight	27	144	2.63	0.829	2.112	4.14	—	—	77.7
» 100 » 200 lb. »	22	200	99.90	4.17	5.938	4 93	3.17	0 28	83.4
» 200 » 300 lb »	17	254	201.97	1.809	7 181	2 85	3.71	0.28	87.6
» 300 » 400 lb »	12	312	301.00	1.719	7.763	2 21	4 25	0 30	88.2
» 400 » 500 lb. »	5	363	402 29	1.579	7.817	1 72	4.60	0.33	88.2

The pigs of the first lot gave the same general results. The number of days required to produce each successive 100 lb. of gain was 125 — 152 — 230 — 286 — 362. The amount of feed per lb. gain was 2.89 — 3.36 — 3.70 — 3.97 — 4.43 lb. in the successive periods of development.

The estimates of the gains show that there is less profit (difference between the sale price of the animal and the cost of food consumed) when pigs are kept beyond the age of quickest growth than when they are sold before the rapidity of growth begins to decrease.

The weight at which it is most profitable to sell pigs full-fed from birth is influenced by ; the method of proportioning the supplemental feed — the amount of the latter — the relation of the price of the supplemental feed to that of maize or other carbonaceous feed — the relative price of feed — the market value of hogs. The live-weight at which it pays best to sell pigs for slaughter was larger in the case of the lots in which the proportion of suppplemental feeds was gradually reduced (viz. those of the 2nd and 3rd experiment) than in that of the lot where this proportion remained constant (animals of 1st lot).

In the 4th experiment, which was carried out in duplicate, the results in both cases being the same, 2 lots of pigs weighing on an average 35.5 lb. per head were compared. Both lots of animals were on rape pasture, the first received a full ration of maize during the three periods of the experiment (each lasting 7 weeks) and the second a limited amount, viz. 2 to 3 lb. daily per 100 lb. of live weight for the first two thirds, of the test and a full feed for the last third. At the end of the first 14 weeks the second lot were not so fat nor in such good condition as the pigs of the first, but during the last 7 weeks they gained weight more rapidly than the others. The amount of concentrated food they consumed per unit of gain was 13 % lower than that of the pigs of the first lot.

The 5th experiment lasted for three periods of 6 weeks each and was a dry-lot feeding test in which narrow, medium, and wide rations of maize were given. The medium ration contained approximately half as much tankage as the narrow one, and the wide ration half as much as the medium one. In all three rations, the proportion of tankage to maize was decreased each week.

For the first and second periods, the pigs fed the most tankage made the most rapid gains and required the least feed per unit of increase in live-weight. For the third period, however, they grew more slowly and required more feed per unit of gain than the animals of either of the other two lots.

660 – **Bee-Keeping in French Guinea.** — (Procès-verbal de la Seance Generale de la Société Nationale d'Acclimatation de France du 24 Janvier, 1921). *Bulletin de la Société Nationale d'Acclimatation de France.* Year LXVIII, No 5, pp 76-77, Paris, May 1921.

Bee-keeping, which was an industry having formerly only rudimentary means at its disposal, in the colonies of French West Africa, now seems to be making satisfactory progress. In spite of the indolence of the natives, the Authorities of French Guinea, have succeeded in persuading them to adopt an improved type of hive, whilst the advice given to the native bee-keeper, has borne good fruit, for whereas 28 metric tons of wax were exported in 1910, the maximum since then has been over 213 tons, and up to 1920, about 200 tons had been shipped annually. Only 75 tons were exported during the first 9 months of 1920, but it is probable that this decrease is only temporary, and that the production of bees-wax in the Colony will soon assume its former proportions, and progress as heretofore.

661 – **Experiment on the Influence of Waterfowl on the Yield of Fish, in Germany.** — WELLERT, P, in the *Mitteilungen der Fischerei-Vereine fur die Provinzen Brandenburg, Ostpreussen. Pommern,* Vol XIII, No. 5, pp. 70-73. Neudamm, May 1921.

VOGEL (1) in his work *Lehrbuch der Teichwirtschaft* had previously drawn attention to the importance of waterfowl for increasing the yield of fishponds, notably owing to the production of a manure containing a proportion of nitrogen and phosphorous, thus providing a regular manuring of summer ponds. The author, wishing to determine the effect of keeping waterfowl combined with pisciculture on the yield of fish in carp ponds, carried out experiments lasting from 1906 to 1920, during which period the yields of two development ponds were carefully registered.

---

(1) P. VOGEL, *Lehrbuch der Teichwirtschaft,* Emil Hubner, Bautzen, 1904 (*Author.*)

During the years 1906-1910, the two ponds, with respective areas of 1.53 and 0.89 hectares were without waterfowl; in 1911-1915, 2000 tame ducks and 200 geese were kept on them. The birds were housed near one of the ponds and let out when about six weeks old. In 1915, the keeping of fowl had to be given up owing to scarcity of food, so that during 1916-1920 the ponds were entirely without fowl.

Increase in weight of fish per morgen (25.532 *ares*)
from 1906 *to* 1920.

1918	234.50	123.00		
1919	87.50	98 00		
1920	180.50	129 00		

According to the author, the decrease in yield during the years 1914-1915 was due to a reduction in the number of fowl in August, 1914; he also explains the higher yield of pond I as due to the greater proximity of the fowlhouse to that pond.

Regarding the modifications in the microflora and microfauna of the ponds due to the waterfowl, quantitatve analysis of the plancton showed that, during the years 1911-1915, the ponds were richer in plancton than in the years 1906-1910 and 1916-1920, and, moreover, emerged plants completely disappeared but grew again after that period.

On account of these encouraging results the author recommends the application of this method, but only allowing the fowl access to the development ponds, as they do too much damage in the spawning ponds and those in which the young fry are kept.

FARM ENGINEERING

662 - Progress of Power-Farming in France. Institution of a Central Committee of Mechanical Cultivation and Establishment of Experimental Stations (1). — I. *Journal officiel de la Republique Française*, Year LIII, No 32, pp. 1524-1530 Paris, Feb. 2, 1921; II. *Ibid*,. No 126, p. 5626. May 11, 1921.

I. — *Progress of power farming.* — Report by J. H. Richard, Minister of Agriculture for France, on the arrangements made to encourage mechanical cultivation, consisting in subsidies granted to groups or syndicates formed for the acquisition and use of motorculture machines, tractors and ploughs. The subsidies varied from 35 to 50 % of the purchase price of the machines during the three years 1916, 1917, and 1918.

The report, which deals with these three years, gives detailed statistics which may be summed up as follows:— In 1916, 29 machines were subsidised; their purchase price was 217 462 fr. and the subsidies amounted to 66 650 fr. In 1917, the number of machines subsidised reached 519 costing 2 818 323 fr., and 1 011 224 fr. was paid in subsidies. In 1918, 381 machines costing 6 464 530 fr. were subsidised at a cost of 2 999 300 fr. Out of the 605 machines which figure in the statistics, only 10 were constructed in France. However, since then the situation has considerably altered.

In 1920, subsidies were applied for on 664 machines of which 246 were of French and 418 of foreign make. The report adds that from January 1, 1918, to December 31, 1919 subsidies amounting to 13 306 219 fr. were granted for the purchase of 1 793 machines of which one was an electrical tillage apparatus. Further it appears from the examination of other applications recived late at the Ministry, that the subsidies would reach 34 340 000 fr. including 12 000 000 fr. for the interior and 22 340 000 fr. for the liberated regions.

II. — *Law of May* 10, 1921, *relating to the institution of a Central Committee of Mechanical cultivation and the creation of Experimental Stations in France.*—

Article I. — A Central Committee of mechanical cultivation is instituted at the Ministry of Agriculture for the investigation of machines for mechanical cultivation. It shall be presided over by the Minister or his delegate and will be composed of: — The Director of the Station for testing agricultural machinery; two professors of the National Institute or of the National Schools of Agriculture; four specialist professors or engineers chosen either from the Central Schools of Arts and Manufactures (construction and working machinery), or from the Schools of Arts and Crafts; and one Inspector General of Farm Engineering (for electrical apparatus).

There shall be associated with this Committeee: — One representative of the Committee of French motor culture, one representative of the Committee of Manufacturers of Agricultural machinery, one representative of the Committee of Manufacturers of automobiles, one representative of the Committee of Importers of foreign machinery and four farmers nominated by the Minister.

---

(1) See R, July 1917, No 650 (*Ed*)

Art. 2 — The land required for the establishment of a Central Experimental Station shall be placed at the disposal of the Committee for its experiments and research.

Art. 3 — Secondary Experimental Stations for motor culture may, after approval by the Higher Council of Agriculture and in agreement with the Committee, be established at the request of Chambers of Agriculture or of Regional and Departmental Agricultural Services.

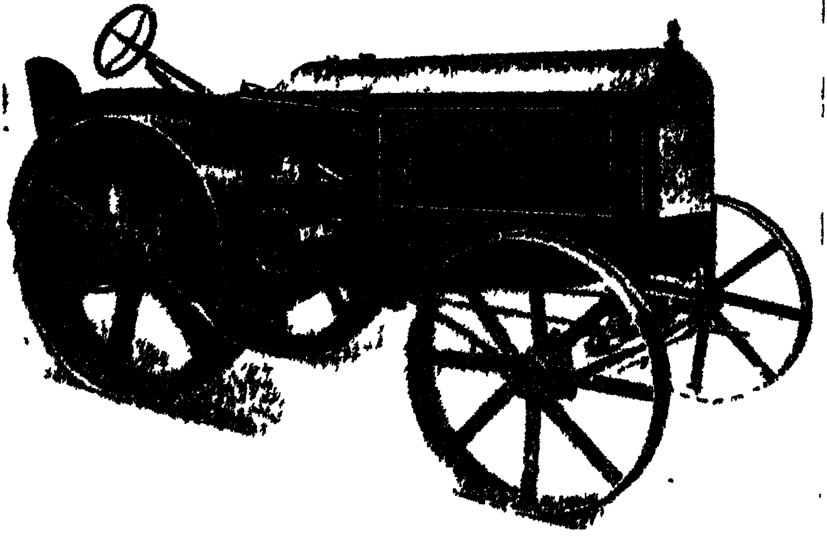
Art 4. — A decree made on the motion of the Minister of Agriculture and of the Minister of Finance shall settle the conditions under which the Central Committee of mechanical cultivation shall act, and shall determine the organisation of secondary Experimental Stations

663 - **Mechanical Cultivation of Rice Fields.** — See Nos 623 and 624 of this *Review*.

664 - **The "Uncle Sam" Tractor.** — DESSAISAIX, R., in the *Journal d'Agriculture pratique*, Year 85, No 15, pp 295-296, 1 fig Paris, Apr 16, 1921

The tractor known under the name "Uncle Sam" was shown by Messrs MATHIEU & Co (55 Rue de Prony, 17e) at the recent exhibition of apparatus for mechanical cultivation at Vincennes, Paris

The machine, illustrated in the figure below is provided with a 4 vertical cylinder motor (0 120 bore and 0.152 stroke), of a good American make, with valves placed on the base of the cylinders and controlled by levers protected by a hood The motor works at 900 revolutions per minute;



The "Uncle Sam" tractor

it is furnished with a speed regulator and runs on paraffin, after starting for a few seconds with petrol. The motor has a 29 H. P. brake working at 26 to 27 HP, the consumption per HP, and per hour amounts to 0.40 litres with paraffin and 0.47 litres with heavy oil. working with paraffin is much more economical in the quantity consumed and in cost.

The motor is cast solid with the gears and gear box and is separate from the frame of the tractor.

The front axle, mounted on a joint and transvers spring has wheels 0.92 m.) in diameter, 0.15 m. width of rim and separated (track) 1.73 m. from each other.

The drying wheels (diameter 1.27 m., width of rim 0.30 m., track 1.07 m.) are fitted with angle pieces when working in fields. The track of the back wheels is narrower than that of the front wheels. The pressure of the wheels on the ground is very slight, viz., 26 kg. per cm. of width of rim of the front wheels and 20 kg. for the back wheels.

The forward speeds are about 4000 and 6000 m. an hour, and the reverse is 2800 m. an hour.

The wheel base is 2.17 m. The principal dimensions are: Length 3.65 m., width 1.89 m., height 1.60 m. The total weight, 2081 kg., is divided shus: — 807 kg. on the front wheels and 1274 kg. on the back wheels. This tractor is very interesting, like all those which can use paraffin, a more economical fuel than petrol.

665 - **Clearance and Upkeep of Firelines by Tractors.** — See No. 640 of this *Review*

666 - **Coupling Binders to Tractors.** — RINGELMANN, M., in the *Journal d'Agriculture pratique*, Year 84, No 27, pp 14-16, figs. 4. Paris, July 1, 1920; No 28, pp 33-35, figs. 3. July 8, 1920.

In principle the coupling of a binder to the tractor should be done in such a way that the man sitting on the binder, whilst seeing that the machine works properly so far as reaping and binding are concerned, can also guide the reaper in spite of any deviations in the horizontal plane which the tractor may happen to make, so that omissions in reaping may be avoided and the edge of the crop to be cut may be straightened.

When the tractor is only drawing one binder, these arrangements are not important, for the driver of the tractor quickly learns to guide the machine, to move it quite in parallel to the edge of the crop and at the desired distance from it; the long shaft of the binder *M* (fig. 1) is replaced by a shaft *Q*, about 2 m. long, coupled at *f* directly to the tractor and furnished, like the shaft, with a support and a connecting rod *h* for levelling the teeth of the blade. Special coupling arrangements are indispensable when reaping is done with 2 or 3 binders attached one behind another and all having to be moved to the side of the blade; lastly, in case of a breakdown in one of the binders, it is necessary to be able to put it out of the line without hindering the work of the binder attached behind it.

To obtain this result, the posterior end of the shaft is jointed to the structure of the reaper and binder, so that the angle, in the horizontal plane, made by the pole with the blade carrier, and consequently with the driving wheel, can be modified at will; at the same time, to avoid straining the structure of the binder, a traction bar joins the joint of the pole with the back of the binder frame and the posterior end of this bar takes the coupling of the pole of the next reaper and binder.

The principle of these mechanisms designed for reapers and binders applies also to mowers when two or three are drawn by one tractor. However, as all these machines (reapers and mowers) work to the side, the more their number is increased, the more the couple resulting from their attachment, which tends to make the tractor deviate, is increased; also turning becomes increasingly difficult when the tractor draws a greater number of harvesting machines, unless cutting is confined to the two long sides of the crop by turning in a large curve without cutting on the two short sides of the field widely cleared of the crop.

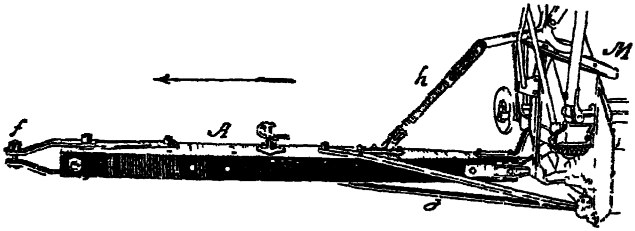


Fig. 1. — Coupling pole of a reaper and binder.

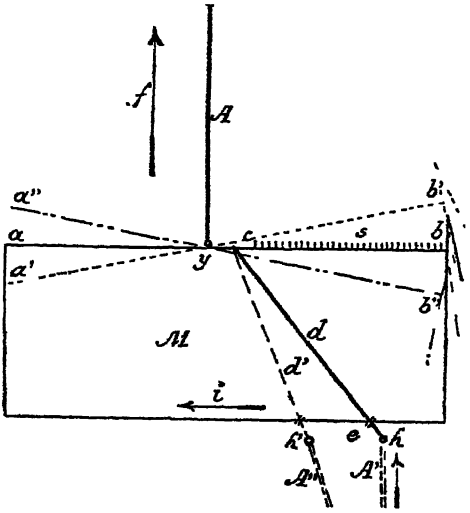

Fig. 2. — Steering of a binder attached to a tractor.

In relatively small fields the cost of taking a round-about turn for the use of several binders working simultaneously absorbs all the saving which might result from the work of 2 or 3 binders drawn by the tractor.

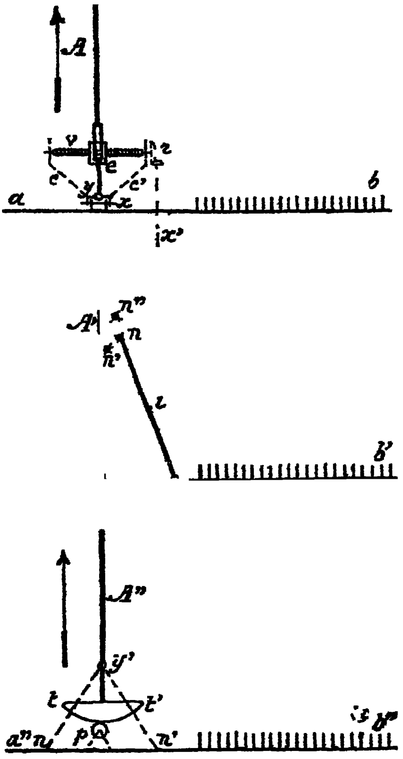

Fig 3 — Principle of some arrangements for slanting the pole of a binder.

With reference to fig. 2, representing diagramatically the horizontal projection of a binder *M*, cutting on the right, the blade carrier of which is situated on the transverse member *ab*, on which the pole *A*, pulled in the direction of the arrow *f*, is jointed at *y*, the angle *Ayb* may be considered. If by suitable means the driver decreases the angle *Ayb*, the transverse member *ab* takes the position *a'b'* giving the binder a tendency to turn to the left, thus diminishing the cutting length of the blade *S*. When the angle *Ayb* is increased the transverse member *ab* slants in the direction *a'b'* giving the binder a tendency to turn to the right, cutting over a greater width

In fig 2, the pole *A* is shown perpendicular to the transverse member *ab*, a position only used when a single binder is attached, for the 2nd and 3rd machines the pole *A* is always oblique and the angle *Ayb* is obtuse so as carry back the point of coupling on the to preceding binder from *h* to *h'*.

Various arrangements are used for altering the angle *Ayb* of fig. 2 while moving. Sometimes a horizontal screw *v* (fig 3) is used which can, in turning, move a nut fixed to the pole *A* jointed at *y* with the structure *cc'* shaped in an isosceles triangle jointed itself at *x*, in avertical plane, with the transverse member *ab* constituting the front cross-piece of the frame of the binder, the frame *cc'* carries the connecting rods which level the teeth of the blade The screw *v* is worked by the conical gearing *r* and the axle *x'* (1) turned either way by the driver of the binder.

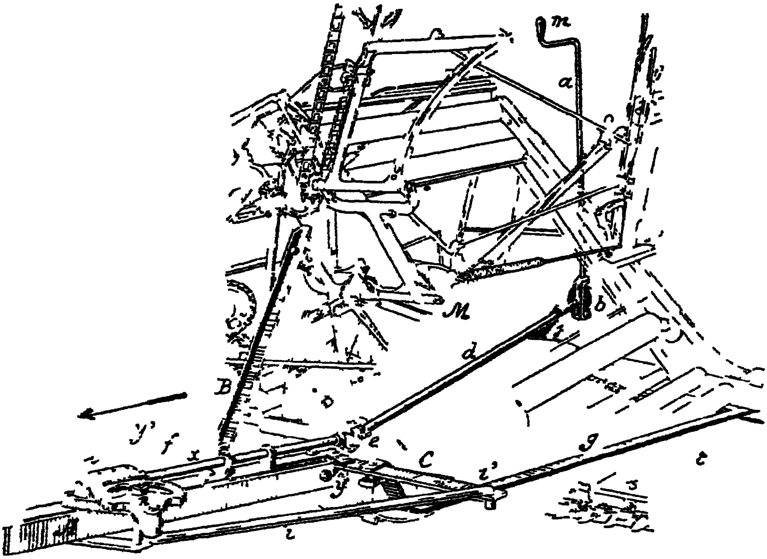

Fig 4 — Mac Cormick device

In other arrangements, there is an inextensible connecting rod *l* (fig. 3) jointed at *i'* to the transverse member *a'b'* and whose extremity *n* can move from *n'* to *n''* relatively to the pole *A'*

In other cases, the posterior end of the pole *A''* carries a toothed sector *tt'* which can turn a pinion *p* whose axis is fixed to the transverse member *a''b''* ; in this case the pole *A''* pivots round the axis *y'* (geometric axis of the sector *tt'*) attached by the frame *ny'n'* to the transverse member *a''b''*

Lastly (fig 2), an oblique traction bar *d*, held in front by the cross piece *yc* and behind, on the structure of the binder by a hook *e*, takes, at *h*, the coupling of the pole *A'* of the next binder, which is drawn by this bar *d* and not by the frame of the machine *M* ; however, owing to the obliquity of the bar, the crosspiece at the back of that structure has a tendency to be displaced in the direction of the arrow *i* by putting the horizontal frame of the platform out of shape. This force *i* is reduced by moving the bar to *d'*, consequently the point of coupling *h* to h', and by the slanting, in the direction A', the pole of the binder attached behind the machine *M*.

---

(1) This arrangement is found in the Massey-Harris mechanism, 138, Avenue Jean Jaurès, described in the *Journal d'Agriculture pratique*, No 12, p 2297, 1920 (*Author*)

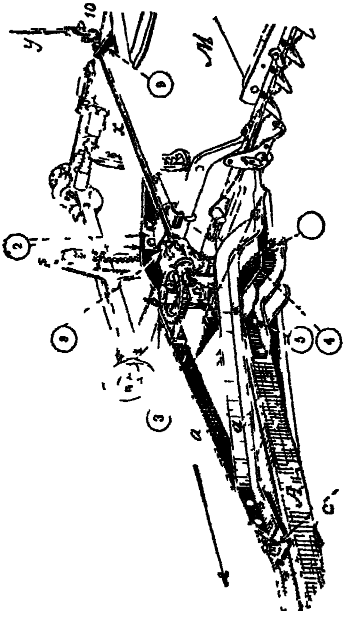

Fig. 5 — Deering mounting

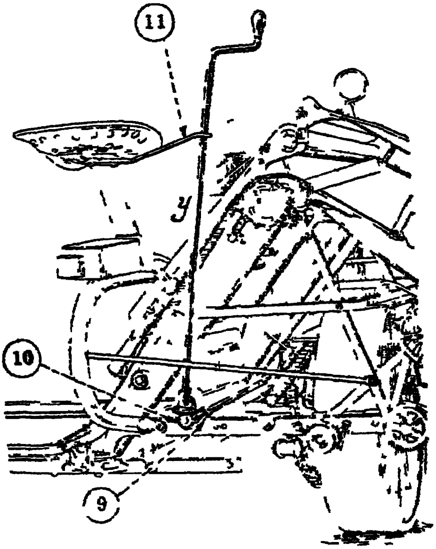

Fig 6 — Back view of a Deering reaper and binder, with the steering handle

In the Mac-Cormick apparatus, of R. Wallut & Co. (168 Boulevard de la Villette, Paris) shown in detail in fig. 4, the pole *A* is jointed at *v* with the front of the frame of the binder *M* (in the plan on the left) a portion of whose blade carrier is seen at *s* The balance of the binder *M* in a vertical plane parallel to the driving wheel is ensured by the angle-iron *B* ; the latter is jointed below to the pole *A* and above to a crank which moves the levelling lever allowing the platform *t* to be inclined and the teeth of the blade carrier *s* to be brought nearer the ground, to a greater or less degree, so as to alter quickly the position of the blade and the height of the cutting.

The crosspiece *C* being fixed to the structure of the binder, steering is obtained by altering the horizontal angle which the pole *A* makes with the crosspiece *C*. For this purpose, the driver has within reach the crank *m* of the vertical axle *a* which, by means of a bevel gear *b* (pinion controlling a wheel) moves the slanting axle *d*, the cardan joint *e* and the shaft *x*, the front end of which carries an endless screw (covered by the plate *v*) which controls the toothed sector *n* which can turn on the shaft *y'*; the sector *n* carries a crank stud *f* to which is jointed the connecting rod *i*, the end *i'* of which is in turn jointed to the crosspiece *C*, that is to say to the structure of the binder; the horizontal movement of the point *f* alters the angle *Ayi'*, and consequently the plane of the driving wheel of the binder relatively to the pole *A*.

The support for the shaft *d* is seen at *j* (fig. 4), and *g* is the slanting bar attached to the front crosspiece *C* for transmitting the tractive force of the pole *A* to the next binder.

In the DEERING mounting, of the Compagnie Intrnationale des machines agricoles (155, Avenue du Général Michel-Bizot, Paris), the principle indicated at *A''* in fig. 5, is used. The crosspiece in front of the binder *M* (fig. 5) is fitted with the triangle *a*, 3, 2 made of angle iron carrying at *c* the vertical axis of the joint of the pole *A*, the end of which is fixed to a toothed sector 4, 7, kept in place by the bolts 5. The sector is moved by a pinion fixed to the wheel *b* driven by the endless screw *v*, the cardan 8, the shaft *x*, supported at 9 and ending in conical gearings 10 which transmit the movement from the vertical axle *y*. The latter is seen again in fig. 6 which gives the back view: the shaft *y* with crank *m* is supported by the cross bar 11 bolted to the seat pillar.

The arrangements described above are applicable when it is desired to attach 2 or 3 binders (or mowers) to one tractor; when only a single machine is used, a simple pole suffices.

667 - **Regulating Double Brabant Ploughs.** — RINGELMANN, M., in the *Journal d'Agriculture pratique*, Year 85, No. 6, pp 114-116, figs. 3. Paris, 12, Feb. 1921.

The stability of the double brabant plough, for given dimensions of the strips of soil ploughed, is effected by the correct position of the furrow wheel and of the yoke hook.

With reference to figure 1, which illustrates the principle of the support of a double brabant plough, with the lifting mechanism at *y*, the axis of the beam is shown at *o*, the wheels *R* whose plane of rotation is on *gr* the rings or washers *b* placed on either side of the hub of each wheel, the lengths *u* and *u'* of which are unequal on each side so that the wheel may be turned round on its spindle, a condition which entails the use of wheels other than the carriage type and bad lubrication of the naves, which cannot be kept suitably oiled.

For a given depth of ploughing, *mr* (fig. 1) and a width *l*, the rim of the wheels *R* should run in the angle formed by the face *mr* with the bottom of the furrow, the yoke hook being arranged to give the plough a slight tendency to go wide; on the other hand the plane of the supports should be perpendicular to the surface *gl* of the ground, and as the wheels run alternately on the fallow and in the furrow, the distance between them *E* or the lenghts *a*, *n*, and *d*, are thus determined by the dimensions of the strip of soil to be turned over

If the depth of ploughing is modified, by altering the height *h* of the beam above the axle, by adjusting the lifting mechanism *y* (or of a lever in the other model), it is necessary, to ensure stability, to modify the distance *E* between the wheels by using the washers *b* which are moved with reference to the nave.

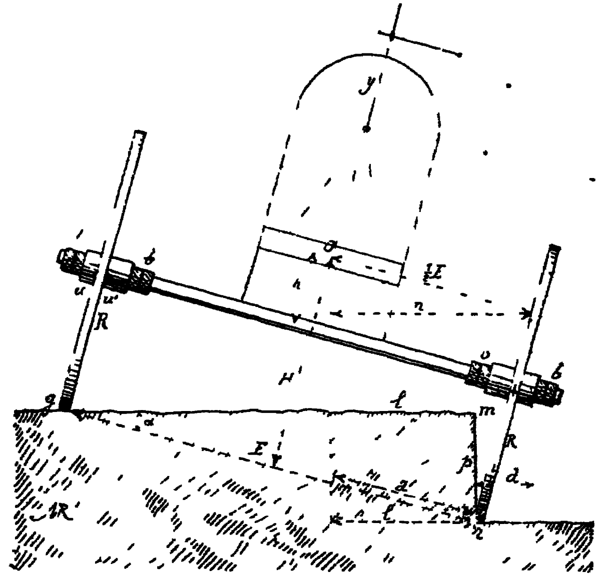

Fig 1 — Front view of the support of a double brabant plough with a lifting mechanism

In regulating the double brabant the ploughman makes successive tentative alterations He first tries to regulate the depth, then he brings the plane of the supports into position (that is to say he modifies the angle *x* of fig. 1), so that it is perpendicular to the surface of the ground, by moving the catches into which the bolt fits which fixes the beam to the support; he next regulates, by means of the washers, the position of the furrow wheel so that its rim rubs lightly, but constantly, the bottom of the face of the furrow; lastly he alters the yoke hook so that the furrow wheel may run under the conditions indicated above. Often the ploughman does not take care in regulating and exaggerates the pressure of the wheel against the face of the furrow, thus increasing the traction effort on the team.

After these adjustments, the double brabant is regulated for one side of the plough; returning in the next furrow the ploughman makes similar adjustments for the other side of the plough

In consequence of tests made by the author in 1896 (*Journal d'Agriculture pratique*, 1896, Vol. I, p. 902) showing that the bad state of lubrication of the wheels caused rapid wear of the spindles, wheels with grease boxes (called " demi-patent ") were made, mounted on an axle in two pieces so that the wheels could be symmetrically separated or brought nearer each other as required. The author also says that the rims of the wheels should be made of iron with a semi-elliptic section in order to increase the stability of the plough by decreasing the resistance of the wheel to traction.

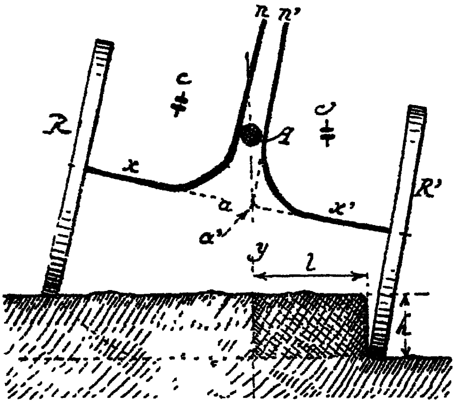

Fig. 3. — Louis Champonnois device for regulating double brabants.

In the device suggested by Louis Champonnois, agricultural engineer, of Villiers-le-Sec par Ceully (Calvados), modification in the depth of ploughing acts automatically on the distance between the wheels supporting the double brabant.

The wheels *R* and *R'* (fig. 2) are mounted at the ends of bent axles *xn* and *xn'*; the arms *n* and *n'* are fixed to the catches indicated schematically at *c* and *c'*. in which fits the bolt which fixes the beam *A* relatively to the wheels; in figure 2, the plane of the supports is shown at *y* and the beam *A* is at such a level that the plane of action of the ploughshare is at ground level *s*, that is to say that the plough, which is not working, is arranged for placing on its transport waggn. The wheels *R* and *R'* are inclined about 10 degrees from the vertical; the prolongations of the arms *n* and *n'* to intersect the prolongations of the axles *x* and *x'* meet them at *a*.

Figure 3 shows the position of the parts, previously referred to, when the depth of ploughing is *h* and the width *l*, *y* being the plane of the support perpendicular to the surface *s* of the fallow; the correct position of the two wheels *R* and *R'*, the furrow wheel having to keep always touching the face of the furrow so as to assure the stability of the plough, is obtained by separating the points *a* and *a'*, the beam *A* then being nearer the ground *s* by a distance sufficient to give a depth of ploughing *h*. By working the lifting mechanism the points *a* and *a'* are made to separate from or approach one another in such a way that the distance between the wheels *R* and *R'* is thus automatically regulated, which ensures the maintenance of the plane of the supports on the line *y* perpendicular to the surface *s* of the ground without any need of altering the position of the catches *c* and *c'*.

The lifting mechanism can act either by bringing the ends of the arms *n* and *n'* nearer to each other, or, which seems simpler, by separating the points *a* and *a'*.

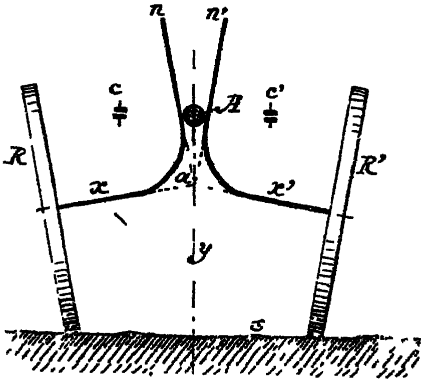

Fig 3 — Front view of a double brabant at work, fitted with the CHAMPONNOIS support.

668 - The Marciandi-Porta Rotary Digger. — TARCHETTI, A., in the *Giornale di Risicoltura*, Vol XI, No 1, pp 5-13, 5 figs Vercelli, Jan 31, 1921

The working of this machine, which the author has tested on several occasions in the field, is cinematic and similar to that of ordinary rotary tillage machines The digging part or spiked-beam, is composed of 4 pairs of spades mounted on the same horizontal axle in the form of hoods and digging a total width of 1.60 m., the digging wheel is raised (for turning and travelling by road) and lowered by means of a lever, which also regulates the depth of digging, within certain limits determined by the diameter of the digging mechanism.

The appended figures show how the digger is attached to the tractor and how the spades work

Each spade is composed of 2 flat, vertical, steel blades, scythe shaped with the concave part cutting; to each of them is fixed, at right angles to the convex edge, another curved blade which does not end at the point of the beak but a little behind it, where it has a retreating and cutting edge: each spade is therefore composed of two halves, each composed of 2 cutting edges one of which cuts the ground in a direction parallel with the direction of the tractor and the other transversely. As the 2 flat blades are 40 cm apart (width of clod), and as the curved blades each project 15 cm., there remains between the latter a space of 10 cm. corresponding to which the earth is not cut by the blades but is torn up owing to cohesion with the rest of the clod already cut. This space is required to give room, at the middle of the halves of the spade for support to a kind of screen or diaphragm (on the right in fig 1) fixed to the frame of the machine and intended to stop the clod of earth cut and lifted by the spade in its rotation and to cause it to fall back turned over when it is separated from the spade

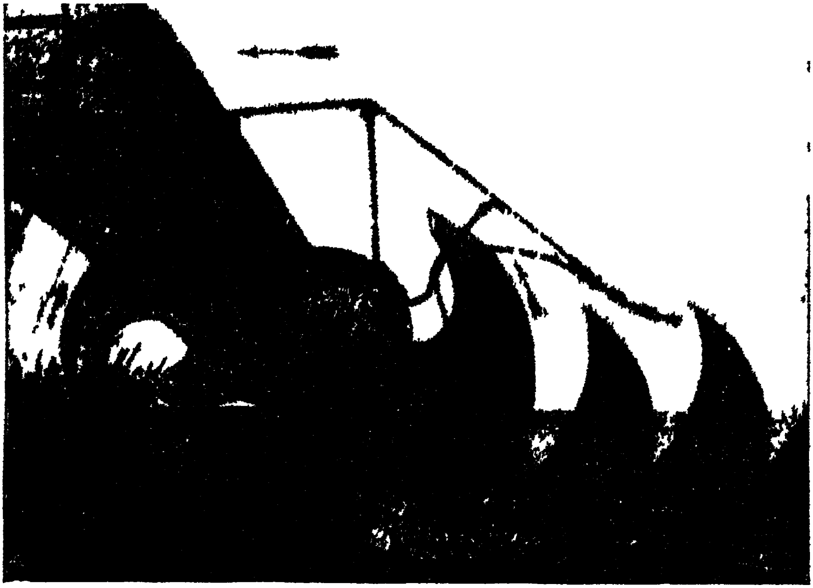

Fig 1. — Section of the MARCIANDI-PORTA rotary digger (one of the flat blades has been removed from the hind spade to show inside the clod of earth at the moment when it touches the screen.

Fig 2 shows diagramatically how the spades work when the tractor advances and the digging mechanism revolves; below is seen the shape and the arrangement of the clods dug up and the numbers indicate the clod turned up by each spade during one complete revolution and also the succession of clods which are, one after another, cut, raised, turned over and thrown down, so to speak, on the bottom of the furrow.

Of course, the convex part of the vertical blades, and consequently the curvature of the blades at right angles, is arranged so that the latter remain constantly, while penetrating the soil, in the groove made by their cutting edge, that is to say they neither compress nor detach the soil, in spite of the forward movement of the tractor.

The same is true for the spade, which is not fixed rigidly on the moving axle, as is seen in Fig. 1, but is placed at the end of an arm fixed to that axle, so that the spade, guided by rollers working in the neck of an eccentric fixed on the frame, accelerates and anticipates the turning over and fall of the clod without interfering with the work of the next spade.

The pace of the tractor and the speed of rotation of the spades must be correlated and governed by the size of the spade. In the machine tested it was ascertained that the spades worked best with clods 40 cm. wide and 18 cm. long ("step" of the spade), that is to say, when the two spades of a pair cut a piece of soil 36 cm. long at each revolution of the digger; so that if the latter makes about 44 revolutions a minute (the normal working pace), the pace of the tractor would be 0.36 metres × 44 = 15.84 metres per minute. With 4 pairs of 40 cm. spades, or a width of 1.60 metres, the machine would consequently dig 15.64 sq m. × 60 × 1.60 = 1500 sq. m. per hour, say, allowing for loss of time in turning, etc, rather more than 1 hectare per day. This new digger proved in trials that it could do perfect cultural work in various kinds of ground-grass land, old ricefield, etc.

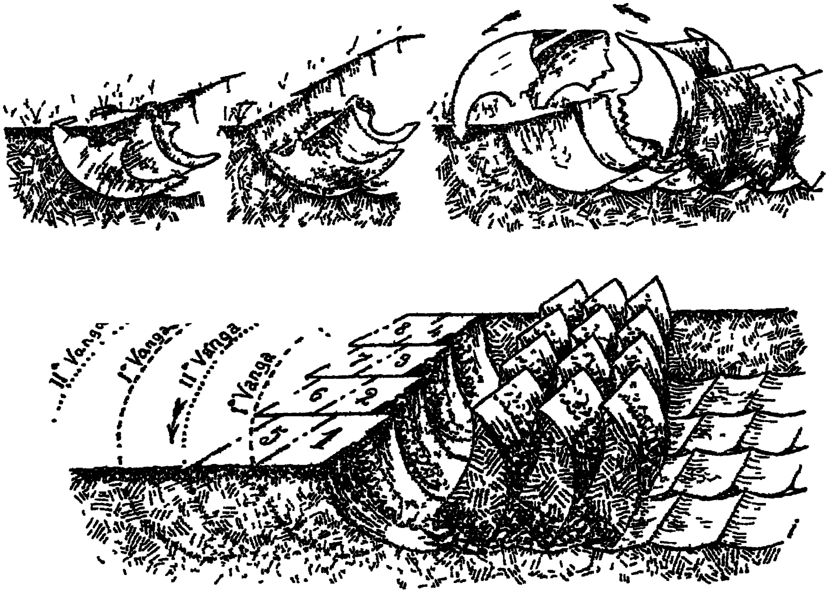

Fig 2 — Sections showing how the spades work *Above*, the process of work of one spade, *below*, the process and effect of work of the 8 spades of the digging mechanism.

The output of this machine is not high, but it could be increased by increasing and enlarging the digging mechanism. It has the advantage of being capable of working to the right or to the left and also of being able to work in the softest and moistest soils, etc.

669 - A Combined Dodder and Plantain Seed Eliminator and Threshing Machine. —

MANRIN G., in the *Journal d'Agriculture pratique*, Year 85, No. 15, pp. 293-294, figs. 1. Paris, Apr. 16, 1921.

Before high-speed threshing machines (which date from 1889) came into use, the cleaning of fodder seeds was done by hand, or, rarely, with a small special machine, the chaff then being passed on to the chaff separator; but, between the two operations it was not noticed that certain weed seeds, such as dodder and plantain, were, so to speak automatically eliminated owing to their shedding their seeds very easily relatively to the shedding of seed by the forage plants.

With highpower threshing machines constructed for forage seeds, effecting consecutively the various steps of cleaning, the weed seeds were not eliminated and it even happened that the machine exercised a disastrous selection by leaving among the seeds of the fodder plants the large seeds of dodder and plantain.

G. DUVAL; 46, Boulevard Gambetta, Saint-Quentin (Aisne), having noticed how easily parasitic plants shed their seeds as compared with forage plants, constructed a machine for eliminating dodder and plantain seeds, in the form of a sieve in the shape of a truncated cone through which he passes the chaff before cleaning it.

DUVAL's machine for eliminating dodder and plantain seeds was then tested by RINGELMANN at the machine testing Station; 12 series of tests were carried out on chaff of various origins (lucernes from the Aisne, white and violet clovers from the Aisne, crimson clover from Vendée, " minette " of the Aisne) and the produce was examined at the seed testing Station. The results were considered excellent. At that time it was a separate machine through which was passed the product furnished by the first thresher; it eliminated all the seeds of parasitic plants and the residue had to be passed on to a second thresher.

DUVAL now presents his dodder and plantain seed eliminator mounted on a high speed threshing machine. The dodder eliminator is placed at the back below the shakers, and receives the produce passed on by the chaff beater, removes the dodder and plantain seed and then feeds the cleaner which is placed below; the latter thus only receives and has to deal with the chaff completely freed from the seeds of dodder and plantain.

According to the construction of the threshing machine, the dodder eliminator may occupy other positions, but it must always be placed immediately in front of the cleaner which it feeds with chaff freed from parasitic seeds.

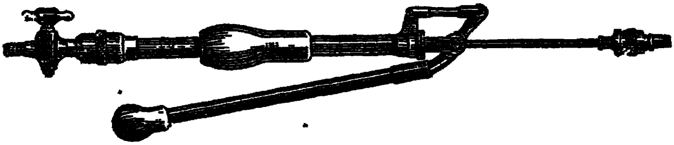
With this system the seed of forage plants furnished by the thresher sells at an enhanced rate which may amount to as much as 15 and 20 % owing to the difficulty that is found in separating dodder and plantain seeds that are mixed with seeds of forage plants, from which only the smallest of these parasitic seeds are eliminated, leaving the larger ones mixed with the seed used by the farmer.

670 - **The "Pax" Sprayer.** — L. D., in *Le Progrès agricole et viticole*, Year 38, No. 20, pp. 477, figs 1. Montpellier, May 15, 1921.

It is well known that with ordinary sprayers, even with the best, too much of the liquid is wasted in spraying bunches of grapes, and it can be understood that, when it is a case of using an expensive solution, such as that of nicotine, there is some hesitation in giving the treatment on the grounds of expense.

The " Pax " sprayer effects a great economy of the liquid. From its powerful jet an excessively fine spray is emitted which envelops the whole grape and is deposited all round it.

The apparatus consists of a tubular brass body (cylinder of the pump), with a wooden handle in the middle; at one end of the body there is the jointed fulcrum of the lever of the pump, at the other end the suction valve with its sieve and the cock to which fits the indiarubber tube connecting the " Pax " sprayer with the receptacle carried on the back of the operator. The pressure is obtained by means of a hollow-stemmed piston moved by the lever. This piston communicates directly with a nozzle fitted with a compression valve.



The " Pax " sprayer.

The apparatus is very simple; all parts are easily got at. Although the spray is emitted under a pressure of 20 atmospheres, almost 10 times that of an ordinary sprayer, the apparatus works very smoothly and the lever can be worked by a woman.

The " Pax " sprayer can be used with receptacles of any kind of sprayer without modification of those receptacles.

AGRICULTURAL INDUSTRIES

671 - **Seed Oil Production in Egypt.** — MILAD, Y. E. (Moâwen, Horticultural Section Ministry of Agriculture), in *The Agricultural Journal of Egypt*, Vol. X, pp. 21-40. Cairo, 1920.

I. COTTON SEED. — The lint of Egyptian cotton seed does not adhere tenaciously to the seed as is the case with American Upland cotton seed or Bombay seed. For this reason it can be stored and transported for long distances without damage caused by heat, and can be crushed and pressed after delinting, without the necessity for reginning or hulling machines.

The author reviews the general distribution of the cotton seed industry throughout the world and states that Egypt exports annually about $^3/_5$ of its cotton seed to Europe, and retains the rest for sowing and for the oil industry. From a calculation made for the 5 pre-war years, 1910 to 1914, the following figures were obtained:

The average annual yield of cotton seed was.	5.217.000	ardebs *
» » export » »	3.571.000	»
Seeds left in the country	1.646.000	»

The seed is pressed in Egypt without decortication.

Details are given of the method of extraction employed. Experiments made in the estimation of oil contents show that neither locality nor variety affects to any great extent the percentage of oil. A number of samples were analysed with the object of ascertaining if there is any difference in the percentage of oil due to local conditions, and this confirmed the above statement. It is worthy of notice that the pink bollworm's attack on the Egyptian cotton has resulted in diminishing the percentage of oil in seed of all varieties. It is also said that the pink bollworm affects the quality of the oil, and this is now under investigation by the Ministry of Agriculture.

The average yield of oil from the cottonseed in present-day markets according to HUGHES, varies from 20 to 24 %.

The most important by-product is the oil cake: the residue after the expression of the oil. This, which as already mentioned, is always taken from undecorticated seed, had the following composition :— Analysis made in 1917. % — moisture 12.86; fibre 22.86; soluble carbohydrates 33.54; proteids 21.08 (containing 3.37 % nitrogen); oil 4.70; ash 4.96. This cotton cake is therefore without doubt a valuable feeding stuff for cattle. The use of the said material as a cattle food or as a fertiliser is not yet practised largely in Egypt; and is worthy of attention on part of the farmer and cattle breeder.

In addition to its culinary uses (1), cottonseed oil is now largely used in the manufacture of soap, both in the crude and refined state, also in the manufacture of candles, glycerine, etc.

FLAX. — The author gives details of the methods of extraction of linseed oil from the seeds of *Linum usitatissimum*. The oil extracted from fresh seed is sticky and turbid; hence, as a rule, seeds are pressed when 2 to 6 months old. Apart from its use as a food, from the industrial point of view it is extensively used in painting on account of its drying properties, and in the manufacture of oil varnishes, printing ink and artifical india-rubber. Boiled linseed oil mixed with powdered cork is employed in making linoleum or floor oil cloth.

Linseed oil cake is used by the Egyptian farmer for feeding milking cows and buffaloes. It has the following composition, which shows that it is very rich in proteids and fat; % — moisture 10.33; fibre 9.42; soluble carbohydrates 35.55; proteids 28.78; fat and oil 8.94; ash 6.98.

---

* 1 ardeb = 121 kilos (1 ton = 8.3 ardebs approx.).

(1) See *R.* June 1918, No. 663 and *R.* July 1918, No. 784. (*Ed.*)

[671]

SESAME (*Sesamum indicum*). — Although Egypt used to cultivate large areas of sesame, these areas have decreased gradually with the growth of cotton cultivation and the yearly average is now limited to 7000 *feddâns* (1 *feddân* = 1.03805 acres), which is not sufficient to meet the demands of the native mills.

The methods of extraction are given, and a description of the various uses of this oil. The crop is exclusively used for oil extraction, owing to its richness in oil.

The sesame oil cake has lately been used experimentally as a fuel owing to the coal scarcity, and is said to be equal to coal in heating power. On account of its comparatively high price it is however rarely used for this purpose or for feeding cattle. When unsound seeds are pressed it is unsuitable for this latter purpose.

GROUNDNUT (*Arachis hypogea*). — The average yield per *feddân* is 10 *ardebs* (750 kilos), and, according to the data for 1918, the total area under cultivation was 14 614 feddâns, compared with 11 512 feddâns in 1914. Apart from its use in soap making, it is also utilised in lubricating machinery, holding the second place to olive oil.

SAFFLOWER (*Carthamus tinctorius*). — An annual plant cultivated as a dye and oil-producing crop. It is widely cultivated in Upper Egypt, but less plentifully in lower Egypt, and is often sown only on the edges of fields. It is grown as a catch crop with wheat, barley and lentils in the provinces of Girga and Quena. The seed contains from 30 to 32 % of oil, and in the native presses 1 *ardeb* gives from 50 to 55 *rotls* of oil (1 *rotl* = 0.99049 lb.). The husk forms about 60 % by weight of the seed.

The seeds are pressed in the same way as the linseed, except that the husks are separated by means of sieves after seed crushing. The cake " bokma " is used for feeding cattle and as fuel. The oil dries easily and makes it fit to replace linseed oil in some cases.

Amongst the minor crops grown for oil purposes are mentioned: — lettuce (*Lactuca sativa*), poppy (*Papaver somniferum*), wild mustard (*Sinapis arvensis*) and salgam (*Brassica napus oleifera*), and on a small scale, sunflower (*Helianthus* spp.), castor bean (*Ricinus communis*) and fennel (*Nigella sativa*).

The author gives a brief historical description and the general geographical distribution of the various plants under consideration.

672 - **" Malafu " or " Lagmi," from the Palm in the Belgian Congo and in Southern Tunis.** — I. VAN DERYST, R. P. H., Le vin de palme ou "malafu" in *Bulletin agricole du Congo belge*, Vol. XI, Nos. 3-4, pp. 219-224. Brussels, Sept.-Dec 1920. II. MARCAILHOU D'AYMERIC, M. A. (pharmacien aide-majeur de 1ère classe à Gabès, Tunisie), Analyse d'un vin de palmier ou " laghmi " du Sud Tunisien, in *Journal de Pharmacie et de Chimie*, Year 113, Pt. 7, Vol. XXIII, No. 7, pp. 272-273 Paris, April 1, 1921.

I. — In the Belgian Congo the so-called " malafu " wine is the fermented sap obtainable from certain palms, including *Elaeis*, *Raphia*, *Borassus* etc. indigenous or otherwise. The varieties utilisable for this purpose are fairly abundant and the sugar palm *Arenga saccharifera* stands in the forefront.

The said sap is usually found in large quantities; the composition is variable and of a complex nature but with a high sugar content and that obtained from *Elaeis* contains as much as 80 gm. and more of sugar per litre of sap. This is nearly all transformed into ethyl alcohol at the end of 24 hours, following the spontaneous fermentation process. The fermentation of " malafu " facilitated by the high temperature prevailing in the Congo (average about 25° C) may in all probability be attributed to a variety of *Saccharomyces cerevisiae* Meyen. When at the highest degree of fermentation, " malafu " is in current use amongst the Europeans as a substitute for yeast, in the manufacture of bread. The liquid is whitish, thick, sparkling and has a luscious and a sour taste, slightly alcoholic. When fermentation is complete, the juice contains 4 to 4 ½ % and even as much as 5 to 5 ½ % alcohol and scarcely 1 % sugar. The fixed acid content is found to be nearly always equable, regardless of the degree of fermentation. The total acidity (fixed and volatile acids) is about 48^{m} per litre.

The methods employed to collect the liquid from *Elaeis* are varied: 1) cutting the peduncles of the males; 2) making an incision in the trunk at the base of the males or at the base of a leaf; 3) cutting down a tree and slitting the terminal shoot.

Whatever may be the method adopted, the extraction of the sap is always injurious to the trees and death is the almost inevitable result in the case of *Borassus* and *Raphia*. Other species such as *Elaeis* prove more resistant, but growth is hindered and there is likely to be a diminution in productivity. Often they have remained sterile for several years. Efficacious measures are therefore evidently essential to prevent the natives chopping the palms in order to obtain " malafu," taking into account their high commercial value.

II. " Laghmi " is obtained from the sap of a vigorous growing tree, and when ready for " ponction " as much as 7 to 8 litres per day for more than one month has been collected. When the quantity obtained is considered adequate, the incision is filled with scraps of vegetation and soil; water is given to the palm is considerable quantities and at the end of a year, normal vigour should be regained.

" Laghmi " has the appearance of an opalescent liquid, resembling orgeat syrup and possesses an agreable taste like sweet wine. It may be kept for several months in sealed bottles, but the natives use it up very rapidly, often even before fermentation. After some months, an amylaceous deposit is left, which may be tested with iodine; the acid content is raised and the gum residue is converted into sugar by the powerful acids.

An extract of 100 gm. dried at 100° C gives 10.5 gm. with ash 0.20 gm. containing potash, soda, lime, traces of phosphates, chlorides, traces of iron and manganese.

Average Composition of " Lagmi " as a result of Analyses made by the author at Gabès (Tunisia).

Density	1.0295
Water	82.00 %
Alcohol (after 8 days)	4.50
Total acidity in H_2SO_4	0.70
Volatile acidity (CO_2)	0.22
Glycerine	2.00
Reduction sugars	0.20
Gums	3.00
Mineral substances	7.00

The extract obtained by evaporation of 100 gm. is partially soluble in alcohol. The portion which remains insoluble has the aspect of molasses and apparently consists of sticky and sweet substances. The soluble sticky elements in boiling water are reprecipitated by alcohol and give the characteristic reaction with fragments of iron.

" Laghmi " is therefore a liquid very liable to fermentation but it is chiefly utilised whilst fresh.

673 - **Vinegar from Cereals and the Vinegar Industry in Italy.** — I. MEZZADROLI, G., La fabbricazione dell'aceto dei cereali, in the *Bollettino dell'Associazione Italiana delle Industrie dello Zucchero e dell'Alcool*, Vol XIII, No. 10, pp 137-142. Bologna, Jan. 1921. — II. IDEM, Divagazioni sui fermenti acetici, *Ibid.*, Vol XIII, pts. II, pp. 160-163, Feb., 1921. — III LICITRA, G B., Fabbrichiamo aceto ma di vino, in *L'Italia vinicola ed agraria*, Vol. XI, No 8, pp 117-118. Casale Monferrato, Feb. 20, 1921. — IV. MARESCALCHI, A , *Ibid.*, No 9, pp. 129-130, Feb 27, 1921.

I. II. — Prof. MEZZADROLI has visited a factory at Taverney (Seine-et-Oise, France) where vinegar is made from cereals and he urges Italian manufacturers to try this industry in view of the fact that wine is very dear and that vinegar made from alcohol or other substances lacks fragrance and strength. He is of opinion that the vinegar made at Taverney from rice, maize, millet, etc., is just as good as the best table vinegars; it has a rich aroma and resembles vinegar made from Madeira or Marsala.

The conversion of the cereals or other starchy substances into sugar is effected by *Mucor* No. 5 BOULARD, introduced by BOULARD into Europe from Indo-China, where the Annamites have used it empirically for centuries in making rice vinegar. Each cereal used gives its special aroma; the finest is rice vinegar, followed by maize vinegar and, lastly, vinegars made from millet and cassava.

Process of manufacture. — Steeping for 2 hours at a temperature of 50°-60° C. in an 8 per 1000 solution of hydrochloric acid; cooking for 40 to 60 minutes under pressure of 4 kg. to a concentration of 25 % (that is to say 25 kg. of grain to a volume of 1 hectolitre). The whole is then poured into a fermentation vat (made of iron, and sterilised); cooling of the vat to 40° C.; sowing of spores of *Mucor* No. 5 BOULARD; when the must contains 20 to 40 gm. of sugar per litre the yeast *Mycoderma acetosum* BOULARD (which is an oriental ferment capable of acting at a high temperature) is sown. As soon as alcoholic fermentation is finished (that is to say about 3 or 4 days after the *Mucor* is sown), filtration is carried out in a wooden pressure filter and the liquid is distributed in the acetic fermentation vats. The temperature during this latter fermentation which last for 15 days must be maintained at 25°-28° C.

The dregs are used as food for livestock. Before sale the vinegar is filtered a second time.

The alcoholic yield (per quintal) is from 37 to 38 litres from maize, 43 to 44 litres from rice and much more from cassava. A quintal of maize gives 360-370 litres of " wine " (containing about 10 % of alcohol) ready for acetification. The vinegar contains about 8 % of acetic acid, which is very high. The apparatus required consists of :— Boilers, vats for steeping the maize, rice, millet, etc., one or more iron pots for the cooking, one or more pressure filters, the usual apparatus for acetification, an air compressor for aerating the vats, and a trough for sterilising the air before it passes into the vats.

II. — Dr. G. B. LICITRA thinks that it is much more profitable in Italy to make vinegar from wine than from cereals or any other raw material in view of the fact that wine gone sour is easy to get everywhere at a price less than that of vinegar and that it produces an incomparably better vinegar both as to flavour and food value. To prove how easily a greater production of vinegar would find à market in Italy, he recalls that the pickled eel industry alone uses 300 000 hectolitres of vinegar a year.

As a model factory where wine vinegar is exclusively made, the author describes that of C. BAULINO at Casale Monferrato. The process of manufacture there adopted consists of :— Analysis and pasteurization of the wine; blending; acetification by selected ferments; depuration (left to settle for at least 3 months); filtration. Two kinds of vinegar are produced, the common kind containing 4 % of acetic acid and a fine kind containing 7 %.

IV. — In Italy vinegar is also manufactured from alcohol; in 1920, 6700 hectolitres of anyhdrous alcohol were so treated.

Acetic acid, which is almost entirely of foreign origin, competes closely with the national vinegar industry.

674 - **Experiments Made in the United States on the Dry-Air Sterilisation of Dairy Utensils** (1). — AYERS, S. H. and MODGE, C. S, in *Journal of Dairy Science*, Vol. IV, No 2, pp 79-90, Tables 6 Baltimore, 1921.

The authors, with a view to testing the possibility of applying to the practical dairy-industry the process of sterilising by means of a current of hot air, carried out experiments for the purpose of determining the temperature of the heated air and the length of time required to sterilise (2) milk-cans at farms, and also in places like dairies, where the sterilisation process must be continual.

---

(1) See MOAK H., Dry Sterilisation of Dairy Utensils in *Hoards' Dairyman*, 1920, No. 5, pp. 274-288 (*Authors' note*) See also *R.* Nov 1917, No 1074, *R* March 1920, No 364; *R.* Oct. 1920, No 1036. (*Ed*)

(2) Destruction of non spore forming bacteria, of *B. Coli* and of heat resistant lactic bacteria. (*Ed.*)

Taking as a basis the data of preliminary experiments made in the laboratory which showed theoretically that good results seemed likely to be obtained in sterilising dairy utensils, especially since the temperature for the purpose could be kept below that used in the preliminary experiments (1), the authors proceed to sterilise milk-cans.

Three milk-cans of the capacity of 3.8 litres which had contained sour milk, or cream were used. In order not to destroy the bacteria, they were washed in warm water at 45° C. without soda. Two of the cans were then exposed for 15 and 30 minutes respectively to a current of air heated to 110° C. The third can served as a control. Six minutes was necessary to raise the temperature to the required height. In fact, thorough sterilisation could be effected by exposing the milk-cans for 30 minutes to the current of hot air, 15 min. however did not give satisfactory results, as is shown by some figures taken from the table giving the details of the experiment. Thus, the number of bacteria per milk-can rose respectively to 1 400 000 000 — 1 570 000 000 — 3 111 000 000 in the control cans; to 800 — 1500 — 4200 respectively in those heated for 15 minutes, where as in the case of the milk-cans heated for 30 minutes, the number had greatly decreased, being only 200 — 200 — 400 respectively.

While heating in this manner up to 110° C. amply suffices for the sterilisation of all dairy utensils used in farms, it is not enough for continued sterilisation, such as is practised in dairies, or where a large number of milk-cans have to be sterilised in a short time. The authors tried to shorten the duration of the action of the hot air current by raising the temperature in the cans to 120 — 130 — 140° C respectively. The milk-cans, which were of a a capacity of 3.8 litres, were subjected to the same treatment as in the previous experiments.

The best results were obtained by raising the temperature of the milk-cans from 44.4° C. (after washing), to 142.2° C., and by exposing them to this temperature for 2 minutes. Then, the number of bacteria varied between 100 and 700 per milk can.

CONCLUSION. — Sterilisation by means of a current of hot air is applicable to dairy utensils. How to render the process industrially practicable is a question of technique and expense.

675 - Micro-organisms Persisting in Milk after Pasteurisation; their Rôle in the Decomposition of Hydrogen Peroxide. — FOUASSIER, M., in the *Comptes rendus de l'Académie des Sciences*, Vol 171, No 5, pp 327-326. Paris, Aug 2, 1920.

In continuation of his previous researches (2), the author has ascertained that hydrogen peroxide, added after pasteurisation, has an antiseptic action with regard to the lactic ferments which milk picks up during the varying period of time which precedes its consumption. That action is all the more prolonged when the milk is protected from dust bearing

---

(1) The absolute thermal death point of all cells (*Ed*)

(2) See *R*, Oct 1920, No 1035 (*Ed*)

B subtilis or *Tyrothrix*, such as is found in cowhouses. The spores of these germs, being resistant to pasteurisation, can consequently grow in the milk, by their catalytic properties they contribute in a large measure to the total decomposition of the hydrogen peroxide, when this antiseptic is used ; moreover, they hasten the development of lactic ferments by providing them with a more easily assimilable element, owing to the peptonnising action which they exert on the albuminoids of milk.

676 – **The Storage and Curing of Mandarin Oranges at the Batangas Commercial Citrus Station, Philippines.** — DE LEON, J., in *The Philippine Agricultural Review*, Vol. XIII, No. 3, pp. 214-216 + diagr. 1, pl. 1. Manila, 1920.

A storage chamber consisting in a vault dug into a hillside, about 6 ft. high and 10 ft. square was made (the diagram shows the plan of the construction, and the plate shows the method of entrance). The purpose of this underground chamber was to secure uniform temperature and moisture conditions. No ventilation was provided.

The fruit from the Batangas Station orchard was harvested on January 31, 1920, and about 1500 oranges of the commonly grown Batangas mandarin variety were placed in this vault.

The result was very successful; the fruits soon assumed a deep orange colour and, the rind became thinner and the flesh less stringy and of better texture ; the flavour of the fruit also was improved. The curing was entirely finished 20 days after placing in the vault, the experiment, however, was continued to determine what length of time such oranges could be held in storage. Data are given of the comparative merits of two kinds of picking, one by clipping the stems of the fruit with shears for that purpose, the other by plucking the fruits from the tree by hand. It appears that there was a larger loss in clipped fruits than in those picked in the ordinary way, and that a slightly larger loss was found in the green than in the ripe fruit, and that size of fruit did not make any difference in its keeping quality.

These results have proved that mandarin oranges may be stored for a longer time than has hitherto been possible, not only without spoiling their flavour and appearance, but actually greatly improving their quality. According to the methods used, 20 days is the longest period that is economically feasible. It is hoped next year, however, by more careful handling, by disinfection of the fruits before storing, and by ventilation of the underground storage chamber, greatly to increase the length of time for storing.

677 – **Cold Storage of Fruits Liable to Deterioration.** (1) — CRUESS, W. V., OVERHOLZER, E. L., and BJARNASON, S. A., in *California Agricultural Station, Bulletin* 324, pp 25-43. Berkeley, Cal., 1920.

The authors rapidly pass in review the previous work of FULTON and DARROW on the methods of preserving small fruits by cold-storage. They then recount the results of their own experiments, in which freshly-gathered cherries, apricots, loganberries, strawberries, blackcurrants, and freshly-prepared grape-juice were subjected to different treatments, before being placed in the cold chamber, and after several months of cold-storage, examined, in order to ascertain their colour, texture, and aroma, and subsequently used in making various products, such as jellies, syrups, tinned fruits, preserved fruits, jams and ices.

---

(1) See *R.* Feb. 1921, No. 218. (*Ed.*)

It has been found, that, whereas fruit which is not treated, and is kept at a temperature of about 0° C., loses its flavour, and spoils, after some 3 weeks, the same fruit preserved in water, or syrup, at a temperature varying from —11° to —13° C., retains its flavour and colour for at least 1 month. The best results are obtained by crushing the fruit, with or without the addition of sugar, and keeping it at a temperature of —11° to —13° C. Grape-juice preserved at this temperature is much superior in aroma and flavour to pasteurised grape-juice. The breweries, which on account of prohibition, can no longer make beer, are very well equipped with plant suitable for the cold storage of soft fruits and of fruit-juice.

PLANT DISEASES

GENERAL INFORMATION

678 - **The Organisation and Working of the Italian Phytopathological Service.** — MINISTERO PER L'AGRICOLTURA, DIREZIONE GENERALE DELL'AGRICOLTURA, *Rules for the Application of the Phytopathological Regulations*, pp. 24. Rome, April, 1921.

A brief account of the present organisation of the Italian Phytopathological Service, together with a summary of the directions for the application of the phytopathological regulations issued since 1913, especially in connection with the by-law of March 12, 1916, No. 723 (1).

It contains a specimen of the permit-form necessary for dispatching certain prohibited produce to the interior of the kingdom, and also of the immunity-certificate form for exportation outside Italy.

DISEASES NOT DUE TO PARASITES OR OF UNKNOWN ORIGIN.

679 - **The "Nerume" or "Mal Nero" of the Walnut in Campania, Italy.** — TROTTER, A., in the *Rivista Agraria*, Year XXVI, No. 2, 7 pp. Naples, February, 1921.

On a farm belonging to the Commune of Sant'Anastasia (Province of Naples) there are about 700 walnut-trees which should be in full bearing, but for some years, two-thirds of them have shown signs of withering. The foliage is very scanty, the shoots of the year are short and weak, and the pith is more or less brown; during the summer, the leaves turn yellow, and in June, a larger or smaller number of the small nuts are shed. Finally, the branches become partially or wholly withered, and when the course of the disease is very rapid, the whole tree succumbs. From cracks or lesions in the trunks, there exudes, especially in spring, a blackish, somewhat mucilaginous substance, which frequently comes out from small bubble-like cavities in the heart of the tissues. These are, however, often not very noticeable, but an unfailing symptom of the disease is the more or less distinct blackening of the living tissues situated immediately beneath the cortex, which also extends irregularly to some extent up the trunk. As a rule, only the base of the trunk and the large roots are thus attacked, the lower branches remaining immune.

The whole root system, as well as the larger roots, are infected to a certain degree, and crystalline deposits are often found in large numbers in the tissues. On the thick roots especially as far up as the root-collar, or even higher, are seen masses of whitish mycelia or thin black rhizomorphous filaments which wind among the tissues, or make their way between the wood and the cortex. The white mycelia sometimes assume arborescent forms, which are very characteristic, being arranged in a fan-like manner. Sometimes the mycelium causes the de-lignification of the large roots, which become quite soft.

---

(1) Cf. INTERNATIONAL INSTITUT OF AGRIC., *Annuaire international de législation agricole*, Year VI (1916), pp. 876-887. Rome, 1917. (*Ed.*)

A cursory investigation reveals the fact that the soil on which these walnut-trees are growing varies in depth, but is everywhere shallow, and further, rests upon a very compact bed of rocks which, from their nature cannot easily be penetrated by the roots, and contain but few elements suitable for plant food. It is thus permissible to suppose that the roots of the walnut-trees, when the latter have reached a certain age, do not only meet with an obstacle preventing their further expansion, but are also unable to abstract from the soil all those substances which are necessary to the life of the tree. Further, it is well-known that walnuts need rich deep soil, and therefore do badly where the soil is poor and shallow. All these circumstances contribute to lower the activity of the root-system, and predispose it to the attacks of the cryptogamic flora of the soil, which derive great benefit from the humidity resulting from the impermeability of the sub-soil. Hence the constant presence of large numbers of mycelial hyphae which can be seen from out side, lie hidden under the cortex, or wind concealed from sight through the various tissues of the cortical and ligneous zones. Another fact of a general nature must also not be lost sight of, viz., the climatic conditions. In Campania, rain falls frequently and heavily from October to March, so that the ground is constantly moist; if to this fact is added the relatively warm temperature of this region which prevents the soil freezing, even during the coldest months, it is easily understood, that the cryptogamic soil flora has every opportunity of growing with extreme rapidity, and of attacking the roots during their winter rest and, moreover, when they are already weakened by complex conditions of a cultural nature.

It is advisable to scarify the infected wood, and to disinfect the lesions, but this is not enough to control a disease which originated and has its chief extension, in the root system. Therefore, unless it is decided not to take any measures, seeing that the soil is probably quite unsuited to the cultivation of walnuts, the only thing to be done is to use substances to destroy the fungi in the soil and prevent their growth. This would at all events give a certain respite to the roots, so that the length of the life of the tree would be prolonged and a fairly good crop of walnuts secured for a few years. Carbon bisulphide could be injected to a depth of 40-50 cm., 30-35 gm. being used per square metre; other suitable substances are a 2.5—3 % solution of sulphate of iron, a 5 % solution of sulphate of copper (the roots having been properly uncovered), or quicklime.

These remedies must be applied at two different seasons, quicklime, carbon bisulphide or copper sulphate being used in the winter from November to December, and sulphate of iron sprays in the spring, soon after the leaves have unfolded.

DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS

680 - **Biology of *Puccinia graminis* f. sp. *Tritici* in the United States.** — See No. 611 of this *Review*.

681 - **"Vuiteboeuf" and "Bretonnières". — Wheat Varieties in the Swiss Jura, Resistant to Rust.** — See No. 617 of this *Review*.

682 - **"Calabacillo" Cocoa Variety Resistant to Disease in Dominica, West Indies.** — See No. 596 of this *Review*.

683 - **On the Use of Coloured Screens in the Control of the Cryptogamic Diseases of Plants.** — LANCE, R., in the *Comptes rendus hebdomadaires des Séances de l'Académie des Sciences*, Vol. CLXXII, No. 19, p. 1201. Paris, May 9, 1921.

Blue and violet rays have been used successfully in the medical treatment of certain human skin diseases.

They can also be employed in practically the same manner in the control of cryptogamic diseases of plants, especially of the vine, by forming on the surface of the leaves, stems, flowers and fruits, a coloured screen through which the blue, violet and ultra-violet rays pass.

In order to obtain such a screen, a very light coloured mixture is sprayed in fine drops upon the surface of the parts of the plant that are to be protected. This support is made by mixing in water a substance such as sulphate of lime, lime, kaolin, talc, etc., upon which are fixed, by means of freshly-precipitated alumina, bluish-green, blue, indigo, or violet dyes, (especially ultra-marines) which are innocuous to plants.

The following compound is especially suitable:

Ultramarine	blue	650 gm.
»	green	250 »
»	violet	100 »

This is mixed in several litres of water, then 2 kg. of sulphate of lime and from 1350 to 1400 gm. of powdered quicklime are added.

When the mass is uniformly coloured, the colouring matters are fixed on the screen by incorporating with it 1 kg. of sulphate of aluminium, or 1.500 kg. of alum.

The lime decomposes the sulphate of aluminium or alum, liberating alumina which fixes the colouring matter upon the support and at the same time makes it adhere better to the plant.

When the reaction is finished, the volume of the water is made up to 400 litres, and the spraying is carried out with any of the ordinary types of apparatus.

684 - **Fungicidal Zinc Mixture.** — LANCE, C., in the *Comptes rendus hebdomadaires des Séances de l'Académie des Sciences*, Vol. CLXXII, No. 19, pp. 1201-1202. Paris, May 9, 1921.

Both zinc chloride and sulphate are employed as antiseptics in medicine.

Certain products containing zinc can also be used with great advantage as fungicides and vehicles for pigments, so as to form coloured screens to be used in the control of cryptogamic plant-diseases.

Under these conditions, the antiseptic action of zinc is added to the toxic effect of the blue, violet, and ultra-violet rays.

In order to prepare this zinc mixture, 1 kg. of zinc sulphate is dissolved in 100 litres of water, 500 gm. of powdered lime being added to precipitate the zinc in the form of the hydroxide, and subsequently decompose all the aluminium salt used as a fixative; then in the mass thus obtained are incorporated 80 to 100 gm. of the colouring matter. When this has been done, 250 gm. of sulphate of aluminium, or 375 gm. of alum are added and the mixture is very vigorously stirred for a quarter of an hour. Then, after filtering it is ready for use.

685 - **The "Pax" Sprayer.** — See No. 670 of this *Review*.

686 - ***Sclerospora philippinensis*** **n. sp., a Peronospora Injurious to Maize and Other Gramineae in the Philippines.** — WESTON, W. H JR., in *Journal of Agricultural Research*, Vol. XIX, No. 3, pp. 97-122, figs. 3, 12 pl. Washington, D. C., 1920.

A very serious fungal disease recorded for the first time in 1916, and briefly described in 1918, attacks maize in the Philippines. It is of common occurrence in the islands of Mindanao (Cotobato Valley), Cebu, Negros, and Luzón (Provinces of Batangas, Laguna, Rizal, Cavite, Bulacan, Tarlac, Pampanga, Nueva Ecija, Pangasinan, Ilocos Norte, La Unione and Isabela), and appears to have existed for over ten years in some of these localities.

The injuries wrought by this malady known as the Downy Mildew of maize are extremely serious. Under favourable conditions, the fungus is able to destroy entire fields, and in some districts, the natives have been obliged to give up growing maize. Further, the losses cannot be lessened in any way by using the diseased plants for forage, for cattle appear to dislike it greatly, and will only eat the forage, if it contains a large proportion of healthy maize.

As a rule, the disease manifests itself by the appearance of more or less extensive yellowish streaks on the leaves accompanied by the formation of a white downy covering, especially on the parts which have become chlorotic; by the abnormal growth of the vegetative portions of the plant, and by the imperfect development of the ear, which becomes partially or completely sterile. The change in colour is the first and most striking symptom, while the presence of the downy investment affords the most certain index of the disease. The effects of the latter may show themselves from the moment of the development of the third or fourth leaf, to the formation and ripening of the tassel and ear.

Maize is the only crop that is attacked in the open field by this parasite. The disease has however also been found to attack, though to a less extent, *Euchlaena luxurians* and *Andropogon Sorghum* in the experiment plots of the College of Agriculture belonging to the Philippine University. Hybrids resulting from crossing maize with *E. luxurians* are equally susceptible to the malady. Inoculation experiments carried out on numerous other Gramineae have given negative results.

The pathogenetic agent is a peronospora belonging to the genus *Sclerospora*. It appears new to science, and has been described by the author under the name of *Scl. philippinensis* n. sp. This fungus is characterised by the predominance of its conidial stage, the absence of oospore, at least so far as is known at present, and by its conidia invariably giving rise to hyphae on germination. In the latter respect *Scl. philippinensis* differs from the typical variety *Scl. graminicola* (Sacc.) Schroet, which is distinguished by its short conidial stage, the predominance of its oospores, and the zoospores resulting from the germination of its so-called conidia (zoosporangia). *Scl. philippinensis* presents striking analogies to the following species which have recently been described and attack all varieties of maize: *Scl. javanica* Palm. (in Java), *Scl. Maydis* (Rac.) Butl. (in the British Isles), and *Scl. Sacchari* T. Miy (in Formosa, Queensland and Fiji).

Maize is usually attacked by this parasite while its seedlings are very young, the mature plants generally escape. By the time the symptoms manifest themselves, however, the mycelium of *Scl. philippinensis* has already invaded the tissues of its host to a large extent. The mycelium may be found in nearly every part of the plant, with the exception of the radicle system; it is most abundant in the cells of the vascular of the sheath and in the mesophyll. The conidiophores which unite to form the above-mentioned downy covering, are produced in large numbers by the fungus, but only during the night when the surface of the leaves is covered with dew or rain-water. The thickness and persistence of this covering of moisture greatly influence the size and growth of the conidiophores. The conidia, which also vary much in dimensions and shape, germinate rapidly (if they are fresh), in water, and in different cultural media at temperatures ranging from 6.5° C., to 25° C., always giving rise to hyphae ; when they are dry, they lose their germinating power, hence their diffusion and the infection of new plants nearly always take place before dawn. In spite of all the researches that have been made, it has not yet been discovered whether *Scl. philippinensis* produces any oospores, or other resting bodies. The fungus appears to spread by passing from one plant to another. A *Sclerospora* of which, so far, only the oospore stage has been found occurs on *Saccharum spontaneum* L., a very common wild graminea growing in the Philippines. It remains to be determined whether this fungus is connected with the species (*Scl. philippinensis*), of which the conidial stage grows on maize.

687 - ***Peronospora Hyoscyami*** **Injurious to Tobacco in Florida, and Georgia.** — SMITH. E. F., and Mc KENNEY, R. E B, in *United States Department of Agriculture, Department Circular*, 174, 6 pp. Washington, D C., April 1921.

At the request of the tobacco-planters in Florida, the seed-beds growing near Quincy were inspected on March 29, 1921. They were found to be seriously attacked by a fungal disease (mildew) which appeared to have nothing in common with the other tobacco diseases previously reported in the Malaysia and Australia.

The disease in question made its appearance almost at the same time' about March 1, in four widely separated seed-beds in Gadsden County (Florida). It generally started at one end, and then spread over the rest of the bed, in some cases by direct enlargement of the infected spot, and in others through the development of other infected patches. In most cases, the entire bed became diseased within a week from the first appearance of the parasite. By April 5 the mildew had already spread to at least twenty-six seed-beds in the county of Gadsden; on April 8, it was reported from many places in the adjoining county of Decatur (Georgia)

The disease seems to be caused by *Peronospora Hyoscyami*, originally described by DE BARY as found on *Hyoscyamus niger* in Europe. It appears never to have attacked tobacco in Europe, but has for many years done great injury to that plant in Australia (New South Wales and Victoria). It has also been reported in South Africa. In 1855, it was observed in South California on *Nicotiana glauca*, a plant that was introduced into that country from Argentina. The disease must also exist in Texas, for in the mycological collections of the United States Department of Agriculture, there are young tobacco plants gathered in 1906 at Halletsville, which are attacked by a Peronospora that is considered identical with that recently found in Florida.

It is not known how the disease was introduced into Florida, but it is improbable that the few seeds imported into that country conveyed the infection. Very likely, however, it found its way into the United States by means of the second-hand mats used for packing the tobacco which comes from Sumatra. On the other hand, the pest may have reached Florida by way of California and Texas, especially if this species produces no oospores, and is the same as that found on *N. glauca* in California, in which case, the disease may have been directly imported through the medium of the débris accumulated on the shores of the S. Atlantic or of the Gulf of Mexico, since the examination of the United States National Herbarium has shown that *N. glauca* has been collected at New Jersey (1897), at Quarantine Station in South Carolina (1889), and on several occasions at Pensacola in Florida (1880, 1897, 1903, etc.).

The rapid spread of the disease in the two countries is easily explained. The fungus produces a large number of dry, powdery very light conidia, and further, the atmospheric conditions were most favourable to its diffusion Observation has shown, beyond any manner of doubt, that the parasite has been in many cases carried from one seed-bed to another by the agency of visitors, who transport on their boots, or clothing, the conidia of the parasite from infected to healthy beds. The diffusion of the fungus in the same seed-bed is certainly attributable to a large extent, to the action of wind, and perhaps the latter contributes in some measure to its spreading from one bed of tobacco to another.

It is at present impossible to predict the further course of the malady in the United States; probably henceforth the tobacco-grower will find the fungus a very dangerous pest, and the only way in which he will be able to obtain a good crop, will be to employ all the means at his disposal for combating this new enemy, such as sowing in sterilised soil, using seed of undoubted purity, and observing hygienic rules in the treatment of seedlings, so that the disease cannot be introduced from other seed-beds into his own.

Seeing that the climate of Florida is very damp, and that the method of culture adopted there in growing the fine wrapper tobacco (shading the fields with laths and cloths), increases the moisture of the surroundings, and given the fact that freshly introduced diseases do greater injury in a new country than in the land where they originated, prudence would recommend that young plants (however healthy in appearance), grown from infected seed should not be cultivated in these shaded fields in Florida. Further, entrance into immune seed-beds should be denied to persons coming from infected plantations.

As soon as the presence of the disease was known, the destruction of the small number of badly infected beds was advised. It was also recommended to spray all healthy, or slightly attacked, plantations with a dilute solution of Bordeaux mixture, which contrary to what had been observed in Australia, appears to have given good results in Florida. The best results are certainly obtained by spraying late in the afternoon, when the leaves of the young tobacco plants show a tendency to assume an erect position; this allows of the remedy reaching more quickly the lower surface of the leaf which is the most likely seat of the infection.

688 – ***Pleospora infectoria*** **var.** ***aucubicola*** **n. var., an Ascomycete Injurious to** ***Aucuba japonica*** **in Italy.** — MONTEMARTINI, L., in the *Rivista di Patologia vegetale* Nos 3-4, pp 33-35 Pavia, April 1, 1921

During the last year, the upper and external leaves of two specimens of *Aucuba japonica* with variegated foliage, which are growing at Montubeccaria (Province of Pavia) have presented a blackened and scorched appearance, as if they had been burnt. The first sign of disease is the occurrence of black patches; these are nearly always situated at the tip of the leaf, although sometimes they are also to be found on the edges, The patches are at first clearly marked off by a line from the rest of the leaf. but later on extend over the whole lamina which withers, curls up and finally dies.

The new leaves that grow to replace those that have withered and fallen, are speedily attacked in the same manner. The disease appears and spreads in winter and summer alike.

The mesophyll of the blackened leaf is invaded by a brown septate mycelium; numerous short hyphae passing to the exterior of the felt-like surface of the older part, where they produce a large number of the short conidial chains characteristic of an *Alternaria*. Subsequently, on the same surface, there appear small papillae, which are perithecia resembling those of *Pleospora* and containing ascospores with five transverse septa. In artificial cultures, these ascospores have always produced an *Alternaria*.

These perithecia, from their general characters and the olive-green of the ascospores, must be attributed to *Pl. infectoria*, further, the shape, size and colour of the *Alternaria* (*Alt. tenuis* Nees) representing the conidial stage, point to the conclusion that we have here to do with a variety of *Pl. infectoria* Fuck.

As the fungus in question was certainly parasitic upon a plant which hitherto it had not attacked, the author is of opinion that it should be regarded as a distinct variety, and has given it the name of *aucubicola* (*Pl. infectoria* Fuck. var. *aucubicola* n. var.).

INJURIOUS INSECTS AND OTHER LOWER ANIMALS

689 - **Destructive Insects Recently Observed in California.** — Essig, E. O., in *Monthly Bulletin of the Department of Agriculture, State of California*, Vol. IX, No. 4, pp 140-143, figs. 3. Sacramento, California, April, 1921.

The Mexican bean-weevil (*Spermophagus pectoralis* Sharp), was found infesting beans at San Francisco in 1915, and again in 1920 (December). The insect appears to have been imported.

The barnacle scale (*Ceroplastes cirripediformis* Comstock), had hitherto only been taken in greenhouses in various parts of California, but in 1920, two specimens were collected in a citrus orchard, where however the species was rare.

The Spanish scale-insect (*Chrysomphalus dictyospermi* Morgan), has been found on several occasions on ornamental plants in greenhouses in California, chiefly on *Kentia* spp. The author recently observed it completely killing some young avocado trees (*Persea gratissima*), in a greenhouse at Berkeley.

A small nitidulid beetle (*Carpophilus dimidiatus* Fabr.), has often been taken on soured and decaying fruit in Southern California. The adults are usually found in the flowers of *Opuntia* spp., but had not been considered of any special economic importance, until large shipments of shelled pea-nuts arriving at San Francisco from Java were found to be seriously injured by the beetle.

Other insects taken on the same lots of shelled pea-nuts were the caudelle (*Tenebroides mauritanicus* Linn.), the red flour-beetle (*Tribolium castaneum* Herbst.), the sawtoothed grain-beetle (*Silvanus surinamensis* Linn.), and the Indian meal-moth (*Plodia interpunctella* Hübn.).

Dried copra and copra products imported to San Francisco were found to be seriously damaged by the cigarette beetle (*Lasioderma serricorne* Fabr.). On the same products, *Silvanus surinamensis*, *T. castaneum*, and the red-legged ham-beetle (*Necrobia rufipes*) were also observed.

690 - ***Pectinophora (Gelechia) gossypiella*** **as a Cause of Diminution in Cotton Seed Oil Percentage.** — See No. 671 of this *Review*.

691 - **Effect of Spraying on Composition of Oranges.** — See No. 609 of this *Review*.

692 - **The Importation and Acclimatisation in Uruguay of *Aphelinus mali*, a Hymenopteron Parasitic Upon the Woolly Aphis *(Eriosoma lanigera)* of the Apple Tree.** — Sundberg, R., and Trujillo Peluffo, A., in the *República oriental del Uruguay, Ministerio de Industrias, Defensa Agricola, Boletin mensual*, Year II, No. 3, pp 65-81, figs 14. Montevideo, March, 1921.

With a view to testing the efficacy of the chalcid hymenopteron *Aphelinus mali* in controlling the woolly aphis of the apple-tree (*Eriosoma*

[*Schizoneura*] *lanigera*), the " Defensa Agricola " of Uruguay obtained from the United States Bureau of Entomology some colonies of this aphis which were attacked by its endophagous parasite; they arrived at Montévidéo on January 13, 1920. The material was at once sent to Sayago, and pieces of branches of apple-tree bearing the infected colonies were attached to the branches of young apple-trees that had been severely attacked by *Er. lanigera*, special cages being placed over them.

These apple-trees were first examined in February in order to ascertain the results of the experiment. On February 15, and still more on the succeeding days, the increasing numbers of the adult hymenopteron and of aphids that had evidently been attacked by the parasite proved that *A. mali* was developing and spreading.

The results being so far successful, measures were taken to propagate the hymenopteron by using larger apple trees (which were also enclosed in cages) of different species and growing in the open in various places. The results were eminently satisfactory. Apple-trees to which colonies of the aphis had been attached were examined on March 16, and it was found that the endophagous parasite had obtained a firm footing.

The authors give a description of the genus *Aphelinus*, a short account of *A. mali* and some information regarding the life-history and habits of the latter, based upon the observations and experiments made out of doors and in the laboratory in Uruguay.

As the acclimatisation of *A. mali* in the territory of the Republic has now been ascertained, the « Defensa Agricola » has turned its attention to increasing systematically the propagation centres of this insect which, there is every reason to hope, will prove of great assistance to apple-growing.

693 - A New Preparation of Copper Aceto-Arsenite (ParisGreen) and Its Practical Advantages in the Control of the Animal Pests of Plants. — ESCHERICH, K., in the *Deutsche Landwirtschaftliche Presse*, Year XLVIII, No. 15, pp. 104-105. Berlin, February 23, 1921.

The use of Paris Green (copper aceto-arsenite) in the form of powder presents various difficulties. In order to obviate these, the insecticide has been recently placed on the market in Germany in tablets, each about the size of a tablet of chocolate, and containing sufficient of the compound to make a hectolitre of spraying-mixture. Each tablet is divided by grooves into five smaller divisions, one of which is enough to make twenty litres of the mixture for spraying. Each of these smaller divisions is, in its turn, subdivided transversely, into equal parts, one of which is sufficient for preparing 10 litres of spray. In this manner, the weighing of the substance, an operation entailing loss of time and of material, is completely dispensed with.

Further, the neutralising agent has been incorporated into the tablets, so that the troublesome business of adding lime is wholly unnecessary.

Another and more important practical advantage possessed by the new preparation is its considerably increased power of suspension, as compared with " Uraniagrün " (the name usually given in Germany to aceto-arsenite of copper in powder form)

The experiments made by the authors have proved the new preparation to be entirely satisfactory in every respect.

694 - **The Control of *Euproctis chrysorrhoea*, a Macrolepidopteron Injurious to Fruit Trees and Forest Trees in Orléanais, France, during 1920.** — URSAT, J. and GAUMONT, L, , in the *Comptes rendus de l'Academie d'Agriculture de France*, Vol VI, p 23, No 581-583 Paris, 1920.

In 1919, *Euproctis chrysorrhoea* increased in numbers to such an extent in the Department of Loiret, that in the spring of 1920, the fruit-trees and forest trees of Orléanais were covered with the nests of this insect.

Hence it was imperative to take energetic measures for the destruction of the caterpillars. In the first place, the Prefect issued two decrees obliging all owners of estates to destroy before March 15, any nests of *E. chrysorrhoea* that existed on their property.

Subsequently, the Departmental Agricultural Office not only circulated popular leaflets, but also decided to give the sum of 30 000 fr. in prizes for nests collected by the school-children, who were awarded a prize of 10 fr. for every 1000 nests collected from fruit-trees, and 5 fr. for the same number taken from the hedges

A certain number of school-masters, and officials at the mayoralties undertook, under the control of the delegates of the Departmental Agricultural Office, to count and destroy the nests and distribute the prizes. The Office gave them a bonus of five francs per 1000 nests received.

A total of 2 183 179 nests was thus obtained, but a much larger number was, however, destroyed by the horticulturists and Railway Companies of the region on their own account.

The total sum distributed in the form of prizes was 33 389 93 fr.

695 - ***Dryopeia hirsuta* n. sp., An Aphis Injurious to Rice in the Philippine Islands.** — BAKER, A C , in *Monthly Bulletin of the Department of Agriculture, State of California*, Vol X, No. 4, pp 159-160, figs 3 Sacramento, California, April 1921

A morphological description of a new species of aphis, *Dryopeia hirsuta*, of which specimens were collected several times in 1919 at Los Baños (Philippines), where the insect lives upon the roots of rice and does considerable damage to the crop.

This species is closely related to *Dr. bella* Kock.

696 - **An Undetermined Mite Injurious to the Potato in India.** — MANN, H H , NAGPURKAR, S D , and KULKARNI, G S , in *The Agricultural Journal of India*, Vol XV, Part 3, pp. 282-288, pl. 2. Calcutta, 1920.

In the district of Poona, where the potato is much more cultivated than in any other part of Western India, the plants grown during the rainy season in 1917, were found to be seriously attacked by a peculiar disease which, on account of the reddish colour assumed by infected fields, was known among agriculturists under the name of " tambera." In years when this malady was particularly prevalent, the yield was so low, that the grower hardly obtained as many potatoes as he had used for seed.

The symptoms of the disease are as follows: at all stages of the plant's growth, but generally a month after it has sprouted, patches, of a slightly blackish colour and somewhat oily-looking, make their appearance on the lower surface of the leaves especially on the young foliage. These patches subsequently become red, spreading and increasing with great rapidity, and finally assume a bronze tint. The upper leaves acquire a bunched-up appearance, the edges become wrinkled, and the leaf-hairs are very prominent. Gradually, all the leaves wither, beginning with those at the top of the stem; the main stock however still remains green for some time, but finally also loses its colour, and withers. The plant tries to react by sending out a series of auxiliary shoots, which lose no time in being attacked themselves, and end by withering. All this takes place within thirteen or fifteen days. The disease usually manifests itself after the tubers are formed, and when they are about the size of a walnut. The tubers develop no further, and hence the crop is very light, and consists of very small potatoes. At the beginning, only a few plants are attacked, but the disease extends in patches, with the greatest rapidity, so that the whole field is soon infected.

Recent researches have shown, that the disease is not confined to the Poona potato area but is also found in other districts, and even in Sind. Further, it has been discovered that it also attacks the winter potato crops, but in the last case, it gives rise to little apprehension, and may even escape notice.

All attempts made to discover the immediate cause of the malady had proved ineffectual, until in 1919, the attention of the authors was attracted by the description of a very similar disease which had been noticed in 1917, in Hawaii, and was attributed by CARPENTER to a mite probably belonging to the family *Tetranychidae* (1). The investigators then turned their attention to looking for this parasite, and soon discovered countless numbers of a minute mite, which in all its characters resembled that found in the Hawaii Islands, in all the diseased portions of the potato-plants, and especially on the lower surface of the leaves.

The authors, however, did not consider that the undoubted presence of this mite was sufficient to prove that it was the cause of the disease. They therefore carried out many experiments, both in the laboratory and the open field, upon healthy potatoes, shoots and even only leaves attacked by the mite, and taken from diseased plants. The results, which were quickly obtained, were invariably and clearly positive.

Excellent results were obtained in the control of the pest by spraying infected plants growing in pots, or in the open, with lime-sulphur, or dusting with dry sulphur; the former remedy however proved less efficacious than the latter. The treatment was applied three times: when the plants were three weeks old, when they were nearly six weeks old, and finally after they had been planted between two and three months. The difference between the sprayed and the unsprayed fields in their neighbourhood was very noticeable. As the use of sprays is new to the cultivators, it is probable, that the dry sulphur treatment, though less efficacious, will be the remedy most commonly applied, at least for the present.

---

(1) See *R* Nov. 1918, No 1314 (*Fd*)

[696]

All the varieties of potato that are usually grown are quickly attacked by the mite, if the conditions are favourable. The English variety " Epicure " seemed, from the result of experiments, to be endowed with a certain amount of resistance, but in order to be sure of this fact, further researches are necessary.

As regards the propagation of the mite from one year to another, it would appear, judging from the conditions of the zones where the present investigations were carried out, that the disease may be spread by the potato plant itself. Indeed, although there are in that zone two quite separate crops—the rainy season potato crop (" kharif "), and the winter one (" rabi "), which grow at regular intervals, nevertheless the seasons are not clearly distinct, and practically, potato-growing continues without interruption from the June of one year to the following March. The " kharif " crop is sown in June and July, and lifted in September and October, sometimes even as late as November. The " rabi " potatoes are planted from November to March ; so that this very late crop is harvested at the time the " kharif " potatoes are planted. Scattered plants growing from tubers remaining in the soil from the preceding crop are also to be found in the fields. Thus, there are always potatoes growing in the research zone, and although the winter crop is not seriously attacked by the parasite, it is however not entirely immune. The low temperature prevents much injury being done and so little attention is paid to the matter. The mite renews its destructive work at the return of the hot season, in April or May, and is probably spread by means of the cultural operations carried out at this time in the fields of " kharif " potatoes, although it is quite possible, that it has other plant hosts. A mite, recognised as identical with that living on the potato, has been found on *Cyamopsis psoraloides* at Baroda, Padra, Surat and Poona. Potato plants infested with the mite attacking *C. psoraloides* soon manifested the characteristic symptoms. Experiments were also made on the capsicum and tomato, but these remained quite immune. It is, however, very advisable, that further experiments and investigations should be undertaken in connection with this subject.

697 - ***Cacoecia franciscana*, a Microlepidopteron Injurious to Apples in California.** — PENNY, D. D., in *Monthly Bulletin of the Department of Agriculture, State of California*, Vol. X, No. 4, pp. 146-150 + 3 figs. Sacramento, California, April, 1921.

In the Pajaro Valley, in the Watsonville district (California), apples at picking time, and while stored during the winter, have of recent years, been subject to the attacks of the larvae of the small tortricid moth (*Cacoecia franciscana* Wals). This article gives the description of the different stages of the insect, and also a short account of its life-history.

The damage done by the caterpillar consists in a peeling of the skin of the apple, involving little loss of the pulp. The area affected may be small, or extensive, it is usually well-defined, and has a clear-cut, sculptured appearance. The apples may be attacked on the side, but the larvae usually injure the cavities of the calyx and peduncle.

Two other lepidoptera closely associated with *C. franciscana*, *Pandemis pyrusana* Kearf, and *Peronea* sp., have been observed in the Watsonville district, and their larvae. superficially resemble the caterpillars of the former insect, though the adult forms are quite distinct.

698 - ***Phloeosinus* sp., a Beetle Injurious to the Cypress in Mexico.** — RIQUELME INDA, J., in the *Memorias y Revista de la Sociedad Cientifica "Antonio Alzate,"* Volume XXXVIII, Nos. 11-12, pp. 401-405, 2 figs. Mexico, F. D., Jan. 1921.

Some of the many cypress-trees of the " La Hormiga " Farm situated on the edge of the Chapultepec forest were found to be infested in 1918, as they had been already in 1909, by a beetle belonging to the genus *Phloeosinus*. This coleopteron is iron-grey in colour, cylindrical and about 1 mm., or 1 ½ mm. in length. It excavates galleries between the bark and the wood of the tree that act as host. Some of the cypresses seemed to have already succumbed to its attacks.

There is some reason for believing that there is only one annual generation of this insect in the Federal District of Mexico.

In order to hinder the spread of this pest, it was advised to fell the dead cypresses without delay, and to remove the bark and burn it on the spot. All the bare surfaces of the trunks were also to be cauterised. Those trees which the beetle has only just begun to attack (they can be recognised by the fact that the upper branches are usually first affected), can be saved if these branches are removed and burnt on the spot. Should the injury begin at the end of the trunk, the tree must be cut down and burnt; the wound should at once be covered with the cement used in grafting.

It may be added that all the branches and fragments of old wood lying about on the ground ought to collected and burnt. These different operations are best executed in winter.

INJURIOUS VERTEBRATES

699 - **Injury Caused By the Rodent, *Hypodeus glareolus* to the White Fir in Switzerland.** — HUNZIKER, W., in the *Schweizerische Zeitschrift für Forstwesen*, Year LXXII, No. 4, pp. 97-100, figs. 1. Berne, Apr. 1921.

It had already been observed that, in some parts of the Canton of Aargau and also in other Cantons of Switzerland, the young white firs had lost the top of their terminal shoots. This damage had been in turn attributed to squirrels, cross-bills, jays and, in some cases, to roe-deer. Of late years, however, it has been observed to occur especially frequently in the woods belonging to the Canton and Communes in the neighbourhood of Murgenthal, Oftringen, and Rothrist. Very many young white firs are seen that have lost the tip of their terminal shoots. As a rule, such trees put forth several lateral branches that take the place, to some extent, of the principal shoot whose development has been arrested, and this causes a deformation of the tree which later reduces the amount of saleable timber.

The injuries noticed in the above-mentioned woods were quite typical. In trees 50 centimetres high, and even in taller specimens that were six or eight metres high, the terminal shoot had been severed at the tip by a clean slanting cut with every appearance of having been made with a knife Careful investigation, however, revealed the fact that, in the case of many firs, the extremities of lateral shoots had been removed while in others the buds alone were absent.

Occasionally at long intervals, shoots that had been partly severed, but otherwise uninjured still hung to the branches, while others lay yet beneath the trees; this shows that the marauder usually carried off his prey. In very rare instances, these shoots were seen to have been partially gnawed, which proves that the damage could not be attributed to birds, but must be the work of rodents

Observations made in 1919 in the woods belonging to the Canton of Lenzburg, where the same damage had been wrought, showed that the mischief had been done at night. Further, the ground beneath the first that had been attacked was perforated with numerous holes and galleries made by the rodents, and shoots cut in different ways were even found within them.

These facts pointed to *Hypodeus glareolus* Wagn. as the culprit responsible for the injuries to the white fir, for this animals is an excellent climber.

The truth of this supposition was proved at last in February and March, 1920, at Murgenthal where, by the help of clever stratagems, not only were several of these rodents caught beneath a group of white firs that had been severely injured in the above-mentioned manner, but some of the little animals were surprised and caught on the trees when in the very act of devouring the buds. It has further been found that *Hyp. glareolus*, when in captivity, readily eats not only seeds, fruit, and meat, but also shoots of the fir.

It is only a few years ago (1911) that *Hyp. glareolus* was said to be rather rare in the Canton of Aargau. Now, however, it is by no means unknown in the vicinity of Murgenthal. It is also found in granaries, where it is often caught. Perhaps the destruction of the foxes has had something to do with the unusual increase of these small rodents.

Organisation of Agricultural Book-Keeping in Norway

Office for Research on Farming Conditions of the " Det. Kgl. Selskap for Norges Vel " (Royal Society for the Welfare of Norway).

By M. KROSBY
General Secretary.

In 1907, H FIVE, then Professor of Agriculture, later Agricultural Councillor, collected infomation on farming conditions in several districts in the east of Norway (See *Tidsskrift for det norske Landbruk* [Review of Norwegian Agriculture], 1909, p. 21 *et seq*)

In 1910, H FIVE, obtained a scholarship awarded by the "Society for the Welfare of Norway" for the purpose of studying research methods relating to economic conditions of agriculture in Germany and Switzerland

In the *Review of Norwegian Agriculture* for 1910, p. 315 *et seq*, he gave an account of the manner in which it was proposed to carry out this work in Norway, as the " Society for the Welfare of Norway " had decided to take up the question, and, in 1911, established a Research Office regarding farming conditions

Two main objects were proposd :—

1) To work so that complete well ordered accounts might be kept generally by farmers.

2) To collate the results of the accounts of various types of agricultural properties in different parts of the country, to elaborate them, and to endeavour, as far as possible, to make them useful to practical and theoretical agriculture

1) Since 1915, the work done with the object of generalising book-keeping has consisted chiefly in giving annual courses of instruction in book-keeping for agricultural officials. These officials, in turn, hold courses of instruction for the farmers in the districts. In this way it is hoped that, with the help of these local courses, every farmer who wishes to keep accounts of his farm may be given instruction. The number of farmers who have received instruction in this way from 1915 to 1920 was as follows:—

In 1915	1126	In 1918	209
1116	1148	» 1919	481
1917	516	» 1920	about 1250

The considerable decrease in the number during the years 1917-1919 was due to the fact that, during these critical years, it was difficult, both for teachers and farmers to find time for accounts.

The Research Office tries to help progress in book-keeping by selling accounting requisites direct to the farmers.

2) Researches relating to the farm itself are based on an intimate collaboration between the Office and the farmers who have signified their willingness to participate in such work by giving information regarding the economic situation in agriculture. The Office makes use of a special system of book-keeping which is explained in detail in H. FIVE's book entitled *Veiledning i landbruksregnskap* (Text-book of Agricultural Book-keeping). The accounts year runs from April 1 to March 31.

The farmers who have agreed to participate in the researches are instructed by means of a short course, in the system and the work they have to do. The farmers are specially asked to make daily entries. All work of abstracting and checking is done by the Office, which, at the time the first balance sheet is made out, helps to determine the more difficult entries; moreover, the book-keeping is controlled for a certain time after accounts have been opened. By distributing the work in this way. the work and time required from each particular farmer is restricted,

It is quite understood that such an organisation of book-keeping is necessary when results of accounts are to be obtained from *small agricultural holdings*. It is chiefly in such cases that knowledge of the manner in which the work should be done is lacking and that there is the smallest amount of time available for keeping accounts. This has great importance in Norway, where the properties in most cases are *small agricultural holdings*.

Besides making out a complete balance sheet as on April 1st, the farmers who co-operate in this work keep a combined cash-book and day-book (called "cash day book") arranged according to the "system of headings." The Office advises them to enter the totals of the entries in one place, the cash entries under the heading "Cash", and the credit entries under the heading "Total" before the heading "Cash", and to refer it to the Office to constitute a partial double-account. Most of the farmers take advantage of this offer, which makes it easier to keep the book.

The farm labour employed, the work done by the farm horses, as well as the land under various crops and their yields are entered on special forms.

In the accounts a distinction is made between "*professional use*" and "*used for consumption*." Professional use is subdivided into:— *a*) Farming strictly speaking, including the production of crops and the upkeep of farm animals; *b*) the forest; *c*) subsidiary business, or business outside *a*) and *b*). Used for consumption is divided into:— *a*) Domestic economy; *b*) private consumption. It is chiefly information concerning professional use called farm, that was desired and which has been most completely elaborated. On special printed returns the transactions are subdivided and the more important entries are carried forward separately both as gross and net totals under receipts and expenditure; the latter are called *net* receipts and *net* expenditure of the farm (1).

The number of accounts worked out each year has been:

For the	1st	accounts	year	(1911-1912)	39	accounts
›	2nd			(1912-1913)	42	»
›	3rd	›	›	(1913-1914)	73	›
›	4th	›	›	(1914-1915)	82	»
›	5th	»	»	(1915-1916)	110	›
›	6th	›	›	(1916-1917)	101	›
›	7th	›	›	(1917-1918)	92	›
›	8th	›	›	(1918-1919)	102	›
›	9th	›	›	(1919-1920) . . .	about 100	»

For the year 1920-1921, the number will be greater, several participators having been inscribed commencing from April 1, 1920. The farmers who take part have not to bear directly the cost of these researches. Instruction, material, publications and the work of working out the balance sheets are provided gratis; in return the Office reserves the right (guaranteeing discretion) of publishing such of the results of the researches as may be of public interest.

The disturbing influence of the war on the level of prices and the excessive increase in prices which occurred during the war years have made research work relating to farming conditions of the last few years extremely difficult. As has been noted in the last reports, it is, in these circumstances, very difficult, not to say impossible to judge correctly the results of the different years from an accounting standpoint. It is impossible to avoid variations in the reports between the results of accounts of different agricultural properties and of different districts, variations which are not caused in an entirely objective manner.

In order to make the best possible comparison of the different accounting years, the attempt was made to prevent, as far as possible, the super-values from figuring directly in the balance sheet. Thus, no super-value has been entered for the land, buildings, machinery, etc., except when there has been corresponding expenditure in the way of improvement.

---

(1) See on this subject:— H. Five, "Results of book-keeping on agricultural properties in Norway" No. 7, for the year April 1, 1914-March 31, 1915. (*Ed.*)

3) Besides the work undertaken with the two objects above mentioned, the Office has, since 1916, annually collected information regarding increase of wages for the more important kinds of wages in agriculture. In 1916 and 1920 information was also collected regarding hours of work, their number, distribution, etc. The publication of this information has so far consisted only in annual provisional abstracts relating to wages, as it has not yet been possible to publish detailed information.

SECOND PART

ABSTRACTS

AGRICULTURAL INTELLIGENCE

GENERAL INFORMATION.

700 - **The Agricultural Development of Brazil in the "Message" of H. E. Epitacio Pessoa, Addressed to the National Congress at the Opening of the XI^th Legislature.** — Rio de Janeiro, May 3, 1921.

The message addressed by the President of the United States of Brazil, EPITACIO PESSOA, to the National Congress on the occasion of the opening of the XIth legislature may be defined as a complete review of all work in progress and a truly dynamic programme of further undertakings. The problem of agriculture is also fully considered.

After dealing with the important question of emigration and the creation of new centres of colonisation to which the Government of the Republic is devoting every effort, the President dealt with the work of the Department of Agriculture.

The following is a short statement of the more interesting points:—

AGRICULTURAL COLLEGE. — The College of Agriculture and Veterinary Medicine was re-organised by Decree No. 14120 of March 29, 1920. A course of industrial chemistry has been added, so that the College now includes 3 classes of higher study:— Farm engineering, veterinary medicine, and industrial chemistry.

A demonstration field for experiments, which will be visited by the fourth-year agricultural student, has been established at Deodoro and placed at the disposal of the College.

BIOLOGICAL INSTITUTE OF AGRICULTURAL DEFENCE (See *R.*, April 1921, No. 442).

GENERAL AGRICULTURAL EXPERIMENTAL STATIONS. — The first agricultural experimental Stations were created by Decree No. 8319 of October 20, 1910. The work of the General Station deserves special mention, especially as regards the selection of the sugar cane and the remedies against *Tomaspis parana* Distant, one of the worst pests of citrus plantations.

AGRICULTURAL APPRENTICESHIPS. — These receive and keep out of the way of vice thousands of young people under age, who are employed on work in the fields and whose future professional work is thus prepared for.

[Abstract No. 700]

The number of these apprenticeships, which are subsidised by the State, increases constantly and their good effect becomes increasingly manifest.

SERVICE OF AGRICULTURAL INSPECTION AND PROPAGANDA. — This Service specially looks after the organisation relating to the preparation of an agricultural map, an indispensable guide for the exploration and thorough evaluation of soils. The Service has already divided each State into physiographical zones according to conditions of soil, climate and altitude, and the extent and distribution of cultivation. These data will be registered and completed after examination of the geological returns.

The propaganda Service also encourages the use of fertilisers, of which in 1920, it distributed 30 000 metric tons; this is, however, a very small quantity in view of crops which require much greater amounts, such as coffee and sugar cane. In 1920, 601 tons of good seeds were distributed among farmers and they were supplied with 35 226 fruit tree plants.

Regarding control of plant diseases, 4131 cases of formicides, 10 cases ses of carbon bisulphide and 2697 kg. of various insecticides were distributed.

EXPERIMENTAL STATION FOR THE CULTIVATION OF CEREALS. — Recent investigations have shown that Brazil could produce all the wheat required for local consumption. In the States of Rio Grande do Sul, Parana, Santa Catharina, there are great areas where the conditions of soil and climate are admirably suitable for wheat growing.

In addition to the arrangements already made for increasing the production of wheat, the Brazilian Government has instituted an Experimental Station for the cultivation of cereals at Alfredo Chaves (Rio Grande do Sul). The land placed at the disposal of the Institute covers 75 hectares and has been suitably divided into plots and pieces for genealogical selection and multiplication of selected types

Although work was not commenced until July, 1920, it has been possible to make some temporary nurseries, sown in accordance with all the rules of the art, which will help very much the initial selection of the parent plants, to be used afterwards in the work of genealogical selection. The seed has been brought from Uruguay, France and Czechoslovakia and comprises 33 varieties of wheat, 6 of barley, 11 of oats and 2 of rye. Two similar Stations have been organised for the States of Santa Catharina and Parana.

SEED SERVICE. — Decree No. 14 825, of August 24, 1920, created a Seed Service charged with the multiplication and selection of seeds, experiments of adaptation and acclimatisation, genetic researches on the use of good seed.

Fields for production of and experiments on, selected seeds have already been organised at the Stations of Deodoro, Rezende and S. Simão. The first produces 400 hectolitres of maize and 37 hl. of rice ; the second 600 hl. of maize and 2 000 hl. of rice ; the third 900 hl. of maize and 255 hl. of rice.

The results obtained prove that it is desirable to constitute new fields suitably distributed all over the country in accordance with the commercial conditions and the environmental conditions of the different zones.

COMMERCIAL CLASSIFICATION OF AGRICULTURAL PRODUCE. — The necessity of establishing, as has already been done in the case of coffee, a commercial classification of certain agricultural produce for which there is a large trade, such as rubber, cotton, cereals, textile fibres, cocoa and tobacco, is now recognised, as ungraded products placed on a foreign market are always valued below their real worth.

The Government is already taking an interest in the solution of this important question.

COTTON SERVICE. — The Cotton Service, created by Decree No. 1417 of March 27, 1919, has at length, after a period of preparation, been able to commence its work and the utility of this new Service is becoming more clearly marked. At a time when a lack of raw material is felt in the manufacturing centres of the whole world, Brazil naturally takes a keen interest in the production of an article so much in request (1). Experimental Stations and testing fields have been instituted for the improvement, selection, and propagation of the best varieties, for the study and improvement of local varieties, for the control of diseases of cotton, etc.

By means of enquiries and statements made in the different States it has been possible to identify diseases of cotton, some of which are quite new to Brazil Among those previously known may be mentioned *Pectinophora* (*Gelechia*) *gossypiella* and *Alabama argillacea*, which cause damage which is estimated, in some cases, to amount to 80 and 90 %. To prevent the introduction of foreign parasites, a Service of supervision and control is required; agencies for this have already been constituted in some of the cotton-producing States.

The results obtained in the States of Sergipe and Parahyba for the control of *Pectinophora gossypiella* are most encouraging; their example will also be followed by the other States. To complete the work the Federal Government will send out and distribute all necessary instructions to the competent authorities and agencies so as to regulate control and make it more efficient.

The Cotton Service has carried out a series of investigations relating to the sterilisation of seeds and to the pernicious effects of too high temperature in insufficiently ventilated store houses. At present 2 co-operative fields are being organised in the State of Maranhão, 3 in Piauhy, 2 in Rio Grande do Norte, 5 in Parahyba, 4 in Pernambouc, 1 in Alagoas, 4 in Sergipe, 2 in Bahia, and 1 in Minas Geraes.

---

(1) Regarding the possible development of cotton cultivation in Brazil, see the very interesting Report made to the Brazilian Minister for Foreign Affairs by Dr Deoclecio DE CAMPOS, Commercial Attache to the Brazilian Embassy at Rome and Delegate for Brazil at the International Institute of Agriculture (*Boletim do Ministerio des Relações Exteriores*, No 16. Rio Janeiro, Oct 1920) (*Ed*)

District Officers will distribute selected seeds, carbon bisulphide, and other disinfectants with all necessary instructions; they will establish control and quarantine for seeds intended for plantations or for export.

Experimental fields are being prepared at the two Experimental Stations of Maranhão and Parahyba; they are intended for the selection of indigenous plants, for fixing the positive characters of those plants and for the acclimatisation of exotic varieties.

A collection of samples of all kinds of Brazilian cottons is being made for the purpose of an Exhibition and a commercial classification of this product is also being worked out.

The Federal Government has made numerous regulations relating to customs and fiscal matters, control against fraud and abuses, with the object of encouraging and increasing the protection afforded to cotton cultivation in the Republic.

VEGETABLE OILS. — When the immense area of the coastal zone, still largely uncultivated, is considered and if the fact that Brazil grows a very large number of oil palms is also remembered, the enormous wealth which might be derived from the cultivation of these palms invites thought.

The most important palm is the coconut, which elsewhere does not produce fruit until the 8th year, whereas in the climate of Brazil it begins to produce from the 4th year, especially when it is grown close to the sea. Next in importance comes the " babassu " palm which grows chiefly in the States of Piauhy and Maranhão. Exports of the produce of this palm have reached, in less than 10 years, the value of about 13 million *milreis*.

The " tucum " and " macahubeira " palms may also be mentioned and there are other palms, little grown at present but which may give good results later on.

FRUIT-GROWING STATION OF DEODORO. — Experimental fields at this Station were brought under cultivation in 1920 for the seed Service, vine growing, tobacco, the Biological Institute of Agricultural Defense and the Agricultural College.

The Station has sent out 13 209 orange and 444 mango grafts. The Experimental Station of Patagones (Argentina) has sent this Station a collection of various European and Asiatic fruits and the material for study is constantly being added to.

There are two special sections for the cultivation of the vine and of tobacco.

Experimental researches concerning the registration and study of the best exotic varieties of vine as well as the selection and multiplication of varieties already acclimatised, have been undertaken at the Station. It will soon be possible to dispose of materials that will enable each region to be supplied according to its special conditions of soil and climate. Special arrangements have been made to expedite the control of phylloxera and diseases of the vine.

The nursery contains 30 000 vine stocks of 52 of the best varieties.

In addition to the introduction of exotic varieties of tobacco, the

Station is also working on the improvement of indigenous varieties by selection and hybridisation,

SERICULTURE. — An Experimental Station for Sericulture. has been instituted at Barbacena, with the object of organising an important movement in favour of this branch of production.

MOTOR CULTIVATION. — Owing to the scarcity of labour, the Government recommends and facilitates in every way the general use of mechanical ploughing. Regarding the purchase of agricultural machinery generally, of selected seeds, insecticides and fungicides, the Government provides the farmers with these articles at cost price.

LIVE STOCK AND BREEDING. — By means of special credits the Government helps and facilitates the importation of well-bred animals for breeding purposes; a large number of first class animals has thus been distributed to Zootechnical Institutes, in accordance with the environmental requirements of the different States.

In 1920, the Zootechnical Institute of Pinheiro sold 44 bulls (of which 36 were bred by the Institute), 11 donkey stallions, 214 boars, and 22 rams.

The Zootechnical Institute of Lages and the Experimental Demonstration Estates in Santa Marca and Ponta show similar activity and have developed similarly.

To facilitate State work, a suitable subdivision of work of a technical and fiscal character has been provided for the Service of inspection of meat and its derivatives, the cattle trade, milk and its derivatives, protection against disease, etc.

Work and researches with the object of obtaining immunity against babesiosis are strenuously carried out; experiments have been made on 239 animals (of which 122 belong to the State) and only 7 (2.95 %) died under treatment. Important centres of epizootic disease have been removed and the infected regions in the States of Minas Geraes and Rio Janeiro have been reduced to very small areas Owing to the recent re-organisation of the Directorship General of Zootechnology, the Government will in future be quickly informed of cattle disease, so that such prophylactic or therapeutic measures as may be necessary can be at once applied.

HYGIENE AND PUBLIC HEALTH. -- The Federal Government, in co-operation with the different States of the Republic, is organising in a most up- to-date manner the Services which have for object the isolation and extinction of epidemic foci. Thus isolation hospitals and sanatoria for tuberculosis, leprosy and venereal diseases have been instituted. The Oswaldo Crus Institute merits special mention in connection with the study of tropical diseases; yellow fever is almost extinct.

In rural centres the work of prophylaxis and treatment was amalgamated and centralised by means of agreements between the Governments of Minas Geraes, Maranhão, Parana, Pernambuco, Para, Parahyba, Rio Grande del Norte, Rio de Janeiro, Alagoas, Bahia and Matto Grosso.

Decree No. 3987 of January 2, 1920, has attached the Institute of Serotherapy to the Oswaldo Crus Institute as the technical section for the culture, preparation and supply of vaccines and for the organisation of the sanitary Services relating thereto.

During the first quarter of 1920 the Institute has furnished the Health Department with 183 000 tubes of vaccines.

701 - **Spontaneous Sulphuretted Hydrogen Fermentation: Effect on Seeds of Leguminosae and Digestive Troubles Caused by Poisoned Flour.**— See No. 706 of this *Review*.

CROPS AND CULTIVATION

702 - **The Influence of Temperature and Rainfall on the Yields of Certain Kinds of Wheat at Svalöf and Ultuna, Sweden. — Recent Development of the Organisation of the Service of Agricultural Meteorology in Sweden.** — WALLÉN, A., in *Geografiska Annaler*, Year 1920, Part. IV, pp. 332-357. Stockholm, 1920.

Results of a series of observations on the course of meteorological factors, the growth, and yield in grain and straw of Sammetsvete, Bore and Grenadier wheats at the two Stations of Svalöf and Ultuna.

Sammetsvete (Svenskt Sammetsvete) is a selected indigenous Swedish wheat (Svenskt Landvete); it is noted for its great resistance to winter cold, which enables it to give satisfactory crops even under very severe climatic conditions. It is also very early but it has the defects of weak straw and poor resistance to rust.

" *Bore* " *wheat* (Borevete) originated from English wheat cultivated at Svalöf. Though not so resistant as the indigenous wheat to the rigours of winter, it is, however, sufficiently so, as to permit its flourishing in those regions of Sweden that are south of Mälar. Its straw is strong, it ripens late and has poor resistance to rust.

" *Grenadier* " *wheat* is a selection from the English wheat " Shiriff ". In strength of straw and date of ripening it does not differ from " Bore " wheat which it resembles also in its susceptibility to rust: it stands cold badly and suffers from it even in the most southern districts (Scania).

Statistical data regarding the production of grain and straw are available for the following periods:— *Sammetsvete* 1890-1917 (at Svalöf), 1897-1917 (at Ultuna); *Bore* 1896-1917 (at Svalöf), 1897-1917 (at Ultuna); *Grenadier* 1895-1915 (at Svalöf).

Regarding meteorological figures, temperatures and rainfall have been registered from one month of August to another; the data have been taken from the records of the meteorological Observatory of Lund, the nearest to Svalöf, and the records made at that station have been used for Ultuna.

TEMPERATURE AND YIELD IN GRAIN. — If the coefficient of correlation between the yield in grain and the temperatures of different periods is calculated, it appears that, for a good harvest, low temperature in autumn and high temperatures during the rest of the growing season are required.

The negative correlation between the autumn temperatures and the harvest (September and October) becomes positive at Ultuna (+ 0.34 for Sammet and + 0.26 for Bore), whilst at Svalöf the negative values are always rather high (— 0.37 for Sammet, —0.41 for Bore, and —0.30 for Grenadier). This different behaviour is explained by the fact that sowing is much later in the north than in the southern districts and that September and October temperatures are required to ensure good growth of the young plants before winter. On the other hand no such need is felt in Scania where the temperatures are always high. In August the coefficients are always negative both at Svalöf (—0.27 for Sammet) and Ultuna (—0.36 for Sammet and —0.21 for Bore), and the same is the case for the months of November and December (Bore and Grenadier wheats with positive coefficients. but very low ones, constitute exceptions at Svalöf). It is not easy to explain the negative correlation between the autumn temperatures and the harvest. NILSSON-EHLE, in his work entitled " Good and bad years for wheat in Scania ", asserts that excessive heat during the first stages of growth induces luxuriant growth which predisposes the plant to the attacks of *Leptosphaeria herpotrichoides* and to lodging.

In the months of January and February there are positive coefficients which are sometimes very high :— At Svalöf, for Sammetsvete and February temperatures + 0.33 ; for Bore + 0.51 ; at Ultuna, + 0.17 for Sammetsvete and + 0.49 for Bore. These data also show the greater resistance of Sammetsvete to low temperature. The temperature of the months March and April, when winter passes into spring, is very important for the growth of the plants as can be seen from the positive values, sometimes very high, of the coefficient of correlation, especially at Svalöf.

At Svalöf :— April temperature and yield in grain of Bore wheat, $r = + 0.49$; of Grenadier wheat, + 0.17 ; March temperature and yield of Sammet wheat, + 0.28.

At Ultuna the coefficients are lower : — March and Bore, + 0.30 ; March and Sammet, + 0.20.

High temperatures in winter and spring are therefore very generally favourable to grain ; the coefficients of correlation do not, however, enable the different eventual behaviours of each variety to be determined.

For the months of May and June the coefficients of correlation are nearly all positive, especially for Bore (+ 0.66) and Grenadier (+ 0.62) at Svalöf At Ultuna the coefficient for Bore is negative

The most important period is, according to NILSSON-EHLE, that which follows immediately after the flowering stage, at the end of June or the beginning of July ; high temperatures at that period would have a very favourable effect. But that point does not seem to have received any certain confirmation from the present series of observations ; the coefficients of correlation between the yield and the July temperature are low and often of contrary signs. Thus Bore gives $r = + 0.32$, while Sammet gives, for the period 1896-1917, $r = —0.16$.

Perhaps higher correlations relating to shorter periods might be given, relative to each stage of vegetation ; but for that phenological information is lacking.

RAINFALL AND HARVESTS. — The influence of rainfall on the yield in grain appears through a series of rather low coefficients. However, for the Bore and Grenadier varieties, if reference is made to the rainfall of October at Svalöf, positive coefficients worth noting are found (+ 0.27 and +0.41 respectively), while for Sammet the coefficient is negative, though very low. For Sammet and Bore the correlations are positive with January and negative with April and May; the latter result agrees with NILSSON-EHLE's opinion that wheat does not mind a dry spring on good soils, but is rather injured by rain and excessive moisture in spring and the beginning of summer, which tend to lodging and the development of disease (*Puccinia glumarum* and *Leptosphaeria herpotrichoides*).

At Ultuna, the phenomena appear in a slightly different form; a high negative coefficient for December rains (Sammet —0.54 and Bore —0.55). This is perhaps due to snow lying on soil not yet frozen.

For January, there are positive coefficients as at Svalöf; then, contrary to what happened at Svalöf, positive coefficients also in May; it appears therefore that a dry spring is felt more at Ultuna than at Svalöf.

To sum up:—

1) For a good yield of grain at Svalöf low temperatures from August to November are required; at Ultuna, however, that cold period should be broken by high temperatures in September and October.

2) High temperatures in winter and spring give positive results in both places.

3) At Svalöf, rainfall in November and December has no noticeable influence on the harvest, whereas at Ultuna it is decidedly injurious.

4) Abundant rainfall in spring and summer is rather injurious at Svalöf and very favourable at Ultuna.

Regarding the behaviour of each variety, it has only been possible to define it very slightly. At Svalöf:—

1) Heavy rainfall in October would suit Bore and Grenadier, but would be detrimental to Sammet.

2) High winter temperatures have a much more marked positive effect on Bore than on Sammet (the same is true at Ultuna).

3) Grenadier stands rain and excessive moisture in spring much better than Bore and Sammet.

However, the results of these researches are insufficient to enable accurate indications of the character and behaviour of each variety to be formulated: data relating to the most important stages of the vegetative period, with the help of which the relationship between the plant and its environment would be more clearly indicated, are completely wanting.

Hence the necessity of observations on the growth of the plant in open fields and the course of meteorological factors It is with that object that the author has begun in Sweden, with the cooperation of the "Sveriges Allmänna Lantbrukssallskap" and on the lines indicated by Prof. AZZI, to collect bio-meteorological observations relating to each variety of the more important species of cereals, helped in this work by farmers and agronomists.

The information collected at the Central Office of Meteorology and Hydrography is afterwards completed by the addition of those meteorological data which are most important for the growth of plants.

The following forms are so used for autumn wheat in Sweden:—

Autumn report for the commune of . .
Province of . . . . Owner

In this way the Central Office will collect all data required for replies to the questions contained in Prof. Azzi's international forms and these forms will be filled up for Sweden at the Central Office of Meteorology and Hydrography at Stockholm. The whole of this work must facilitate the study of problems in agricultural meteorology, help in solving them and contribute to the development of the new science, agricultural ecology.

703 - **Study of the Bacterial Flora of the Soil.**— I Bargagli-Petrucci, G., in the *Atti della R. Accademia dei Georgofili*, Year CLVIII, Vol. XVIII, Part I, Scientific section pp. 37-46. Florence, Jan. 1921 — II Meeting of March 13, 1921. *Ibid.*, Historic and official portion, pp XVII-XVIII.

I. — At the Third Congress of the "Società italiana per il progresso delle Scienze", in 1913, the Section of Botany passed and presented to the general meeting the following resolutions:—

"The Congress, considering that the bacterial flora of the soil has a most important influence on both wild and cultivated vegetation by the changes and the chemical and physical action which it is able to produce and exercise; considering also that the bacterial flora may vary profoundly under the influence of the geographical, geological climatic, physical and chemical conditions of the soil, expresses the desire that a systematic and accurate study of the bacterial flora of the various soils in different regions of Italy and of the Italian Colonies shall be undertaken, in the interests of science and of national and colonial agriculture."

Referring to this resolution, the author explains briefly, with examples, the importance of the bacterial flora of the soil and of its geographical distribution. He remarks that the whole civilised world abounds at the present time in astronomical, meteorological, geodynamical observatories, etc, which make their observations in a systematic manner while keeping close and constant relations with each other, the first with the object of compiling, by means of well-organised collaboration, the map of the heavens, the second for registering the rainfall or the wind, the third for analysing the movements of the earth's crust; work so organised becomes infinitely more useful than the greatest effort that one of these institutions could accomplish alone. Why should not the same be done in the domain of microbiology?

The problem might be stated practically in the following way:—

1) To study and establish relatively simple and practical methods which will enable indications to be furnished regarding the different biochemical forces in soils (nitrifying, denitrifying, ammonifying, oxidising or reducing).

2) To examine, by means of these methods, the largest number of soils in the most diverse conditions, taking care to keep an exact account of these conditions.

3) To sum up and co-ordinate the data collected so as to draw from them general conclusions and practical rules that may be of use to agriculture.

The first and the last parts should be entrusted to an Institute of to a Laboratory which would fulfill the functions of a central office (and it is by the creation of such an organisation that a commencement should be made), which would decide the methods to be adopted, formulate the most important questions to be solved and then collate the data collected so as to draw from them suitable conclusions. The second part should be entrusted to the greatest possible number of institutions and even of individual specialists, who would undertake to carry out the researches indicated, by means of the methods adopted and with scrupulous precision.

II. — In the discussion which took place on the subject of BARGAGLI-PETRUCCI's paper the President expressed the desire that the International Institute of Agriculture might help in the realisation of the proposed programme and the meeting ended by the nomination of a Committee to study the question thoroughly.

I. CARBON DIOXIDE AND PLANT GROWTH. — BORNEMANN states that the weight of the crop depends very much on the production of carbon-dioxide (CO_2) in the soil. and that market-garden crops only get their carbonic food by assimilation of CO_2 produced in the ground through the leaves and not from CO_2 present in the air, in the average proportion of 0.03 % by volume. The greater the bacterial activity in the soil, the greater the production of CO_2 and the stronger the current from the soil to the leaves. That activity in favoured by the number of times the soil is worked and by organic manuring. If the above-ground, gaseous, supply through the leaves is greater than the underground mineral supply through the roots, the plant is forced to store up reserves (starch, sugar, etc.) or to form organs which consume more especially carbon (C), such as flowers. If, on the contrary, the underground supply is greatest and more especially the supply of nitrogenous material, the plant forms organs whose construction requires plenty of nitrogen, such as leaves, leaf-buds, chlorophyll-containing parts. Variations in lighting and in in the supply of water or CO_2, according to the periods of growth in which the plant happens to be, suffice, according to BORNEMANN, to lead the crop in one direction or another so as to give a greater yield. Leguminous plants, potatoes and root crops only give high yields, if they are under high carbonic pressure ; the author deduces from this their preference for organic soils. In these crops the supply through the roots should first be increased by an abundant supply of nitrogen and water, until great leaf surface is developed ; after that up to harvesting, supply through the roots should be restricted and supply through the leaves increased by means of weeding and sparing use of nitrogenous manures and watering ; it is only in this way that heavy crops of beet can be obtained.

Cereals use the soil chiefly in the earlier stages of growth. BORNEMANN states that tillering is affected by a high carbonic pressure, but when the stalks begin to lengthen (" Schossen "), and the leaf surface decreases with diminished carbonic pressure, the aerial supply also tends to take the lead because of the progression of the season and of the lighting. But to bring to complete maturity all the numerous ears the supply through the roots must always be kept ahead of the aerial supply until the commencement of maturation, by means of a cover dressing of soluble salts (1).

---

(1) It is, however, known that at least in southern countries, cover dressings of nitrates in late spring, very often decrease the grain yield of cereals (*Ed.*)

The ratio of the two alimentary factors is not easy to regulate in the case of oilseed crops.

Leguminous plants, owing to the ease with which they obtain their requirements in nitrogen, water and mineral substances by symbiosis or by the effect of their powerful root systems, make the best use, according to the author, of high pressures of CO_2, the reason why the periods of growth are shortest when the production of CO_2 in the soil is highest. If the carbonic pressure is increased, the first flowering is earlier and more numerous and the stalks are shorter.

According to BORNEMANN these conclusions are experimental and the author gives an account of some of them.

A fine, calcareous, clay-loam soil, which produced only 1 to 2 litres of CO_2 per square metre per day was covered by a close-meshed wire frame, to prevent damage by birds; under the cage a rectangular piece of earth was loosened which ran longitudinally east to west and was 1 50 metres wide; it was subdivided into 12 plots 84 cm. wide. A special system of metal tubing, placed level with the surface of the ground and formed of tubes pierced with small holes placed in the middle of the plots and attached to a orthogonal collector, served to distribute the gas to the 6 plots on the east only. Each pair of plots, one of which received gas and the other none, was cultivated as follows:— 1 and 1′ winter wheat, 2 and 2′ oats; 3 and 3′ Victoria peas, 4 and 4′ barley; 5 and 5′ broad beans; 6 and 6′ white mustard. Nutrient solutions were applied during growth, and the ground was kept constantly moderately moist, free from weeds, raked and hoed. The distribution of CO_2 through the system of tubes commenced on April 7, 1919 after the stalks had lengthened, and was continued without interruption up to the following July 13, 10 hours a day with 68 gm. of CO_2 per square metre, that is to, say to the extent that good organic manuring, would provide, theoretically, in decomposing.

The distribution of gas to the wheat commenced after tillering. When the stems began to increase in length, the leaves of the wheat which had been given gas measured 3 to 4 cm. more in length; the stems were thicker and, consequently, the ears were larger and thicker. The lodging of this wheat took place 8 days late.

The ratios between the yields of the treated and untreated plots at harvest time are given in the following table:—

The author remarks that the yield of wheat which was treated with gas would have been greater if the distribution of the gas had commenced earlier and if the supply through the roots had been more abundant. As regards the oats and the barley also, the author thinks that the supply through the roots was insufficient both in proportion to the greater leaf area and to the stronger pressure of the carbonic acid gas (1).

---

(1) These experiments have been described by BORNEMANN himself in his recent work *Kohlensaure und Pflanzenwachstum*, p 84 Berlin, Parey, 1920 (*Ed*)

	Wheat	Barley	Peas	Beans	Mustard
Total weight of plants	1.28	1.40	1.28	1.59	1.49
Total weight of seed	1.20	0.82	1.34	1.76	1.23
Total number of ears	1.02	1.29	—	—	—
Weight of grains of one plant .	—	0.94	—	—	—
Weight of grain in one ear . .	1.19	0,73	—	—	—
Number of seeds per pod . . .	—	—		1.13	—
Weight of one pod	—	—	—	1.26	—
Weight of seeds from one pod.	—	—	—	1.44	—
Weight of 1000 seeds	1.14	—	1.12	—	1.15
Weight of one hectolitre. . . .	1.024	—	1.04	—	1.02

BORNEMANN further concludes that :— 1) The formation of badly nourished grains "Schmachtkorn,, does not depend on an excessive supply of nitrogen but on an excessive supply of carbonic acid, especially during tillering; 2) the more humiferous and active the soil, the greater the production in it of CO_2, the more extensive is the tillering. and the greater the need of dressings of mineral fertilisers (nitrogen included) and in larger quantities than is usual; 3) if the supply through the roots is endangered, owing to drought or other causes, all agricultural operations which favour tillering should be avoided. This new idea furnishes a perfect explanation of many contradictions which are noticed in practice.

Leguminous plants make the best use of farmyard manure as a source of CO_2; the author therefore considers that they should be grown with a mixture of farmyard manure and fertilisers. Next to the leguminous plants come plants with oleaginous seeds.

II. RECENT RESULTS OF CARBONIC MANURING. — FISCHER related the results obtained, in 1919, in the carbonification field installed by RIEDEL at Horst, in the Ruhr district (1). It should be noted that carbonication was interrupted and that the plots treated were on the worst soil.

In spite of that, mangolds treated in the open with carbon dioxide produced, for the first crop 1.7 times more than those not treated and 1.46 for the second crop, fennel 1.36, sugar-beet 1.52, soy bean 1.15 to 3.08, *Lupinus termis*, a plant as yet little known but of appreciable value, 2.52; haricot beans, 1.48. Under glass the tomato gave 3.67 for the early partial pickings and 1.47 for the total crop.

FISCHER states that carbonication produces its maximum effect when all the other factors of production are increased and consequently the fertilisers also; that agricultural gas plants for non-biological CO_2 are only possible near factories; that, for ordinary agriculture, biological CO_2 must be used, produced by the organic matter in the soil, according to BORNEMANN. However, the experiments made by HORST prove that

---

1) See *R.*, June 1920, No. 626. (*Ed.*)

the actual content of CO_2 in the air does not constitute an optimum for crops.

III. GASSING PLANTS WITH CARBON DIOXIDE — CLAASSEN criticises the partisans of carbonic manuring; he does not deny the facts but he does not see by what means industrial, non-biological carbonication can be applied to farming on a large scale. The author believes that, in the experiments hitherto made, the difficulties of purifying and distributing CO_2 resulting from the iron and steel industry have not been sufficiently considered, whilst the additional value of the increments of production is exaggerated. He considers that the increased yield would not cover the costs of interest and amortisation of the purifying apparatus, fans, and the systems of piping for supplying the gas and the cost of working them.

He states that the whole of the CO_2 available in Germany would only suffice for gassing 270 000 hectares and that, consequently, the method could only be applied to farming on a small scale and under glass, while for farming on a large scale the increased carbonic pressure and, consequently, the increased crop, could only be obtained by means of organic manuring, irrigation and suitable preparation of the soil (1).

REINAU, replying to CLAASSEN states, that what he calls "automatic" carbonic manuring, that is to say derived from the decomposition of organic residues in the soil, is certainly the most practical method. REINAU is therefore in agreement with BORNEMANN, who is now studying, with the firm of LANZ, the degree of activity of that decomposition by means of rotary tillage of the soil. But he points out that by taking some trouble the blast-furnace industry could furnish for many weeks pure CO_2 in sufficient quantity.

Regarding the high cost of installation of the distributing pipes. REINAU thinks that the fields for utilising the Berlin sewage (" Rieselfelder ") would require a much greater expenditure than RIEDEL has calculated for gassing. He further expresses the opinion that if the State, for reasons of hygiene, contributes to the cost of agricultural distribution of residues of sewage, it might, for the same reasons, contribute to the cost of installing tubes for delivering CO_2.

REINAU also quotes his previous work on the action of wind with reference to carbonic manuring.

BORNEMANN also replies to the remarks of CLAASSEN; he declares that he has no doubt that gassing with industrial CO_2 will cause an increase, even of 100 %, in the crops, but that at present it is a matter for technicians to solve the problem in the best way. In the present state of affairs non-biological gassing should be limited to kitchen-gardens and gardens, while farming on a large scale only has at its disposal automatic (biological) gassing, for which it is necessary to make a study of the best means to obtain an increased production up to 100 %. It is not possible to deduce from the results of laboratory experiments, as CLAASSEN has done, that, to gas 1 hectare, 100 tons of CO_2 are required, because in the open the economy of CO_2 would be greater. Experiments made on sugar beet, mentioned by BORNEMANN in his recent work, show, on the contrary, that the yield of sugar per ha. can he doubled, and with a good economic result (1).

---

(1) This part of CLAASSEN's criticism has been translated in *Sucrerie, Distillerie, Industries agricoles*, Year 1, No. 1, p. 20. Paris, March 1921. (*Ed.*)

CLAASSEN replies to these remarks that small-scale experiments should be given up, and that it is not right to charge the State with a portion of the expenditure on the pipes. The opinion of BORNEMANN should also be confirmed by repeated experiments on a large scale, all the more as it appears difficult to procure the large quantities of organic manure required.

IV. CARBON DIOXIDE AND PLANTS. — This is a criticism of the recent work published by REINAU (2) RIPPEL denies the practical importance of artificial distribution of CO_2 to plants. It is true that according to MITSCHERLICH, PFEIFFER, and KREUSLER the CO_2 of the air may become a minimum factor, but RIPPEL avers that generally it is not so, since in the last 10 years the relative crops have everywhere increased without gassing and merely by increasing the soil content of nitrogen (N), phosphorous (P), potassium (K) and water (H_2O). Furthermore, REINAU furnishes no proof that carbonic gassing alone increases the crop and as it has not been proved that the CO_2 plays a special rôle, it should only be classed in the category of factors of growth below the optimum.

REINAU thinks that carbonic endosmosis is caused in the leaf, according to physical laws, by the slight potential difference between the partial carbonic pressures outside and inside the leaf, but RIPPEL affirms that carbonic assimilation is regulated by light which is the effective cause of it; it is therefore the plant which regulates the potential difference and not *vice versa*. Physiological phenomena are not explained by physical laws alone.

It would be fantastic, according to the author, to try to deduce from the results of laboratory experiments that the increase of the percentage of CO_2 in the air from 0.0300 to 0.0302 % would cause an increased yield of 20 % in a crop grown in open fields.

---

(1) The author refers to field experiments made in 1917 by SCHULZE, on the advice of BORNEMANN, in Westphalia, in a very rainy district, on 4 ha. of land under intensive cultivation, with a tendency to compactness, but poor in colloids and rich in very fine sand. The experiment was to determine whether with an abundant mineral manuring (including nitrogen), a heavy application of farmyard manure resulted in a large increase in production when the farmyard manure was dug in superficially shortly before sowing and then submitted or not to rapid decomposition by means of rotary tillage with a LANZ "Agricultural motor". The crop on the land thus tilled gave 416 quintals of potatoes against 352 quintals on land tilled, that is to say where the manure had not been unearthed. Sugar beet gave respectively 528 quintals of roots with 17.9 % of sugar against 292 quintals with 16.4 %. See F. BORNEMANN, *Kohlensaure und Pflanzenwachstum*, pp. 101-102. Berlin, Parey, 1920. (*Ed*)

(2) E. REINAU, *Kohlensäure und Pflanzen. Ein Beitrag zur Kohlenstoffdungung der Pflanzen und ein Versuch zu einer geophysischen Pflanzenphysiologie.* Halle, Knapp, 1920. See the reviews in *Biedermann's Zentralblatt*, 1920, p. 252 and in *Chemiker Zeitung*, 1920, p. 208. (*PT*)

RIPPEL concludes from this that further experiments with carbonic manuring are necessary, which will not become a pressing matter until growth due to N, P, K and H_2O in the soil has reached the optimum limit, a condition which is far from realisation.

V. OPINIONS ON THE PROCESS OF CARBONIC MANURING WITH WASTE GASES. — RIEDEL refers to his previous experiments and then criticises the preceeding remarks of CLAASSEN.

He avers that it is possible to get pure gas from blast furnaces, and that large installations of tubing for conveying the gas supply are no more difficult than for water supply, lighting, etc. HORST'S experimental field for gassing which had an area of 30 hectares was fitted up industrially; since manifest indications of gassing can still be seen on the edges of this field it follows that in practice the area to be gassed can be as extensive as is desired. The distribution of gas can easily be regulated and rendered uniform during the day and an excessive concentration injurious to the crops is not to be feared Experience will show what degrees of concentration are most useful.

The economic expediency of these gas pipes in agriculture is most favourable, especially near blast furnaces situated at a lower level them the fields to be gassed. In the neighbourhood of foundries there is also, the technical and economic possibility of gassing thousands of hectares, at a cost to the farmer of only the main pipe, the distributing pipes and the cost of establishment. But economy is not compromised even in the case of large fields separated from the factories by several kilometres of piping. The branch pipes 25 m. apart and 100 m. long only require 100 m. per *morgen* (¼ of a hectare) of cement piping of 10 cm. diameter, and with some petty repairs they will almost last for ever.

The power required to force the gas through the pipes is also moderate if provided by a fan and almost nil (in cost to the farmer) if done by large gas machines.

RIEDEL states that if lupins treated with gas are worth, green, 2.7 times the value of non-treated lupins, in a dry state they are worth 2.9 times the value of non-treated lupins. Thus, BORNEMANN obtained, with mangolds, 85 % increase in roots as well as an increase of 1.5 % of sugar. Gassing therefore makes the root less watery and more savoury.

The author agrees with CLAASSEN and BORNEMANN as to the necessity of encouraging automatic carbonication of soils, but it cannot be denied that pipes for carbonication already work successfully where conditions are favourable and their use should be extended.

Appreciable results will have been obtained if only a few hundred thousand hectares in Germany are treated with gas (1).

---

(1) BAGERON, who has translated and annotated RIEDEL'S experiments, thinks that the experiments should be repeated in France near factories in Lorraine, Normandy and in the Pyrenees Cf *La Vie agricole et rurale*, Year 10, Vol. 18, No 6, p 85 Paris, Feb 1921,

VI. CARBON DIOXIDE AND THE GROWTH OF PLANTS. — BORNEMANN affirms that from experiments made by hims elf and by others it has been shown that well manured and well cultivated soil furnishes more CO_2 than the same soil not manured and badly cultivated. He tries to prove that the greater fertility of the former is due, at any rate in part, precisely to its greater production of CO_2. Soil and experimental arrangements were as in the previous experiments of the same author, the plan of which is given in the text. However, the carbonication is not automatic; it is obtained in the regular method (from non-biological sources) by means of pipe distribution. There was no variations in the conclusions whether the experiments were made with peas, oats, barley, potatoes, onions or turnip-cabbage; they were invariably in favour of non-biological carbonication, which gave increased production which, in the case of onions, reached 210 % (1).

VII. CARBONIC NUTRITION OF CULTIVATED PLANTS. — PFEIFFER, wishing to criticise BORNEMANN'S conclusions made pot experiments from which he concluded that large yields can be obtained even on pure sand without any organic matter and consequently without any CO_2 from the soil.

BORNEMANN observes that results from pot experiments cannot be applied and generalised to hectares by transforming into an *area* of ground small *spaces* occupied by plants. Moreover his experiments on 3 growths in pots, the 1st with air to which CO_2 was added, the 2nd with ordinary air and the 3rd with air from which CO_2 had been abstracted, have shown that, in the first case the plants grew rapidly, accumulated carbohydrates at an early stage or flowered abundantly but formed a their root system; in the second case the epigeal portion of the plant behaved as in the first case, but in a less degree, whilst the root system was ample; in the third case, the growth was purely vegetative, without accumulation of any reserve material, without flowers or lignification in the stalk; the leaves were large but delicate in texture; the root system is still larger and, in the oat, it even developed in the air. These phenomena are due, according to BORNEMANN, to the different nutritive ratio, nitrogen : carbon (N: C) and they could be used analytically.

As it is certain that the plant can profitably assimilate a larger amount of CO_2, the question lies in the way it is to be supplied. The author begins by abandoning all idea of using industrial carbonication, as proposed by RIEDEL, in farming on a large scale, and he thinks that the great practical problem can only be solved by the help of biological carbonication.

JESS also draws attention to the same subject in France. Cf. *Journal d'Agriculture pratique*. Year 85, Vol. 12, No. 12-13. Paris, April 1921. (*Ed.*)

(1) GEHRING comments favourably on these experiments of BORNEMANN and states that by their simplicity and clearness they again prove the great importance of carbonic manuring and that these results are also confirmed by his own experiments made in the summer of 1920. Cf. *Zentral-Blatt fur die Kunstdünger-Industrie*, Year 26, No. 2, p. 13. Frankfort-on-Maine, Jan. 15, 1921.

Certainly the present state of agricultural science does not enable the high positive function of the increase of carbonic pressure to be completely explained, but there are plenty of things which science cannot yet explain; science has not, up to the present explained the relationship between root respiration and leaf turgescence or assimilation. This root respiration and the production of CO_2 which results from it, as well as the influence which the mechanical structure of the soil exerts on it, may explain phenomena the reasons for which are at present unknown In an experimental culture of hemp made in Westphalia, in rotary-tilled soil, one plot was rolled before sowing in lines, the other after sowing; in both cases a light harrowing was given directly after sowing In the rolled plot the height of the hemp was 40 cm. less than in the plot not rolled. The author asks what is the cause and adds that although treatises on plant physiology furnish plenty of information about root respiration, an experment throwing light on the relationship between assimilation and such rules of cultivation, apparently of slight importance, muy be looked for in vain in them.

It appears to BORNEMANN that root respiration deserves special attention in the cultivation of root crops. The amazing increase in production obtained in the experiment with sugar beet (referred to above) was attainable because all factors of nutrition both of root and leaf were at an optimum and because rotary tillage, by producing a very high degree of porosity in the soil, did not permit of any reduction in the assimilation of carbon dioxide through the leaves which otherwise would have resulted from a reduction of root respiration. The author is certain that the sugar beet would give much higher yields in Saxony if, when preparing the fields, the carbonic nutrition and root respiration of the plants were kept in view.

VIII. CARBONIC FEEDING OF CULTIVATED PLANTS. — The same author repeats the objections which he had previously made regarding the pot cultures made by PFEIFFER, and he also replies to the remarks made by RIPPEL and AEREBOE by the arguments mentioned above He adds that he has previously shown that, in order to tiller, the plant should have in its organism a certain excess of assimilated material; this is why in shaded places oats do not tiller well if the soil does not produce CO_2. If the latter is wanting there is no tillering and the plant then develops a single good stem with a single good ear. If the CO_2 in the air is increased the plants are compelled to tiller and they do not accumulate any reserves for further stems so long as new buds are not formed. If, after tillering, the plant only finds the ordinary reserve atmospheric CO_2 it only develops stems from the principal buds that are shorter than the solitary stem of the plant which does not tiller. Thus, according to BORNEMANN, it is possible, by regulating the carbonic supply in a suitable manner, to regulate tillering, and the length, thickness and number of stems.

To study these phenomena of carbonic nutrition, the author recently made use of a prismatic glass box with a square section and moveable sides, the base of which was provided with a wooden frame which could be fitted to the top of a pot. The dimensions and an illustration are given in the text.

The author thinks that the following conclusions may be drawn from experiments made with this novel apparatus on Victoria peas:— 1) non-biological gassing was the controlling factor of the highest yield; 2) in pot experiments, production is also a function of the distance and the order of arrangement of the pots; 3) early death of the lower leaves is due to want of CO_2 and not to want of light; 4) it is confirmed that increasing the amount of CO_2 in the soil causes important increases in the yield.

IX. CARBONIC FEEDING OF PLANTS. — GODLEWSKI, KREUSSLER, and other writers have shown that the actual air content of CO_2 is not an optimum (1). Later, other investigators have expressed the opinion that the importance of the N, P and K in artificial manure ought to be attributed to CO_2. LEMMERMANN admits the certainty of increased production by non-biological industrial carbonication, but he considers that this method is suitable for glass houses and very valuable plants.

Regarding the opinion of BORNEMANN, that farmyard manure and green manuring are less useful to cultivation on account of their content in solid nutritive principles and the improvement which they make in the physical state of the soil than on account of the production of carbon by the CO_2 which they provide, its acceptance would lead to the conclusion that manuring should be done shortly before sowing or as a dressing for cereals; for example the best time would be when tillering commences. However, BORNEMANN does not prove this experimentally, and it is deduced from his carbonic theory, which equally lacks proof.

LEMMERMANN and his fellow-workers have never observed, in their pot experiments, a perceptibly greater production of CO_2 in manured pots than in pots that were not manured. At best they noted a daily production corresponding to 378 gm. of CO_2 per hectare in place of the 9 kg. which a manuring with 400 quintals should theoretically produce, allowing, for the first year, a decomposition of 25 %. In the open fields things occur differently and it is impossible to determine with accuracy the amount of CO_2 set free from farmyard manure or covered green manuring.

Carbon dioxide diffuses very slowly in the air, and it has not been shown how much of it is used as carbonic food for plants.

The result of a preliminary experiment on turnips in pots, all treated with abundance of complete mineral manure, some with the equivalent of 400 quintals of farmyard manure or green manure per hectare, others without, has been that these supplements of organic manure have not increased production.

From a second experiment with 4 series of smaller pots, filled respectively with earth only, earth + farmyard manure, earth + green manure, earth + pipes conveying CO_2 (equivalent to 54 kg. of CO_2 per ha. per day) and buried level with the soil in another larger pot full of the same earth treated with abundance of a complete mineral manure in which turnips grew in the space between the small pots, it resulted that the yields of the

---

1) The *Journal d'Agriculture pratique* attributes to DEMOUSSY priority in researches on carbonic manuring. (*Ed.*)

4 large pots were almost identical; the action of farmyard manure, green manure and CO_2 in the small pots must therefore be left out of account in the organic synthesis of the turnips in the large pots

Field experiments with beet made in a similar way have confirmed that farmyard manure and green manure do not exercise an appreciable influence on the crop so far as the assimilation of carbon through the leaves is concerned. The question being most important, LEMMERMANN states that he intends to continue his researches.

X. CARBONIC FEEDING OF PLANTS AND FARMYARD MANURE. — GERLACH takes part in the discussion by relating new experiments made by himself and fellow-workers, at Bromberg, under glass, by charging the air with carbon dioxide from cylinders, like BORNEMANN. During the different years, the increases (+) or decreases (—) caused by non-biological carbonication of the air and expressed in % of the dry matter produced by the non-treated pots were as follows: —

1916	Oats	+ 15 to 20	1918	Salad	— 31
1917	White mustard	+ 18	1919	Tobacco	+ 5
»	Carrots	— 4	»	Maize	+ 7
1918	Blue lupins	+ 14	»	White mustard	— 25
»	Garden haricots	+ 6	»	Tomatoes	— 25

Moreover, the carbonication did not always cause early flowering.

All these results agree with those obtained by LEMMERMANN at Berlin, but they are in opposition to those of BORNEMANN at Heidelberg, which leads GERLACH to deny the practical importance of non-biological carbonic manuring.

Regarding the other opinion of BORNEMANN on the subject of the possibility and utility of biological carbonication which SCHNEIDERVIND (1) considers plausible, GERLACH recalls that, in his first report, he concluded by stating that this influence of farmyard manure has been exaggerated. Field experiments, in plots of 1000 sq. m made in duplicate at Pentkowo, on sandy clay soil, from 1900 to 1912, have demonstrated that the use of farmyard manure (150 quintals per ha) raises the production of wheat but that a stronger dressing of complete mineral manure increases it quite as much and even more; the positive action of farmyard manure should therefore logically be brought down to its content of N, P and K, and not its provision of CO_2. For sugar beet the replacement of the dressing of farmyard manure (100 to 300 quintals per ha) by subsequent dressings of mineral manures reduced the average yield of roots by 4.8 % and the yield in sugar by 7 %. But GERLACH observes that these differences come within the experimental error and that at any rate, the action of CO_2 should be excluded because the yield in leaves was, with mineral manure alone, 2 % higher than with a mixed manuring (farmyard and mineral manures). That manuring produced, it is true, higher yields for weeded plants, but no experiment proves that this was the result of the CO_2 which was produced there; it is much more reasonable to attribute these advantages of the mixed manuring, first to the N, P and K of the farmyard manure or of the green manure and to the improvement of the physical properties of the soil and, next to the gradual, slow and benefical re-stocking of substances assimilable through the roots, without running the risk of temporary but harmful, nutritive concentrations, or of abnormal reaction of the soil.

---

(1) Die Ernährung der Landeskulturpflanzen, 2nd Ed., p. 231.

Other experiments on the after-effects of farmyard manure on the same field of Pentkowo show that crops of potatoes, oats, rye, barley, wheat, in the second year, where only the chemical manuring had been repeated and which succeeded crops manured in the first year with or without farmyard manure, gave on an average, compared with unmanured control plots, an increased yield of 48 % for crops grown on plots treated the preceding year with a single dressing of complete mineral manure, and increases of 73 to 74 % for crops grown on plots treated the preceeding year both with farmyard manure plus a dressing of mineral manures and with only a double dressing of mineral manures. GERLACH does not understand how this remarkable after-effect of farmyard manure can be attributed to an abundant carbonic supply

Here the farmyard manure was applied in the usual way, but the first experiments of LEMMERMANN on the method of using farmyard manure gave results contrary to those of BORNEMANN, and for this reason GERLACH advises that fresh experiments should be made

In the present state of affairs the author thinks — 1) that it is very risky to advise farmers to use farmyard manure shortly before sowing or as a dressing; 2) that up to the present, proof that farmyard manure furnishes the leaves with CO_2 is entirely lacking.

705 - **The Use of the Ash of *Atriplex Halimus* as a Fertiliser.** — COULOUMA, J., in the *Bulletin de Pharmacie du Sud Est*, reproduced in *Bulletin agricole de l'Algérie, sie, Maroc*, 2nd Series, 27th Year, No 4, pp 66 67 Algiers, April 1921

Atriplex Halimus ("blanquette" in French and "guetaf" in Arabic), formerly restricted to the coastal belt in Languedoc, has gradually spread all over the large stretch of tertiary soil round Béziers. It is common also on the secondary soil of Montpellier (1) The ash of this plant contrary to the general rule, is not carbonated or alkaline but chloride. Round Béziers in September its analysis gives over 66 % of potassium chloride or 42 % of potassium oxide, and less than 1 % of sodium chloride. On the sea coast, the ashes of "blanquette" contain slightly less potassium chloride but they still yield 58 %.

---

(1) The habitat of this Chenopodiaceous plant includes the coastal zones of the Mediterranean, South Africa, America — G ARCANGELI, *Flora italiana*, Loescher, 1894, p 211 (*Ed*)

"Guetaf" covers large areas in Algeria "Guetaf" soil often bears five crops of hard wheat. (*Note by the Ed of Bull Agric de l'Algérie, Tunisie, Maroc*)

Potassium chloride represent $^1/_8$ of the green plant. Analyses made by the author gave :—

Ash	37.26 %	of the dried leaves.
Sulphates	0.80 %	» » »
Potash (K_2O)	42..09 %	of the ash
Chlorine	32.07	» » » »
Alkalinity as Na OH	1.90	» » » »
Potassium chloride	66.55	» » » »
Sodium chloride	0.58	» » »
Insoluble	21.20	» » »
Silica and alumina	3.63	» » »
Lime	11.80	» »
Magnesia	3.08	» »

The ashes are slightly greenish in colour, due to a metal which it has not been possible to determine.

The author recommends the introduction of this plant, which spreads very rapidly, into waste land, and the utilisation of its ash as a potassic fertiliser

706 - On Papilionaceous Seeds with Spontaneous Sulphuretted-Hydrogen Fermentation.

— MIRANDE, M., in the *Comptes Rendus des séances de l'Académie des Sciences*, Vol. 172, No. 19, pp. 1202-1204. Paris, May 9, 1921.

In a previous note (1), the author showed that seeds of *Lathyrus sativus* and *L. Cirera*, which cause the poisoning known as lathyrism, crushed and moistened with a little water underwent aften a few hours, spontaneous fermentation indicated chiefly by a fairly active evolution of sulphuretted hydrogen. Afterwards he found that this property was fairly common among Papilionaceous plants, *e. g.*:— In *Lathyrus odoratus*; all the haricot beans (*Phaseolus vulgaris*); the peas (*Pisum sativum*); the broad beans (*Faba vulgaris*) amd their varieties, notably the Kidney bean (*Faba minor*); various species of *Vicia*; the chick pea (*Cicer arietinum*); and lucerne (*Medicago sativa*).

Other species also gave off H_2S but in smaller quantity, *viz.* :— Lentils (*Lens esculenta*); sainfoin (*Onibrychis sativa*); *Trifolium hybridum*; *Ervum Ervilia*; *Anthyllis Vulneraria*; *Cytisus Laburnum*; *Medicago Lupulina*; *Robinia Pseudo-Acacia*; *Lotus Corniculatus*. Among the lupins, *Lupinus albus* gives a spontaneous sulphuretted hydrogen fermentation as intense as that of the vetches, whereas *L. luteus* and *L. varius* appeared to emit no sulphuretted hydrogen. Some other Papilionaceous plants do not produce H_2S; as for example :— *Amorpha fruticosa*, *Genista tinctoria*, *Melilotus officinalis*, *Coronilla varia*, *Galega officinalis*. The author made equiries to see whether similar facts were previously known: in 1903 GOLA (*Malpighia*, Vol. XVI, 1903, and Vol. XVIII, 1904) noted a fermentation, differing in detail from that described by the author, but also producing H_2S, in the seeds of *Acacia Farnesiana* and of a fairly large number of species of the same genus.

---

(1) See *R.*, June 1921, No. 641 (*Ed.*)

In unbroken seeds the faculty of producing sulphuretted hydrogen, whilst becoming feeble after a time, seems to endure for a long while, thus broad beans about 20 years old still gave a slight, but appreciable, emission of H_2S. The reason why peas and haricot beans do not generally cause any harm to persons eating them is because people do not eat them in a dried and uncooked state. During cooking an emission of H_2S takes place and the water in which they were boiled continues while warm and later when cold to give off H_2S. Now it is well known that food, soup for example, prepared with the water in which haricot beans have been boiled, causes digestive troubles. Peas, the split peas of commerce, have similar effects.

Fresh haricot-bean flour gives off H_2S as strongly as that of the vetches. As it gets old, the flour loses much of its power of emitting sulphuretted hydrogen ; simple contact with water vapour in the air causes slow spontaneous fermentation and loss of H_2S.

Bread made with a mixture of wheat flour and fresh flour of haricot beans showed, in spite of baking, appreciable traces of H_2S. On the other hand with haricot-bean flour exposed to the air, the author no longer found H_2S. But these facts show that feeding on bread made with haricot bean flour may cause digestive troubles.

These facts can be compared with those mentioned by CORNEVIN (*Des Plantes vénéneuses*, 1887, p. 328), relative to seeds of vetches and lathyrism: that author remarked that baking does not remove the poisonous properties of bread made with vetch flour ; the same is true of boiling. His experiments proved that in boiling the poison is partly given up by the water but not completely volatilised and that the injection of that water into an animal always causes death. On the other hand, still quoting the same author, seeds when cooked or boiled lose the greater part of their toxicity and do not cause harm if the water in which they were cooked is thrown away.

707 – **Resistance of Oil Seeds to Prolonged Heating.** — GAIN, A., in the *Comptes rendus des séances de la Société de Biologie*, Vol. LXXXIV, No. 17, pp. 887-888. Paris, May 14 1921.

Oil seeds resist high temperatures better than starchy seeds. The author has found that a temperature of 50° C. maintained for 2 months in a dry stove has no action on seeds of flax, colza and sunflower. Seeds of these plants kept at 60° C. for 1 month, after a preparatory period of 3 days at 50° C. and subsequently kept at rest at ordinary temperature for 1 month before sowing, produced plants which showed no difference fom control plants.

WOROBIEW (*Khosiaistwo*, Year 10, p. 1075, Kiew, 1915) found a delay in germination in wheat seeds that had been heated and notable distinctive characters in the morphology of the plants grown from heated seeds. The author's tests with oil seeds gave uneven results Generally, he recorded earlier germination, especially for sunflower seed, but sometimes germination was slightly retarded.

Flowering is generally a little earlier and fructification a little more advanced with plants grown from heated seeds, but the latter result was not general. The vigour of the plants is not affected. By further increasing the temperature of heating, it is evident that the less vigorous seeds may be destroyed. Thus a method of heating seeds, worked with discretion, might, in genetic laboratories, be a convenient means of improving the homogeneity of lots before sowing. Knowing the range of critical temperatures for a given seed, it would be possible to heat the seeds at a temperature *T*, for a period of time *N*, and a selection would be effected which would give, for the plants raised from the seed which resisted heating, an individual average yield in weight higher than would be the case if all the initial seeds of the lot germinated.

708 – **The Effect of Temperature Upon the Ripening of Sweet Maize.** — APPLEMAN, O. CHARLES, and EATON S. V., in *Journal of Agricultural Research*, Vol. XX, No. 11, pp. 795-805, Washington, March 1, 1921.

Sweet maize is considered ripe when the growth of the kernels ceases, and the chemical changes have nearly attained equilibrium. The maturing of the grain consists essentially in the loss of water.

The chief changes in the percentage composition of the grain during ripening are the progressive decrease of the sugars and the increase of the starch.

Changes in the composition of sweet maize during ripening
(calculated as percentages of dry weight).

	Starch	Cane sugar	Reducing sugars	Fat	Crude fibre	Total nitrogen	Protein (N × 6.25)
August 3 . .	18.36	19.55	20.07	2.90	7.92	3.33	20.81
» 9 . .	45.42	18.75	5.43	4.44	2.58	2.09	13.06
» 19 . .	60.41	5.85	1.77	6.01	2.30	2.20	13.75

In the very early stages of ripening, the reducing sugars predominate; therefore the stage of highest total sugar content does not necessarily coincide with the stage of greatest sweetness.

Calculated as percentages of dry weight, the changes in fat, crude fibre and total nitrogen occur during the very early stages of ripening, and subsequently remain fairly constant.

The rate of starch synthesis in the kernels seems to be the controlling factor for several supplementary processes. For example, the rate of movement of soluble carbohydrates from the stems and cob to the kernels, and the rate of hydrolysis of cane sugar in the kernels are both controlled by the rate of starch formation. Most of the starch that is stored in the kernels during ripening is formed from carbohydrates already present in the stem and cob when kernel formation begins.

Temperature is, without doubt, the controlling factor for the ripening of sweet maize. If two crops from the same source of seed were planted so that the first would ripen in August, and the second in the cool autumn, the late crop would require 15 days to reach the same stage of ripening as the earlier one attained in 6 days. During this period, the starch content would increase from about 2.5 % to 10.5 % in the first case, and from about 2.7 % to 10 % in the second, while the sugar to starch ratios at the end of this period would be 0.556, and 0.500 respectively.

The authors used several temperature indices in order to estimate the effect of temperature upon the ripening processes; they obtained the best results with exponential indices. Upon the basic assumption that the growth rate is unity at 40° Fahrenheit (4.44° C.), and that it doubles for each rise of 18° F (10° C.), they deduced temperature efficiency values corresponding to temperatures, in whole numbers, from 40° to 99° F. (from 4.44° C. to 37.22° C.); these efficiency values are spoken of as exponential indices.

The rate of ripening being inversely proportional to the exponential indices, a basis was furnished for an approximate prediction, from the meteorological data, of the number of days required for the maize to ripen in different localities, and at different seasons.

709 - **Grafts of the Sunflower on the Jerusalem Artichoke** (1). — DANIEL, L., in the *Comptes rendus des Séances de l'Académie des Sciences*, Vol. 172, No. 10, pp. 610-612. Paris, March 7, 1921.

It has long been known that when a sunflower is grafted on to a Jerusalem artichoke the latter produces reduced tubers but nevertheless stores inuline and becomes less vigorous in growth. It may be asked whether, as has recently been stated, the inuline thus stored is derived, exclusively or almost so, from the dextro-rotary products elaborated by the sunflower graft. If so, the amount stored by the plant in different cases should be approximately proportional to the relative growths and weights of the grafts at the end of their growth, as is the case when *Helianthus orgyalis* is grafted on Jerusalem artichokes, which, like them, produces inuline and grows in a very similar way. With the object of solving this problem, the author made, in 1920, two series of grafts of sunflowers on Jerusalem artichokes and noted that there was no proportionality between the weights of tubers produced and the weights of the grafts.

From this it must be concluded that the reserves formed by Jerusalem artichokes grafted with sunflowers are not derived exclusively or almost so from materials elaborated by the latter, which draws them back into its seed at the time the plant commences to form tubers.

The inuline of the grafted Jerusalem artichoke may originate in two ways:— 1) It comes entirely from the laevo-rotary products produced by the chlorophyll of the stock, whose action is not negligible when the stalk is 80 cm. high, and also from the action of the shoots continually formed by the stock which are difficult to suppress before they have assimilated, however carefully they are looked over; 2) or else it comes only partly from those sources and the remainder from the movement of the reserves of the original tuber, which then behaves similarly to the potato, forming small tubers at the expense of the old one consequent upon a sudden slowing down of growth or to special conditions that hinder its normal development.

---

710 - **Improvement of Certain Cultivated Tropical Plants by Selection at the Phytotechnical Station of Porto-Rico.** — BARKER, E. E, in the *Gobierno de Puerto Rico, Departemento de Agricultura y Trabajo, Estación Experimental Insular, Circular* No. 30, pp. 1-28. San Juan, P. R., July 1920

Synthetic account of selection work done, or being done, at the Phytotechnical Station of Porto-Rico. The improvement of cultivated plants can be obtained by vegetative methods, by isolating and propagating the varieties by bud, or by sexual methods, by means of selection, or by hybridisation accompanied by selection.

SUGAR-CANE. — Bud variations are fairly common in sugar-cane. Such is the origin of the uniformly light coloured " Cristalina " and of the uniformly dark coloured " Cheribón ", both derived from the light and dark striped " Rayada " The results obtained by selection are much more important; for instance P. R.-260 obtained at the Porto Rico Station. At the present moment the cultivation ot sugar-cane in the island is seriously threatened by root-disease. As a remedial measure, the author recommends crossing the variety " Cristalina " with the north-Indian variety " Kavangire " which is proof against that disease.

TUBER-BEARING PLANTS — Even a superficial examination of the products of tuber-bearing plants such as the sweet potato, the potato, the " malanga " (*Colocasia esculenta*) suffices to show how heterogeneous they are; great differences in respect of productivity, shape, size and colour of the tubers are met with in different plants. There is no doubt that it would be possible by line selection to obtain more productive and more homogeneous types.

The following process may be followed:— When harvesting, the plants which produce the greatest number of tubers are selected and kept separate; these are the most productive plants. Selection is then made according to shape and size, aiming at a type of medium size and uniform surface, without protuberances and flaws

The tubers of the plant which is most productive and unites the desiderata relating to shape, size and colour will be kept for seed. At the next harvest fresh sorting will be done and inferior specimens and those of plants which have proved incapable of transmitting their positive characters to their descendants are eliminated. The best tubers are set apart for sowing in a new " cuadro de experimentación " (experiment plot) and the remainder for ordinary sowing. This process goes on from year to year. The number of first class tubers varies each year according to the crops. The author reckoned on 500.

TOBACCO, RICE, MAIZE, COTTON. — These plants are exceedingly heterogeneous both as regards production and quality and resistence to adverse weather or to diseases due to fungi. In all these cases selection can give good results.

FRUIT. — *Citrus myrtifolia* (Chinese), Seville orange tree, mango tree, *Persea gratissima*, produce fruits very different in volume, shape, quality, quantity of seeds, sugar content, colour, structure of the pericarp and time of ripening. Some are distinguished by their heavy production, others by small production. The author insists on the expediency of fixing the characters of the best plants, which should then furnish grafts and thus give rise to new selected commercial varieties. The author, with this object, appeals for the collaboration of horticulturists in the island for discovering and describing the best trees, taking into account the earliness or lateness of ripening, the succulence of the fruit, acidity, flavour of the fruit and the number of seeds. What has already been done on a large scale for citrus trees in the United States might be applied here.

COCONUT PALM. — The plantations of this palm show very great variations between different trees; some have their leaves bent back and drooping, others have them erect, and notable differences of shape and size are also met with. In the plantations at the Station there are trees which produce 100 (some as many as 140) nuts a year, whereas others, although normally grown, only yield 5. There are also differences in the shape and size of the nuts, the size of the seed, and the thickness of the exocarp.

All these qualities can be selected and it is certain that it would be possible in a few years, by means of a series of individual observations, to identify the palms which could most advantageously contribute to the regeneration and revival of the plantations.

COFFEE. — A similar procedure is followed for this shrub, by taking into consideration the quantity and quality of the berries produced by the best shrubs, the appearance and the rapidity of growth, etc. The propagation of the best types could be effected both by seed and by vegetative methods.

Form for observations relating to the coconut palm.

BANANA. — Good results would certainly be obtained by applying these principles to the banana.

A few of the tables used for registering the agricultural and biometrical data are here reproduced to give a clearer and more detailed idea of the method adopted in carrying out the work.

For selection, Porto-Rico is a field which has not yet been worked from the stand-point of plant genetics: the results which may be derived from its application to the creation of more productive types and types more resistant to diseases and adverse weather will only therefore be all the more quickly attained and the more important.

711 - **Characteristics of Norwegian Spring Wheats Compared with those of Other Exotic Wheats, and their Improvement by Means of Selection.** — KNUT VIK, in the *Norges Landbrukshøiskoles Akervekstforsøk*, Year 30, pp. 7-36, 1 pl. Christiania, 1920.

The author first gives the results of comparative cultural experiments made with Norwegian and exotic spring wheats.

TABLE I. — *Results of a series of comparative cultural experiments of Norwegian and exotic spring wheats, during the period* 1910-1918.

Kinds	Weight of 1000 grains gm.	Weight of one hl. kg.	Duration of the vegetative period in days	Waste %	Yield in kg.	
					Straw	Grain
Børsum	29.1	78.0	112	21.6	427 kg.	105 kg.
Jekstad	—	—	111	20.4	100.0 %	103.6 %

Messel	28.3	77.6	111	20.4	98.5 »	96.7 »
østby	30.2	79.0	111	19.8	100.2 »	95.3 »
Kolbe, Svalöf	34.2	77.9	119	15.9	110.6	93.2
Kolbe, Hagendahl	34.3	76.7	123	9.4	96.9	85.2
Montana (American)	—	—	115	21.7	107.17	83.8
Macaroni (American)	43.1	81.8	116	15.3	87.9	68.9

The Norwegian wheats give yields of grain decidedly superior to those of the exotic wheats, and this is certainly due to their shorter vegetative period which enables them to grow and ripen regularly before the autumn cold commences.

There is great possibility of improvement by means of selection in pure lines, for the indigenous varieties are mainly populations constituted by distinct and constant forms.

Norwegian spring wheat belongs to the indigenous type (Landhvete):— ears rather small, flattened and ending in a point; 2-3 grains per spikelet, on an average, rarely 4 (exceptionally 5); small grains (1000 weigh 30 gm.) with a glassy fracture, coloured or not; awns smooth; stalks thin and leaves small.

There are 4 principal forms:—

1) Bearded with brown ears (Snerpet brunakset)
2) Beardless with brown ears (Snerpløs brunakset)
3) Bearded with light ears (Snerpet hvitakset)
4) Beardless with light ears (Snerpløs kvitakset).

Beardless with brown ears. — This form is grown the most. It may practically be considered as beardless, although it really has a few awns at the point of the ear. The lower half of the ear contains more grains than in the bearded types.

Some lines of this type are noted for their high production in grain, which is due to resistance to fungoid disease, especially rust, brown rust, and *Erisiphe*.

Bearded with brown ears. — Awns from 5 to 6 cm. long or more; the brown colour is much more marked than in the beardless form; the 4 or 5 lowest spikelets are rarely fertile and the 2 lowest are often quite empty; the grains are elongated and more voluminous; it tillers less stronggly than the beardless form and the yield is also less, because of its greater susceptibility to fungoid diseases.

Besides this form, which is the commonest (type *a*), there is another, also *bearded with brown ears*, with denser spikelets and a greater number of grains. The grains, however, are rather small (type *b*).

Beardless with light ears. — This also has a few awns slightly developed towards the point of the ear, but quite beardless specimens are not lacking ; the ears are short and dense, and the grains slightly thicker and shorter than in the other forms. It yields less than the two preceeding kinds, and is very susceptible to the attacks of fungoid disease (*Erisiphe graminis* and *Tilletia caries*).

Bearded with light ears. — This kind has not been much studied by the author : in the form of its grains it closely resembles the form *bearded with brown ears.*

The data contained in Table II give a precise idea of the dimensions of the grains.

TABLE II. — *Length and breadth of the grains.*

	Beardless brown		Beardless white		Bearded brown (type *a*)		Bearded brown type *b*)	
	Length mm.	Breadth mm.	Length mm.	Breadth mm.	Length mm.	Breadth mm.	Length mm.	Breadth mm.
1915	5.86	3.10	5.65	3.09	6.22	3.07	—	—
1916	5.92	3.19	5.82	3.00	6.33	3.18	6.05	2.98
1918	5.93	3.36	5.80	3.32	6.35	3.26	5.99	3.11

In selecting by pure lines the existence of forms which might be isolated and propagated with advantage has been noted for each of the principal varieties.

The results of the work of selection for the year 1919 are summed up in Table III (See page 830).

In the group *Beardless with dark ears*, the lines Tr 03 and B 04 are remarkable for their high yield and high percentage of grains. Line Tr 08 is remarkable for the flattened shape of the grain.

In the group *Beardless with light ears*, there are at least 2 very distinct forms ; A 02 is characterised by its high yield of straw and grain, by its high percentage of grain, and of large grains as well as by the weight of 1000 of its grains.

In the group *Bearded with brown ears*, ø 06 is superior to the other lines by the small number of diseased ears, in yield of grain, percentage of grain and of large grains, and by the weight of 1000 of its grains : of all the lines tested it has largest grains ; K 09 is also very different from ø 06, and E 01 is characterised by its earliness. Mo 06 and Mo 07 are derived from a spring wheat from Montana, U. S. A. ; Mo 07 has very strong straw and the author has crossed it with the indigenous Norwegian with the object of strengthening the stalks of the latter.

TABLE III. — *Results obtained with a certain number of pure lines of Norwegian spring wheats.*

	Duration of the vegetative period in day	Infected ears per 15 sq. m.	Relative productivity		Percentage of grain	Weight of 1000 grains in gm.	Result of sorting			
			Straw	Grain			1 > 28 mm.	2 25-28 mm.	3 22-25 mm.

It is at present too early to state any final opinion regarding resistance to disease and adverse weather, productivity, etc. Norwegian wheat has not many forms. However, judging by what has been accomplished up to date, the author states that it should be possible to isolate and propagate new kinds capable of yielding from 20 to 30 % more than the original varieties (populations).

712 - The Number and Behaviour of the Chromosomes in Certain Wheat Hybrids. — HITOSHI KIHARA, in the *Botanical Magazine*, Vol. XXXV, No. 410, pp. 19-24, 1 pl., fig. 2. Tokio, Feb. 1921.

Results of a series of experiments on the number and behaviour of the chromosomes (1) in the F_2, F_3 and F_4 of the following hybrids:— 1) *Triticum durum* × *T. vulgare;* 2) *T. turgidum* × *T. compactum;* 3) *T. polonicum* × I. Spelta; 4) *T. polonicum* × *T. compactum.*

I. NUMBER OF CHROMOSOMES IN THE F_2, F_3 AND F_4. — In the F_1, the number of diploid chromosomes was 35, whereas, in the F_2, there were individuals with as many as 38; the author, basing his opinion on theoretical considerations, believes that other series, for instance, 36, 37... may be found. In order to settle this question, and for the purpose of investigating the combinations of the paternal and maternal chromosomes the following determinations were made:—

1) *Number of chromosomes present in the equatorial plate during the process of heterotypic division:* In some preparations, it was possible to count the univalent and bivalent chromosomes, and even to distinguish them by their shape, size and position.

2) *Number of isolated univalent chromosomes.*

3) *Number of chromosomes during anaphasis.*

The number of chromosomes in the F_2 has been determined as follows:—

TABLE I. — *No. of chromosomes in the* F_2.

Number of plants (in parentheses)	Number of diploids	Number of chromosomes in the gametes ♂	♀	Isolated Chromosomes
T. turgidum × *T. compactum* . (6)	38	21	17	4
id. . . . (10)	32 (?)	14	18	4
T. polonicum × *T. Spelta* . . . (2)	38	21	17	4
T. durum × *T. vulgare* . . . . (4)	31	14	17	3
T. turgidum × *T. compactum.* . (3)	39	21	18	3
id. . . . . . (4)	42	21	21	0
id. . . . . . (6)	38	21	17	4
T. polonicum. × *T. compactum* . (16)	37	21	16	5

It is a fact worthy of note that in plants with the same number of diploids, the combination formulae of the paternal and maternal chromosomes are identical (See Table II).

---

(1) See *R.*, 1919, No. 1116. (*Ed.*)

The number obtained in the case of *T. turgidum* × *T. compactum* (10) is 32; but the number of preparations is not sufficient for an absolutely certain estimate. What is certain, however, is that in some cases 14 bivalent, and 4 univalent, chromosomes have been found.

The presence of one plant which was entirely fertile and had 42 chromosomes deserves special attention.

Table II gives the number of chromosomes in the F_3.

TABLE II. — *Number of Chromosomes in the* F_3.

	Number of chromosomes in the F_2	Number of plant	Number diploids	Number of chromosomes in the gametes		Isolated chromosomes
T. durum × *T. vulgare* . . .	F_2 4 = 31	F_3 4– 1	28	—	—	
		F_3 4– 3	28	—	—	
T. turgidum × *T. compactum*:	F_2 6 (1919) = 38	F_3 6– 8	(38)	21	17	4
		F_3 2– 1	38	21	17	4
		F_3 2– 4	40	21	19	2
		F_3 2– 5	39	21	18	3
T. polonicum × *T. Spelta*	F_2 2 = 38	F_3 2– 6	39	21	18	3
		F_3 2– 8	41	21	20	1
		F_3 2– 9	41	21	20	1
		F_3 2–14	39	21	18	3
		F_3 2–20	39	21	18	3
		F_3 2–21	41	21	20	1
T. polonicum × *T. compactum.*	F_2 1 = ?	F_3 1– 1	41	21	20	1
	F_2 2 = ?	F_3 2– 2	37	21	16	5
	F_2 9 = ?	F_3 9– 1	28	14	14	0
	F_2 11 = ?	F_3 11– 2	40	21	19	2

As regards the F_4, the only data for *T. durum* × *T. vulgarum* refer to the plants F_4 1-7-1 and F_4 2; the respective number of diploids is 42 and 30; the chromosomes in the gametes number, repectively, 21 from both sides, and 21 from one side and 18 from the other; number of isolated chromosomes 0 and 3

II. BEHAVIOUR OF THE CHROMOSOMES DURING THE PROCESSES OF HETEROTYPIC AND HOMOTYPIC DIVISION (POLLEN-MOTHER CELLS). In the hybrids examined, the number of paternal and maternal chromosomes was only equal in the case of tetraploids, or hexaploids (28 and 42), as is clearly shown by reference to Tables I and II.

There is no doubt that the chromosomes from the paternal side, and those from the maternal, arrange themselves in pairs, whereas the supernumerary chromosomes remain isolated.

In the heterotypic, and homotypic, divisions of the nucleus, however, the total number is always equal to the sum of the bivalent chromosomes plus the univalent chromosomes. As in the successive generations, the number of chromosomes increases or decreases (with reference to 35, this being taken as the normal), these hybrids can be divided into 2 groups.

In the equatorial plate of the increasing group, 21 chromosomes are to be counted; in the case of the decreasing group, there are $14 + i$ (i = isolated chromosomes).

The behaviour of the bivalent and univalent chromosomes in the F_2, F_3, and F_4 generations is entirely similar to that of the chromosomes of the F_1.

During the first division, the univalent chromosomes remain outside the equatorial plate, whilst the bivalent chromosomes divide and travel towards the poles. During this time, the univalent chromosomes arrange themselves so as to form the equatorial plate, and themselves also undergo longitudinal division, the two halves moving towards the poles, there to fuse more or less completely with the masses formed by the bivalent chromosomes.

Then the second division immediately takes place, during which the bivalent chromosomes again split longitudinally, whereas the univalent chromosomes divide themselves into two groups which, although belated, travel to the poles of the spindle.

III. Reduction division in the embryo-sac mother cell. — What has so far been said refers to the pollen mother-cells. It would certainly be interesting to know the number of chromosomes present in the egg cell. This it was impossible to determine. The author, however, believes that the mother cells of the embryo-sac divide in the same way as pollen mother cells. The egg cells should have $14 + i$ chromosomes ($i = 0\text{–}7$).

IV. Combination of the chromosomes of both parents. — As has already been said, the normal number of chromosomes in normal pollen grains may be theoretically represented by $14 + i$ (where $i =$ $= 0\text{–}7$). The germ cells would therefore show the following combination: —

$$\left\{\begin{array}{l}14 + 3 = 17\\ 14 + 4 = 18\end{array}\right. \qquad \left\{\begin{array}{l}14 + 2 = 16\\ 14 + 4 = 19\end{array}\right. \text{etc.}$$

provided, naturally, that no decrease in the number of chromosomes had taken place.

In order to estimate the possible combinations that can take place between the chromosome groups of the two parents we have: —

b = the number of bivalent chromosomes 14-21.

i = the number of isolated chromosomes 0-7.

$2b + i$ = the number of the diploid chromosomes.

The author estimates the number and the type of possible combinations for the diploid series at from 28 to 42. The number of combinations varies from 1 to 4. The following are some instances: —

$$\begin{array}{llllll}
 & & b + i = 14 & & & \\
 & & b = 14 & & & \\
 & & i = & & & \\
\mathbf{31} & b - i = 31 & b - i = 17 & b + i = 16 & & \\
 & & b = 14 & b = 15 & & \\
 & & i = 3 & i = 1 & & \\
\mathbf{33} & b + i = & b - i = 19 & b - \quad = 18 & b + i = 17 & \\
 & & b = 14 & b = 15 & b = 16 & \\
 & & i = 5 & i \quad 3 & i = 1 & \\
\mathbf{36} & b - i \quad 36 & b - i = 21 & b + i - 20 & b + i = 19 & b + i \\
 & & b = 15 & b - 16 & & \\
 & & i = 6 & b = 4 & & \\
\end{array}$$

Summarised we have:—

Number of chromosomes	28	29	30	31	32	33	34	35	36	37	38	39	40	41	42
Number of possible combinations .	1	1	2	2	3	3									

But in reality, all the possible combinations are not formed an examination of the descendants of the F_3 and F_4 would show that the union between gametes with a number of chromosomes above or below, 14 (or 21), gives rise to weakly embryos incapable of development.

In order to obtain normal embryos, one gamete at least (from the paternal or maternal side) must have 14 (or 21) chromosomes

V. PRODUCTIVE AND GERMINATING CAPACITY OF THE SEED OF WHEAT HYBRIDS. — In the groups in which the number of chromosomes increases from generation to generation, the fertility also increases progressively

TABLE III. — *The productivity increases with the increased number of chromosomes.*

	Number of chromosomes	Number of ears	Average number of kernels per ear	Observations
P *T. polonicum*	28	20	29.8	
T. Spelta	42	20	16.9	sown too late
F_1 (*T. polonicum* × *T. Spelta*)	35	2	7.5	
F_2 2 *id.*	38	1	10.0	
F_3 2–20 *id.*	39	4	3.5	weak growth
2–1 *id.*	38	2	9.0	
2–6 *id.*	39	3	13.0	
2–14 *id.*	39	4	15.0	
2–5 *id.*	39	5	15.4	
2–4 *id.*	40	4	18.0	
2–8 *id.*	41	4	22.75	
2–21 *id.*	41	7	26.0	
2–9 *id.*	41	2	30.0	

The number of seeds capable of germinating varies, in the cases investigated, from 42.1 to 100 %, whereas the percentage of completely developed plants is much less, being only from 12 to a maximum of 62.1 %. Some gametic combinations, although cytologically possible, give rise to embryos, and hence to individuals, incapable of normal development.

713 - **Possibility of Eliminating Certain Abnormalities in Maize By Inbreeding.** — LINDSTROM E. W., in *The Journal of Heredity*, Vol. XI, No. 6, pp. 264-277, figs. 3 Washington July, 1920.

It is a significant fact that the great majority of inherited characters known in maize are recessive to the normal type.

The following characters are of this nature: dwarfness, ramosa ear, liguleless leaf — white, greenish-white and yellow seedlings (having no chlrophyll, or very little) — golden, green-striped, japonica, fine-striped, and lineate-leaves (these phenomena are due to irregularities in the development and distribution of the green tissues), being all simple Mendelian recessives to the normal type of maize.

The relation between such recessive characters and the question of inbreeding is very intimate. Continued inbreeding of maize is nearly always followed by a decrease in height, yield and fertility, for since maize is normally a heterozygote, the many negative variations, on account of their recessive nature, generally remain concealed. But when inbreeding progressively augments the possibilities of the union of homozygotes, abnormal types become increasingly probable, and are of frequent occurrence. On the other hand, it might be supposed, that these negative characters having been individualised and isolated in the heterozygous condition by means of selective inbreeding, the remaining plants, since they are relatively free from such abnormalities, would possess only the better characters. This, however, is true only to a very limited extent. It is most likely, that the genetic factors giving rise to the inferior characters are correlated with the favourable ones, being present in the same chromosome; thus in discarding the first, the second are eliminated, and no result is obtained.

We are therefore confronted with the problem of the distribution of the unfavourable factors in the chromosomes. The work analysed gives the results of a series of researches on the distribution of some such factors, especially those concerned with chlorophyll development and distribution. Chlorophyll abnormalities are very prevalent in all types of maize, and vary from a total absence of all pigment (shown in white seedlings), to shades of light-green almost indistinguishable from normal green; in all cases, they decrease the yield to a greater or less extent by diminishing the assimilating capacity of the plant.

At least 8 factors that influence the inheritance of chlorophyll have already been reported:

1) produces white seedlings
2) » greenish-white seedlings
3) » yellow seedlings

4) produces golden plants
5) » green-striped plants
6) » fine-striped plants
7) » lineate plants
8) *Japonica* plants (with greenish-white and greenish-yellow stripes).

In addition, there are 3 new factors still under investigation, making a total of 11 factors governing the formation and expression of chlorophyll in maize. Two of them, l (*yellow* seedlings) and g (*golden* plants) are linked in inheritance.

TABLE I. — *Data relating to the 4 segregated progenies.*

Pedigree No	Purple starchy seed		Purple sugary seed		Colourless starchy seed		Colourless sugary seed	
	Green	White	Green	White	Green	White	Green	White

Theoretical .	448	149	149	50	149	50	50	17

RELATION OF WHITE SEEDLINGS TO ALEURONE AND ENDOSPERM FACTORS — A sweet maize with coloured aleurone of the genetic composition ii AA CC Pr Pr R R su su WW, was pollinated by a plant with starchy, colourless endosperm heterozygous for the factor producing white seedlings (ii AA CC Pr Pr r r su su Ww).

The F_1 endosperm was starchy, and of a purple colour in all the grains. The F_1 plants were, however, all of a normal green. Ten of the latter were self-pollinated. The F_2 grains in all showed a distinct 9 : 3 : 3 : 1 ratio of purple starchy — purple sugary — colourless starchy — colourless sugary grains respectively. Among the ten F_2 seedling-progenies, six produced nothing but green seedlings, while four showed a sharp segregation into green and white seedlings.

Progeny 2959 has been segregated and totalled separately because it showed indications of pollen contamination.

The interrelation between the Ww factor pair (governing chlorophyll inheritance), and the Su and su pairs (determining respectively starchy endosperm and sugary endosperm), using the data from the 3 ears, 2955, 2956, 2969, is shown to be as follows:

	Su W	Su w	su W	su w
Observe	507	161	155	46
Calculated	489	163	163	54

The results thus approximate to a 9 . 3 . 3 . 1 ratio very closely The proportion of green seedlings to white is always 3 · 1, both in the starchy group (Su), and the sugary group (su), therefore w and su are not linked in inheritance, but occur in different chromosomes. If the relation between aleurone colour (R = coloured aleurone and r = colourless) and chlorophyll development is considered, similar results are obtained:

	RW	Rw	rW	rw
Observed	482	155	180	52
Calculated	489	163	163	54

There are approximately 75 % green seedlings and 25 % white seedlings in both the coloured aleurone group, and the uncoloured aleurone group thus w and r are not linked, but are transmitted independently.

The same occurs in the case of the factors r and su:

	R Su	R su	r Su	r su
Observed	489	148	179	53
Calculated	489	163	163	54

The preceding facts demonstrate, that the abnormal development of chlorophyll in the white seedlings is not linked with either the character su (sugary endosperm), nor with the character r (colourless aleurone).

RELATION BETWEEN THE FACTORS DETERMINING DWARFNESS AND THOSE DETERMINIG GREENISH-WHITE SEEDLINGS — In maize, dwarfness is a simple Mendelian recessive to normal green. Greenish-white seedlings contain very little chlorophyll at first, but under favourable conditions of light and temperature, they gradually assume a light green colour. It has beenpossible to bring some of these seedlings to maturity.

Several green plants heterozygous to the greenish-white factor (V v), were pollinated by homozygous, green, dwarf plants

The F_1, progeny was all tall and dark green. When self-pollinated, the F_1 plants produced two distinct types: one consisted entirely of green seedlings, the other segregated into green and greenish-white seedlings in the ratio 3 : 1. Both sorts segregated into tall and dwarf individuals, in the ratio 3 : 1,, as is shown by Table II.

TABLE II. — *Seedling progenies of F_2 from self-pollinated normal green plants of F_1 heterozygous for tall dwarf and greenish-white.*

Pedigree N	Tall green	Tall greenish-white	Dwarf green	Greenish white
2862	63	24	27	11
2871	52	21	20	6
2991	57	19	16	5
2992	52	22	20	7
3019	178	52	52	11
Total . .	**402**	**138**	**135**	**40**
Theoretical (9 : 3 : 3 : 1)	402	134	134	45

The characters of dwarfness and greenish white chlorophyll are thus transmitted independently, hence the corresponding genetic factors must be in two distinct chromosomes.

RELATION BETWEEN DWARFNESS AND XANTHOPHYLL PIGMENT. — The seedlings of some variations develop a yellow colour apparently due to the pigments xanthophyll and carotin. This character is recessive to normal green.

Table III gives the data relating to hybrids obtained by the self-pollination of normal green plants heterozygous for height and colour.

TABLE III — *Seedling progenies from self-pollinated normal green plants heterozygous for tall-dwarf and green-yellow seedlings*

Pedigree No	Tall green	Tall yellow	Dwarf green	Dwarf yellow
3006	180	72	87	
3011	32	7	11	
Total . . .	**212**	**79**	**98**	**24**
Theoretical (9 : 3 : 3 : 1).	232	78	78	26
Theoretical on 1 : 1.4 linkage . .	225	85	85	18

The figures obtained do not agree very closely with the 9 : 3 : 3 : 1 ratio, and seem to correspond better with what would be expected in the case of linkage. The latter, giving a gametic ratio of 1 : 1.4 would account for the number of tall-yellow and dwarf-green gametes being larger than that of the tall-green and dwarf-yellow gametes. (See Table III).

CONCLUSIONS. — The presence of a very large number of genetic factors having a negative influence upon the development of chlorophyll is thus clearly shown in the chief commercial varieties of maize, and as they lessen the assimilating capacity of the leaves, the productivity of the plant is decreased. On the other hand, as has been demonstrated by the facts set forth above, the genetic factors governing these abnormalities in the development and distribution of chlorophyll are distributed in different chromosomes. Therefore, the elimination of these negative determinants would inevitably remove the positive characters of which the factors were present in the same chromosome. To succeed in a system of maize-inbreeding then, it is essential to begin with the best material available which is as free as possible from abnormalities and defects. It is probable that the inbreeding of such stock might be carried out quickly and therefore with very little loss of height, yield, or fertility, and would at the same time improve the uniformity of the type.

714 - **Selected August Maize from Piacenza.** — ZAGO F., in *L'Italia agricola*, Year 58, No. 5, pp. 145-146, 1 plate. Piacenza, May 15, 1921.

The author applied to the selection of August maize from Piacenza the method of HOPKINS (Firstly, selection in the field of the finest ears on the most vigorous plants; secondly, growing in separate plots, the grain of each ear; thirdly repeated selection from the selected produce so as to fix the characters) and he describes the good results which he obtained.

August maize from Piacenza is a good variety, ripening early, medium height, regular ears, large grains, of a fine orange yellow colour. In 5 years of selection the author has obtained a greater uniformity of plants, regular ears and an increased production

715 - **Cross between Peas with Coloured Pods and Peas with Green Pods.** — DE VILMORIN, J., in the *Comptes rendus des Seances de l'Academie des Sciences*, Vol. 172, No 13, pp. 815-817. Paris, March 1921.

There are varieties of coloured flowered peas whose pods show a coloration that is more or less violet, sometimes quite violet: such a coloration is *dominant* over the normal green. The character "violet pod" may also superimpose itself on the character "yellow pod", and produces a very pretty fine bright red.

In the results of numerous crossings made at Verrières, plants with white flowers were found, which showed on the quite young green pods slight traces of violet, or else, in the case of plants with yellow pods, slight traces of red.

The hypothesis is, therefore, that the violet tint is inherent also in the white flowered plants but that it requires, in order to be completely manifest, the presence of the factor of pigmentation, derived from plants with coloured flowers.

If this supposition is correct, by crossing white flowered plants with pods slightly shaded with pink, with coloured flowered plants with green pods, a hybrid with violet pods ought to be obtained in the F_1. This is exactly what happened. In 1917 a cross was made between a white flowered pea with pink shaded pods and *Pisum elatius* which has a purple flower but a green pod; 2 plants were obtained in the F_1 generation, both with violet pods. Similar results were obtained in another cross made in the same year, using pollen from a pea with pink-coloured flowers and green pods.

Owing to the diversity of characters among the plants used for crossing, the F_2 generation shows great variability both in the colour of the pods (greens, violets or purples, yellow or red-violet on yellow) and in the colour of the flowers (whites or purples, plus a few plants with pink flowers derived from the second crossing).

Great differences were also noted in the colour of the ripe seed, which might be mottled garnet or plain garnet (the *Pisum elatius*, from which the pollen was taken, has mottled seeds) or else plain white or mottled white with the white flowered plants. That was for the first crossing; on the other hand in the second crossing with the coloured flower specimens, the seeds had a red tint that was plain or mottled.

These characters are distributed numerically in proportions manifestly Mendelian which, however, have not yet been established with accuracy owing to the limited number of F_2 plants.

716 – ***Butiarecastrum Nabonnandi*, a New Palm Obtained by Crossing *Butia capitata* v. *pulposa* Beccari with *Arecastrum Romanzoffianum australe* Beccari.** — ROBERTSON PROSCHOWSKI, A., in the *Revue Horticol*, Year 93, No. 17, pp. 260-261, fig. 1. Paris, May, 1921.

Among the exotics which stood the hard frosts of December 16-17, 1920 on the Côte d'Azur best, may be mentioned a hybrid palm obtained about 30 years ago by P. NABONNAND, Manager of the horticultural establishment of Cannes-Eden (Golfe Juan, Alpes Maritimes) by fertilising *Butia* (*Cocos*) *capitata* v *pulposa* Beccari with the pollen of *Arecastrum Romanzoffianum australe* Beccari (*Cocos flexuosa* Hort.)

The author proposes to name this hybrid *Butiarecastrum Nabonnandi*; it is clearly distinguished from its two parents by the growth of its leaves and by its appearance, and resembles *Howea*, from which however it is distinguished by a thicker trunk, equal to that of the mother plant *Butia capitata*. The trunk is smooth and without rings (like its parent *Arecastrum*) which adds to its ornamental character, since the cicatrices of the fallen leaves are much more crowded and close together.

The specimen described by the author was about 9 m. high; the leaves, which are 5 m. long, are at first erect and then curved back at the end; there are about 30 of them; as soon as they dry, instead of remaining to rot on the tree (as happens on *Butia*), they become detached spontaneously, from the trunk. The sword-shaped leaflets, 80 cm. long and 4 to 5 cm. broad, are about 1 cm. apart.

The non-thorny petiole (character inherited from its male parent) is, at the point to insertion, of a fine mahogany red, which passes into a greenish brown to become a fine olive green up to the tip. The spadix, about 2 m. long and 1 m. broad is fairly branching. According to NABONNAND, the fruits are, according to the specimens, sometimes globular, sometimes slightly ovoid, rather resembling those of *Arecastrum;* their colour is yellow ochre and they have fibrous flesh. The growth of this hybrid is at least 3 times more rapid than that of the mother plant *Butia capitata* and it is at least as hardy; some young specimens stood as much as —10° C. without injury.

It is therefore a plant of rare ornamental value, whose very great hardiness would permit of its being planted in countries with climates less mild than that of the Côte d'Azur

717 – **Heating of Seeds as an Aid to Selection.** — See No 707 of this *Review*.

718 – **Results of Cultivating Selected "Todaro" Wheats, in the Molise, Italy.** — IOSA, G., in *L'Italia agricola*, Year 58, No. 3, pp. 65-72, figs 5. Piacenza, March 15, 1921

The TODARO (1) wheats, that is to say the pure kinds bred by this scientist on the estate of the "Società bolognese produttori sementi," near Bologna, are suitable to the climate and rich cool soils of Northern Italy and to those of Central Italy when well cultivated; but this does not exclude the possibility of their being successfully grown on the plateaux, in the zone of the hills of medium elevation and on the even slopes throughout the southern Apennines. Some kinds even, such as "Carosella 91," originally from that region cannot but find favourable conditions there.

Experiments made in 1920 in the Molise have demonstrated the possibility of obtaining from TODARO wheats higher yields than those given by the local kinds of wheat. These experiments were carried out at two centres:— 1) at Campobasso, in the zone of the central hills of the Province, at altitudes of from 600 to 700 m.; on mould or somewhat clayey soils, rich and well tilled; the wheat succeeded maize or clover; 2) at Boiano, on a plateau at an altitude of 500 m., on rather compact, cool, deep soils; wheat sown after maize (the head of the rotation), on green manuring with *Galega* or after clover

The most typical kinds for given exigencies and aptitudes were chosen for experiment such as:—

Rieti 1. — Glumes very light yellow; spikelets compact. Very early and strong growing. Not being sufficiently resistant to lodging and rust, it suits hilly land where these faults are less important. As it sheds its grain readily the harvesting has to be carried out quickly.

---

Rieti 11. — Ears better developed and less flat than the preceeding variety; with a few supernumerary spikelets. Vegetation period longer than in the case of other kinds of the same type. Remarkably strong growth. Poor resistance to lodging, none to shedding grain, but very strong to rust. Suitable for good hill soils and for flat land not too rich in nitrogenous matter.

Cologne 12. — High productivity; early; very resistant to rust. Sporadically subject to total or partial failure of the basilary spikelets; inclined to shed grain Specially suitable for localities subject to rust, such as the shut-in plateaux of the Apennines.

Results of experimental cultivation of wheat in the Molise.

"Gentil rosso", semi-bearded 48. — Ear slightly bearded on the spikelets of the upper third or half and beardless in the lower part. Very productive; resistant to lodging; sufficiently resistant to rust. Suitable for good hill soils that are well tilled, and for richer soils in the plains.

Carosella 91. — The "Carosella" wheat originated in the Molise, where it has 2 types of ears:— 1) With spikelets quite beardless; 2) with spikelets the upper third or quarter of which is furnished with more or less rudimentary awns. "Carosella 91" resembles the second type, the extremity of the ear being bearded. It is one of the best varieties selected by TODARO. Tall but strong stalks; leaves with a characteristic bloom; ears long and rich, very resistant to lodging and fairly resistant to rust, high productive (slightly inclined to shed its grain). It is suitable for fertile soils in the plains and medium hills.

The results of the experiments are summarised in the foregoing Table. With the exception of "Cignarellone," which by its productivity and resistance to rust has equalled the TODARO varieties and sometimes has even surpassed them, all the other local wheats have had a lower unit production (from 1.4 to 13.3 quintals per hectare). The variety which has shown itself the most constantly productive, and which is really very valuable, is "Carosella 91" which is suitable for hills of an altitude of between 400 and 700 m in the Southern Apennines.

"Gentil rosso" 48 and wheats of the "Reatino" and "Colognese" type have behaved in a rather variable manner but they have yielded, in certain cases, fairly large crops and they have proved, in short, good wheats for the plateaux of the Apennines and for cool zones in hill country in the South.

719 - **Sweet Potato. — I. Cultivation along the Southern Coast Belt South Africa; — II. Chemical Composition and Comparative Analyses of Tubers.** — JURITZ, C I., (Agricultural Research Chemist, Capetown), in *Journal of the Department of Agriculture, South Africa*, Vol II, No. 3, pp. 229-239, and No. 4, pp 310-352 Pretoria, March-April 1921.

I. — In connection with the production of alcohol on a large scale, in order to serve as a basis for liquid fuel, attention has lately been drawn to the possibilities of utilising the sweet potato (1). Although at present the extent of this cultivation adequately suffices to meet the demand along the southern Coast belt of the Cape Province which is restricted to the employment of the tuber as human and stock food, the author considers that the area indicated can produce sweet potatoes to a far greater extent to meet the coming demand.

The most favourable conditions for cultivation are bright days and warm nights, a medium rainfall, which is available during a growing period of from 4 to 6 months annually. Although the crop adapts itself to other soil conditions (2), it attains perfection in light sandy loam with a somewhat clayey but well drained sub-soil, (standing water around the developing tubers is most harmful). In the Division of George the most abundant producing area, the flourishing farm of ROBERTSON at Little Brak River is taken as an example and the methods of cultivation described in detail. The varieties grown here are the common 6 months, the red-skinned 3 months, the yellow skinned 3 months and the British East African white-skinned. The first is the most in demand on account of its keeping qualities. The sweetest of the four is the yellow, the next the red and the least, the white.

---

(1) See No. 764 of this Review. (*Ed.*)

(2) Behaviour of Sweet Potatoes in the Ground See *R* Aug 1918, No 851. (*Ed.*)

The author describes the two methods of propagation by tuber slips and cuttings from the runners; the latter is the method principally adopted in South Africa. A comparison is made with the propagation methods in the United States and in Queensland. In the former, the sprouted slips are employed in the north for the main crop, while the runners are used only to provide the seed tubers for the following season; south of Virginia the runners provide the main crop.

Although irrigation is oten practised for sweet potatoes in America, ROBERTSON does not recommend this proceeding unless absolutely necessary. For open crumbly soils he advises the planting of cuttings in a damp soil, and for compact soil, irrigation should not follow but precede planting; sandy soils may however, be irrigated after the cuttings are in.

On the farm under consideration rotation is found distinctly advantageous, including in the rotation a leguminous crop.

It is evident that sweet potatoes need potash and in the Northern States U. S. a successful fertiliser used (1) to be recommended, containing 4 % nitrogen; 8 % phosphoric oxide, and 8 to 10 % potash. The potash requirements are evidenced by the analyses of the ash (KÖNIG) which shows a potash content of 50.31 %, and 46.15 % (ROBERTSON).

Chemical composition. — The average composition of the sweet potato according to a series of analyses of tubers from different countries is shown as follows:—

Principle constituents	Average for 12 series (1)	United States (2)	England (3)	Japan (4)	Azores (5)	Malaga (6)
Water	71.86 %	73.39 %	70.98 %	76.19 %	86.45 %	69.10 %

[719]

Samples of each class of sweet potato grown at Little Brak S.Africa were collected for analysis. The percentage results are shewn in Table II

Yield. — In the Union of South Africa, according to the 1918 Agricultural Census, the area under sweet potatoes in the 4 provinces amounted to 20 392 acres. The total production amounted to 69 141 150 lb. (3390 lb. per acre), the Cape Province heading the list with 12 162 acres under cultivation. However, as much as 16 300 lb. per acre has since been reported at Little Brak, where the soil is black alluvium and had been irrigated before ploughing: It was manured with $^1/_2$ ton "potato fertiliser" with the following percentage composition: phosphoric oxide (total) 8.0, (citric soluble 7.5); nitrogen 3.5, potash 6 0 and lime 16 0. The season was dry and the crops had received no subsequent water other than occasional showers. This may be taken as a sample of the possibilities as regards yield.

The author summarises the comparative yields in the United States, and also describes investigations begun there for the purpose of determining the identity of different varieties of sweet potatoes and for developing the most suitable method of utilising the plant as a stock food in regions where it can be cheaply produced (1). A general investigation was carried on at the same time of dry rot, stem rot, and other diseases of the sweet potato, and the remedial measures were studied and suitable treatment recommended.

Reference is also made to the experiments carried out at Barbados (HALL and BOVELL, *West Indian Bulletin*, Vol. V, No. 1, pp. 44-52, 1904) for the purpose of ascertaining the best varieties for cultivation. Twenty-eight varieties were planted of which White Gilkes (6 months) gave the best returns, the next 3 in order being Hurley, Minuet and Vincelonian.

With regard to storage, a preliminary sweating process is strongly recommended — 2 weeks' storage in a well-ventilated cellar, at a dry temperature between 80° and 90° F. The temperature is allowed to fall later to about 65° F, and is maintained at this point.

A common method also employed is in making about 20 to 30 bus. into a pile and covering with straw If the temperature is maintained at 40°F, the tubers will undergo sweating, as desired. This may be followed by covering the pile with earth, gradually more and more thickly up to a thickness of 4-6 in.

A local method of storage practised in South Africa is to dig a trench, fill it with tubers piling them into a ridge 3 ft. above ground and covering with a water shed roof of sods, leaving an air-hole.

To give an idea of the cost of production per acre, the author has collected statistics from the United States as applicable to cultivation in South Africa, and estimates the total cost at £16.10s 2 d. excluding hauling to market. This will however vary according to the district. On the other hand the produce of an acre has often realised as much as £2 to £30.

In connection with the cost of production in Cape Province, ROBERTSON has supplied the following information :— Excluding ploughing and harrowing, the cost of cutting shoots, dividing them into required lengths, making water furrows, holes, planting, closing up, irrigating after ploughing, is approximately 18/- per acre (using boys, natives, women and other cheap labour). For adequate cultivation, the crop requires horse hoeing 3 times, hand hoeing twice, irrigation once, amounting to 24 - per acre. — Digging and bagging £4 per acre so that here the total cost approximates to £6.12 s. excluding costs of bags, carting, cuttings and manure.

720 – **Feeding Value of the Pods and Seeds of *Prosopis Stephaniana*.** — *Bulletin of the Imperial Institute*, Vol. XVIII, No 4, pp. 478-479 London, Oct.-Dec 1920.

Pods and seeds of the leguminous shrub, *Prosobis Stephaniana* were forwarded to the Imperial Institute from Cyprus with a view to ascertaining their value as feeding stuffs. This species is indigenous to Cyprus, but occurs also in the Punjab, Afghanistan and the Caucasus

The analysis gave the following percentage results: for whole pods, pod cases only, and seeds only, respectively :— moisture 10.1, 10.4, 9.5; crude proteins, 13.0, 10.4, 18.2; fat 2.6, 2.5, 2.8, carbohydrates (by difference) 56.8, 56.2, 58.0; fibre, 14.1, 17.0, 8.4; ash, 3.4, 3,5 3.1. The nutrient ratio was 1 : 4.8, 1 : 60, 1 : 3.5, and the food units 96, 89, 111. No alkaloids or cyano-genetic glucosides were detected in the samples.

The pods (freed from seeds) contained 3.8 % of sugar (calculated as dextrose), so that they differ materially in this respect from carob pods which contain from 30 to 50 % of sugar. No tannin was present. The value as feeding stuff is somewhat reduced by the highly fibrous nature of the pods, and the hardness of the seed coat .The pods of the allied species *P. juliflora* which contain a large percentage of sugar (25 to 28 %) are stated to be used as a feeding stuff, and trials might therefore be made with *P Stephaniana* pods and seeds.

721 – **Cotton Growing in the Belgian Congo** (1). — LEPLAE, E (Directeur général de l'Agriculture au Ministère des Colonies), in *Bulletin of the Imperial Institute*, Vol. XVIII, No 3, pp 352-402, figs 2, pl 2, London, July-Sept. 1920, and *Bulletin Agricole du Congo Belge*, Vol XI, Nos 1-2, pp. 80-105, pl 1. Brussels, June, 1920

It seems likely that Central Africa will some day supply the European markets with a much larger and better cotton crop than was hitherto expected. The Uganda Protectorate and Nyasaland are already among the cotton producing countries, their soils and climates having proved quite suitable to the growing of a very useful type of cotton. The author shows that conditions favourable to cotton cultivation extend also to the centre of Africa and cover a large tract of country Transport facilities by river and rail throughout the Belgian Congo have been considerably improved during the war, and several cotton producing districts are now shipping a few hundred tons of cotton to Antwerp and the cotton mills of Belgium.

---

(1) See *R.* Jan 1914, No 3. (*Ed*)

Experiments were commenced six years ago in the Lower Congo District and were gradually extended further north. They are at present in progress at Maniéma and at Sankuru. Notwithstanding the adverse meteorological conditions, several attempts were made under the Congo Free State Government to introduce cotton amongst the crops grown by settlers or natives. American, Egyptian and Peruvian cotton seed was tried in the State Agricultural Station, but gave no definite practical results.

In 1909 a new and more thorough experiment in cotton cultivation was however conducted under the superintendence of J. **Claessons**, Agricultural Engineer, who formerly owned a cotton farm in Oklahoma (U. S. A.). From 1913 onwards, the encouraging results here reported are due to the untiring activity of the American expert E. **Fisher**.

Cotton trials were first conducted at Kitobala (Lower Congo), 1913-15, at Nyangwe (Maniéma) and Stanleyville (Upper Congo) 1914-16, at Babadi (Loukala) near Lusambo, Sankuru (1916-17).

Lower Congo. — About 50 acres of cotton were planted in 1913, and several quite satisfactory results were obtained. But the unreliability of the rainfall was proved in a decisive manner, as the rains were very irregular and scanty, and large tracts of cotton in the unirrigated fields were a total loss. Of the various varieties tried at Kitobola, Triumph long staple and Simpkins short staple gave the biggest returns.

Upper Congo. — The rainfall at Nyangwe (Maniéma) is regular, with about 52 cm. of rain, and only 2 months of dry weather. The first planting of cotton in 1914 covered 55 acres, the same varieties being grown as were planted in 1913 at Kitobola. Nearly all the land consists of a sandy loam with a clay subsoil, easy to plough after the first time, and also easy to cultivate. In 1915 an area of 135 acres was planted and the first really normal trials undertaken. On account of the seasonable weather no trouble was experienced in the 1915-16 season in keeping the fields clean and the plants in proper growing condition. The proper distance to plant depends largely on the quality of the soil and the varieties to be planted. The average for most of the American varieties on lands of average fertility is about 1.20 m. between the rows and from 35 to 50 cm., in the rows, except for short stapled varieties such as Simpkins which is of small growth, and is planted 1 m × 30 to 35 cm. Five seeds per group is sufficient, planted at a depth of from 25 to 44 mm.

The best time for planting long-stapled varieties seems to be December, and for short-stapled cottons, January. Simpkins can be left as late as February 15. Native cottons are planted in October. Three weeks after planting, the seeds grew so rapidly that they were ready to be thinned out, and the land was cultivated. A month later and this was repeated and the cotton was hilled.

The gathering of the cotton began in 1916 in April, but that is unusually early compared with the normal possibilities.

The author gives full details of the varieties grown, and their respective yields. These include Nyasaland, Allen Long Staple, Sunflower Long

Staple, Simpkins Early Prolific, Triumph Big Boll, Peruvian Red Short and White Long Staples, Greenseed and Blackseed, Zeidabi (long stapled), Sunbeam (American long stapled), Sakellaridis and Abassi (Egyptian).

Amongst these, it was evident that Simpkins proved the best adapted for native cultivation, as it is quick growing, and quick maturing, and one of the most resistant cottons to drought, insect attacks and fungoid diseases and general unfavourable weather conditions. It is fully developed 3 to 3 ½ months after being planted, and ripens within the following 2 months. The author considers that this is the only variety which would have any chance of success near the Equator, where the dry season is very short. The sole disavantage is the shortness of its fibre, which, however, is very strong.

The Triumph Big Boll has three superior advantages namely: 1) it yields well; 2) it requires far fewer bolls to make 1 kilo. of cotton than the other varieties and owing to the large size of the bolls, a much greater quantity of seed-cotton can be gathered daily, thus reducing the cost of picking etc., but it requires a far longer time (4 months after full development) than Simpkins to ripen and the weight of the bolls causes the limbs to bend to the ground and accumulate dirt, and makes the plant subject to attacks of insects and rodents. In a locality with well-defined and lengthy rainy and dry seasons, this variety is recommended, as the quality of the cotton and the staple is excellent, and the fact that the variety is less resistant to drought and disease than Simpkins can be dealt with effectively under such circumstances.

The Egyptian cottons have been an almost complete failure. In the absence of irrigation and more suitable climate, they will always give disappointing results.

Central Congo. — Two cotton growing districts have been established here. 1) The Maniéma district around Kassongo. This district will be able to ship cotton through Stanleyville and the West Coast, or through Tanganyika-Udjidji-Dar-es-salam and the East Coast; 2) The Kasai-Sankuri-Katanga districts, with the country surrounding Lusambo, and Kabinda (Eastern Katanga). This second district has extensive savannah lands, and is thickly populated, cattle rearing is generally possible and roads can be easily constructed. Cotton will have to be shipped to Stanleyville and Matadi

Northern Congo. — The most interesting district for cotton growing in the north is the Uelle, where the rainy season starts in April and lasts until November; the dry season extends from then onwards till April, with a short period of rain in February. Trials were started in the Uelle and Ituri districts in 1919 by the Vice-Governor, Colonel de MEULEMEESTER. Large fields were planted by the natives of the Kilo-Mahagi region and some 1500 acres were covered. Samples of this cotton have now been received in Belgium, and are of good quality.

GENERAL. — The area of land planted in the Congo by the natives was 1125 acres in 1916; 2000 acres in 1917, about 2500 acres in 1918;

and 2000 acres in 1919 (the reduction in this case being due to an epidemic amongst the natives), and 5000 acres in 1920.

The average yield of seed cotton is 528 to 616 lb. per acre. In fertile fields, however, the yield rises to 880 to 1320 lb. per acre, without any application of manure.

The average yield of lint is somewhat above 176 lb. per acre. To obtain 1 ton of lint, therefore, requires 12 ½ acres. The average yield of lint in the United States being 200 lb. per acre, usually, on manured land, the yield of 176 lb. for the Belgian Congo, must be regarded as satisfactory.

Although direct cultivation of cotton by white settlers is not excluded or hindered by the law in any way, it seems that the industry will be carried on principally by the natives, who can produce seed-cotton much more cheaply than a settler.

722 - **Cotton Prospects in the Philippines.** — ESPINO, R. B. (College of Agriculture, Los Baños) in *The Philippine Agricultural Review*, Vol. XIII, No. 3, pp. 186-209. Manila, 1920.

The author's aim is to give the planters and prospective planters in the Philippines a guide in the selection of species or varieties and in the cultural phases of the cotton growing, in consideration of the great possibilities of growing it successfully in this country in the future.

A resumé is given of the various varieties of commercial cotton derived from the 7 species of *Gossypium* indigenous in different parts of the world, and the statistical distribution as regards acreage under cultivation, bales of cotton produced, exports and imports. Stress is laid on the last mentioned, namely the imports, as this has a direct bearing on cotton prospects in the Philippines. Japan imports a large quantity of raw cotton (1 ½ million bales) and has up till now imported the larger part from the United States (which produces about 58 % of the world's cotton), but, considering the geographical situation of Japan, in connection with the Philippines, there are obviously opportunities, in store for the latter where the soil and climate are exceedingly well adapted to cotton and labour is plentiful.

Up till now cultivation has been almost entirely confined to the provinces in Luzon. Some 3053 hectares in the Ilocos provinces, were devoted to cotton in 1902, yielding 68.2 % of the 1 322 118 kg. of the entire production of the Philippines. In addition to this 239 ha. in Batangas, and 266 ha in La Unión were reported to have produced in 1902, 21 266 and 362 464 kg. of cotton, respectively. This gives ample evidence of the fact that pest-resistant varieties already exist in these areas, in spite of the objection raised that the prevalence of insect pests is the chief drawback to cotton planting in this country

REVIEW OF FIELD TEST. – In connection with the acclimatisation phase of the problem, several cultures were started in 1920 at the College of Agriculture, Los Baños, in which varieties or species of native and foreign cotton were grown simultaneously. These cultures will probably be repeated each year until a time is reached when the yield can no longer be increased by acclimatisation, or when one or more varieties shall have been found to be the most promising.

Investigations concerning the best months for planting native varieties, and the study and control of insect pests are to be made

In 1911, the Bureau of Agriculture reported the results of preliminary tests. Certain native types of cotton were found to exhibit such encouraging results that it was considered necessary to conduct a more detailed and systematic investigation Native varieties were compared in the field with some American types. The results obtained showed that the varieties Toquillo, Gapaz Kinachila and Gapaz Sangley or Candava, made a luxuriant growth, much superior to the American types, but matured somewhat later than the latter varieties. As regards yield, the Toquillo and Kinachila were much inferior to the American cottons but the Sangley compared favourably with the same. The native varieties were practically free from the attacks by the weevil, but the American types were, however, very badly infested.

From the 1912 field work, it has been concluded :— 1) That the cultivation of American and other foreign species on a large scale from imported seed at least in the vicinity of La Carlota is an unsafe investment ; 2) that the native species Torquillo and Sangley are the only two that can be recommended for cultivation on a large scale ; 3) the seed should be sown so as to bring the plants to maturity not later than the middle of the dry season. After that period, heavy rains are liable to set in with such frequency as to impair the quality and quantity of the floss.

The author reviews, in general, the history of cotton, the economic importance, the classification of cotton fibre, climatic environment in various countries, preparation of the land, cultural operations, diseases and pests.

The author considers that the Philippine Government should thoroughly investigate the relative suitability to varieties of the varying climate and soil conditions, etc. owing to the evident possibilities in store for this country in connection with cotton cultivation.

723 - **The Oil of South African Marcola Nuts (*Sclerocarya Caffra*).** — *Bulletin of the Imperial Institute*, Vol XVIII, No 4, pp 181-183, London, Oct-Dec. 1920.

The marcola nut is the product of *Sclerocarya Caffra* Sond, a small tree 20-30 ft. in height, belonging to the Natural Order Anacardiaceae. The tree is found only in Natal and the Transvaal, being very plentiful in the Bush Veld, and the Low Veld. The fruit is a drupe and when ripe is about the size of a small hen's egg, and of a yellow or greenish yellow colour. The thin pulp which surrounds the nut has a flavour similar to that of the mango, but is much more acid.

About 1 ¼ cwt of the nuts, collected in the Pretoria District were recently forwarded to the Imperial Institute for analysis in order to ascertain whether they would be of commercial value. The nuts were of irregular shape, averaging 5 gm. in weight and containing 1 to 3 kernels.

The shell which was very tough and fibrous, was covered with a thin layer of dried pulp of a pinkish brown tint. The nuts consisted on an average of 90 % shell and only 10 % kernel.

The kernels contained 5 % moisture and yielded 56.2 % of oil, equivalent to a yield of 59.2 % from the dry kernels. The oil, which was clear, limpid and pale yellowish-brown in colour was examined with the following results in comparison with corresponding figures recorded for a sample of maroola oil from the Northern Transvaal: specific gravity at 15° 0.9167 compared with 0.9153; melting point of fatty acids 25.0° C to 24.3° C, acid value 3.7 to 3.2; saponification value 193.5; iodine value 76.6 % to 72.9 %; soluble volatile acids 0.1; insoluble volatile acids 0.45; unsaponifiable matter 0.6 % to 0.93 %.

The kernels of these maroola nuts give a good yield of oil of the "non-drying" type which would be suitable for soap manufacture and possibly for edible use. In view, however, of the difficulty of cracking the nuts, and separating the kernels, it seems very unlikely that the nuts could profitably be used as a source of oil.

724 - **The Rubber Plant of the Mexican Deserts** (1). — Forvin, V., in *La Nature*, No. 2248, pp. 148-149, figs. 3. Paris, March 5, 1921.

The "guayule" was known to the natives of Mexico long before the Spanish conquest. They extracted the rubber by mastication and used it for making balls for games. But the shrub did not attract scientific attention until 1852, when an American botanist, Dr. J. M. Bigelow, attached to a Commission charged with settling the boundaries of the new frontiers between the United States and Mexico, discovered it near Escondido Creek (Texas).

It was described in 1850, by Prof. Asa Gray, of Harvard University under the name *Parthenium argentatum*. Its common name in Aztec means "rubber tree."

For a long time it was considered of no value except as a good fuel. The Mexican miners cleared thousands of hectares of it for smelting, and the great industrial value of guayule was only suspected about 1876 when a block of rubber extracted from this shrub was shown at the Philadelphia Exhibition.

In 1888 the first attempt at exploitation was made by sending 50 tons of bark to New York, and 18 % of rubber of excellent quality was obtained. In the same year samples were sent to England and Germany, but the German chemists declared that guayule would never have any commercial value.

However, an American company installed an experimental laboratory at San-Luis-de-Potosi in 1901, and obtained such promising results that the first factory was built at Jimulco, which commenced to produce crude rubber on an industrial scale in 1905. By the end of 1910 the capital engaged in the new industry totalled 65 million gold dollars.

---

(1) See *R.*, March, 1919, No. 320. (*Ed.*)

The habitat of the guayule is fairly clearly defined. The plant appears to have originated in the desert of Chihuahua, which forms the northern portion of the Mexican central plateau, and has spread over all the neighbouring arid regions situated at altitudes of from 1000 to 2000 m. It is found in the south of Arizona and of New Mexico. Its habitat covers 290 000 sq. km. of which 70 000 sq. km. can be worked industrially. The shrub is not more than 1 m. high. It differs from most rubber-producing plants by the fact that the rubber is contained in certain kinds of cells instead of being in the latex. F. E. LLOYD, professor of plant physiology at the Polytechnic Institute of Alabama, who has devoted years of study to guayule has not yet been able to discover what physiological rôle the secretions of rubber play in the life and growth of the plant. He has, however, proved that these secretions are less abundant in summer and this may provide a key to the mystery.

Now that rubber plantations are reducing production to avert a fall in prices (1), it may seem strange that the existance of a new source of the product should be noticed. Guayule, however, has advantages which should merit the attention of several Colonies. It thrives on arid and desert lands where any other crop would fail, subject to the condition that the soil contains a certain amount of lime, and it will grow on high plateaux where rain is infrequent and small in amount. It withstands considerable differences of temperature and even braves the neighbourhood of freezing point. Lastly, in spite of its small yield in rubber, which is an average of 12 % of the total weight of the shrub, it can be profitably worked throughout the year.

Extraction is not complicated, and the factories have copied the native process, which consists in chewing the bark and roots. After washing in plenty of water, the shrub is crushed between rollers under a fine spray. The mass obtained is sent through turbines which separate the rubber. The crude product is sent to the refineries.

In 1914, several laboratories, both in Mexico and the United States, endeavoured to domesticate guayule, which is reproduced either by seed, or by root suckers developing on the roots nearest to the surface. But the war stopped these interesting researches, and although, owing chiefly to the work done by Prof. LLOYD, it is known how to cultivate the shrub, it is still unknown whether the cultivated guayule will retain its rubber content outside its natural habitat. Two years before the war Germany tried to introduce guayule into its East African Colony. The war put an end to the experiments. But the author thinks that it is not impossible that Algeria and Morocco may contain arid lands where the rubber plant of the Mexican deserts might become a new source of wealth.

[724]

725 - The Effect of the Age of the Trees on the Quality of the Rubber. — DE VRIES, O., in *Bulletin Agricole de l'Institut Scientifique de Saigon*, Year 3, No. 3, pp. 89-91. Saigon, March 1921.

The older trees generally possess a latex with a higher rubber content than the younger trees, which naturally influences the yield of rubber to a large extent.

After conducting several experiments on special lines, and by a careful selection of material, the author is now able to present the following information concerning the characteristics of old and young trees.

1) The resistant quality of the resin from old trees is not to any marked extent stronger than of the young trees. In some cases where young trees have not been tapped for some time, less resistance is evident, without necessarily attributing the same to the youth of the trees.

2) The "slope" or type of tension curve is usually the same, occasionally rather better with old trees.

3) The time for vulcanisation becomes appreciably less for old trees; the oldest trees in Java (plantations established from 35 to 40 years) giving the lowest average of all;

4) The viscosity is nearly always of finer quality with old trees, often not coming up to the average with young trees.

Attention is drawn to the fact that in every experiment here undertaken, rubber was prepared in crêpe form as it has not yet been found possible to obtain smoked rubber.

It is interesting to note that these results only partly support the idea that rubber is of better quality when obtained from old trees, e. g. the question of viscosity. The fact that inferior quality rubber is occasionally put on the market by new plantations may be partly attributed to the fact that as a general rule, the older plantations are better equipped and in better working order, and thus encouraging the produce of rubber of more uniformly sound quality.

The author adds that young trees yield a comparatively low quantity of latex with low rubber content, which becomes even more diluted when the cleansing water mixes with the latex, etc. When the dilution of latex is not standardised, these factors often lead to an entire change in qualities relative to the above mentioned properties.

Attention is drawn to the fact that when "Para balls" in Brazil are coagulated with acetic acid, vulcanisation is rapid as a result of the age of the trees; on the one hand, keeping the balls, in a state of moisture for some time, encourages increased speed in vulcanisation, whilst on the other hand, smoking out somewhat retards speed. The results thus in the end coincide. On a Java plantation (Sidoredjo near Samarang) the latex coagulates in a normal way with acetic acid, giving a crêpe after 1 hour 40 minutes, whilst by following the Brazilian coagulation method, only 55 to 65 minutes is required for vulcanisation. However, the latex from the old trees in Brazil treated with a standard mixture and coagulated with acetic acid should give a gum which will vulcanise more slowly.

726 - **Biological Notes on the Gum-Arabic Acacias of the Egyptian Sudan** (1). — PERROT, Em., in the *Comptes rendus de l'Académie des Sciences*, Vol 171, No. 4, pp. 258-260. Paris, July 26, 1920.

About 95 % of the gum arabic of commerce is produced by a small tree, *Acacia Verek* Guill. and Perrot (*A. Senegal* Willd). The Egyptian Sudan (chiefly Kordofan) exports annually nearly 20 000 metric tons of it, whereas Mauritania and Senegal hardly produce more than 2000 metric tons. The other gum-producing species in the Sudan are *A. Seyal* Delile and *A. arabica* var. *nilotica*.

In the course of a recent mission, in February-March, 1920, the author with M. ALLAUD, studied the conditions of growth of the gum trees as well as the method of collection and the trade in gum.

A. Verek commences to form part of the Sudanese bush in the region north of Khartoum and becomes more and more abundant further south in the provinces of Senaar, Gedaref, and Kordofan, but especially in the last named; it then appears in places in the form of fairly thick natural forest which is called " guénéas " and in which the trees are worked by the natives. In the dry season they methodically tap the trees by removing a narrow strip of bark with a crude hatchet (" ferrar ") ; the gummy exudation is thereby considerably increased. In the Province of Kordofan the rainy season lasts from the end of May to the middle of October, and the rainfall is from 300 to 400 mm. During this season of vegetative rest the leaves fall, the air becomes extremely dry, the winds are steady and the temperature exceeds 45°c. in the shade, falling at night sometime several degrees below zero.

The smallest crack in the bark can spontaneously cause the production on the outside of rounded pieces, more or less coloured, called " wady " (wild) gum ; in addition, an insect often punctures the tree at the point of junction of the small branches, and the tree then exudes small spiral threads of gum which are collected and constitute " vermiform " gum. After the barking, along the edges of the wound, rounded, soft and colourless pieces show themselves which dry rapidly and constitute the fine white Kordofan gum.

In seeking to ascertain the best conditions for the gummy exudation the author has formed a certain number of conclusions of which the principal are as follows: —

1) The gum does not exude except during the period of greatest dryness, from December to April, when it is picked every 5 or 6 days.

2) The trees growing in the smallest valleys, or merely in places where the sub-soil, owing to clay strata, remains moist or damp, only produce a few pieces of gum. Also, if the least drop of rain falls after barking has been carried out too early or too late in the season, the first or last picking is spoiled.

3) By simply working the soil to attempt the growth of crops between the trees the production of gum is reduced considerably.

---

(1) See *R.*, March, 1921, No. 292. (*Ed.*)

4) The conclusion is therefore that the formation of gum must have as principal object, owing to the reluctance with which it parts with its moisture, to preserve in the tree the amount of moisture necessary for its vegetation during that period of extreme dryness when the desiccation is really extraordinary.

If it is desired to work natural stands, the fact must be kept in view that, as in the case of other desert species, the root system is extremely developed in depth and diameter. A density of not more than 80 to 100 trees per ha. should therefore be preserved, so that there may be very little shade. If the exuding gum heals the wounds, it is a secondary object, as the rough work of barking, which causes injury often up to the cambium, does not apparently otherwise injure the tree.

In Senegal and Mauritania, except among the Peuhls, a tribe which has come from the East, the practice of barking is unknown. The author recommends its introduction since it would enable the yield to be increased by from 3 to 5 times

727 - **The Cultivation of the Vine in Italy during the Last Fifty Years.** — SCANO, G., in the *Giornale vinicolo italiano*, Year 47, No 22, pp. 211-212, 1 diagr Casale Monferrato, May 29, 1921.

In the quinquennium 1870-1874 vines were grown in Italy on 1 869 300 ha. and from 1915 to 1919 on 4 348 800 ha., an increase of 2 479 500 ha., or 132.6 %. This area is distributed over the 16 regions of Italy as shewn in the table,

	Average area in hectares		Increase (+) or decrease (—)
	1870-1874 (1)	1915-1919 (2)	per cent.
Piedmont	117 300	283 800	+ 141.6
Liguria	37 000	52 600	+ 42.2
Lombardy	140 800	246 300	+ 74.9
Venetia	243 000	679 200	+ 179.5
Emilia	168 500	860 000	+ 410.4
Tuscany	226 800	603 500	+ 166.1
Marches	94 800	383 300	+ 304.3
Umbria	50 500	222 900	+ 341.4
Latium	44 000	122 500	+ 178.4
Abruzzi and Molise	170 600	127 900	— 25.0
Campania	103 000	276 400	+ 168.3
Apulia	95 800	204 600	+ 113.6
Basilicata	46 500	30 700	— 34.0
Calabria	95 000	40 700	— 57.2
Sicily	211 500	172 400	— 18.5
Sardinia	24 200	42 000	+ 73.5
Total	1 869 300	4 348 800	*av.* + 132.6

---

(1) Data from *Relazione intorno alle condizioni dell'agricoltura nel quinquennio* 1870 a 1874.

(2) Data from *Notizie periodiche di Statistica agraria per gli anni* 1915-1919 published by the Minister of Agriculture

These areas represent, in 1870-1874, 6.5 % of the whole area of the peninsula and, in 1915-1919, 15.2 %, and respectively 7.1 % and 16.5 % of the agricultural area. The region which had the largest area under vines in 1870-1874 was Venetia (243 000 ha.); Tuscany came next (226 800 ha.) and Sicily third (211 500 ha); in 1915-1919 Emilia stood first (860 000 ha.); then came Venetia (679 200 ha.) and Tuscany (603 500 ha.) some way behind.

The region with the smallest area of vineyards in 1870-1874 was Sardinia; in 1915-1919, Basilicata had least.

The greatest extension took place in Emilia where 681 500 ha. were added, and the least in Liguria where the addition was 15 600 ha.; the greatest falling off in area was in Calabria (54 300 ha.), the least in Basilicata (15 800 ha.).

In most of the regions the area under vines has more than doubled, in some (the Marches and Umbria) they have quadrupled; in Emilia it has become 5 times as large. Only in 4 regions (the Abruzzi and Molise, Basilicata, Calabria, Sicily) has there been a decrease. The increase of area under vines has taken place mainly in the North and Central regions of Italy, whilst there has been a decrease, really very slight, in Southern Italy.

728 – **Trentino Vines: — Rossara and Nosiola** (1). — DALMASSO, G, in *L'Italia agricola*, Year 58, No. 3, pp. 78-80, 1 pl Piacenza, March 15, 1921; No 4, pp. 104-105. 1 pl. April 15, 1921.

I. — ROSSARA. — This name or similar names ("Rossera," "Rossea," "Rossarina," "Rossarola") often recur in books on the vine although the vines described may not always be identical with the Trentino stock.

As far as the author knows this vine has only one certain synonym, viz., "Geschlafene," which is used in the Upper Adige; a less certain synonym is "Schwarzwälsche."

In the Venetian Tridentino 2 types of Rossara are distinguished, one with medium bunches of grapes which tend to an ellipsoidal shape and with deeply dentate leaves, the other with large pointed bunches of large round grapes and with leaves slightly dentate. The author describes the second type.

Area of cultivation. — This type is extensively cultivated pretty generally in the Trentino and the Upper Adige as a heavy yielding variety.

Description. — *Stock* very vigorous, growth very strong.

Leaves medium or large, generally 3 lobed, defoliation rather late.

Bunches large or even very large, generally pyramidal, more rarely cylindrical, rather crowded, often winged (in the smallest variety the bunch is more squat and loose).

Berries big, generally spherical (ellipsoid in the smaller variety); in colour varying from red to bluish-red, skin thin but fairly tough, pulp very juicy; flavour simple and pleasant. Stones 1 to 3 in number, fairly large, light yellow.

---

(1) See R March 1921, No 302 (*Ed*).

Maturation in the 3rd period late.

Practical information regarding the vines. — The Rossara vine likes fertile soil in plains not too low in altitude; in such a situation it gives abundant yield. In poor stony soils, however, it gives irregular yield.

In certain situations it is subject to drop its fruit. It should be pruned long, in fact it is almost exclusively trained on a " pergola " (trellis roof). At the Institut of San Michele, the average yield over 30 years of the Rossara vine has been 108 hl. per ha.

It is very much affected by anthracnosis and winter cold; it is more subject to mildew than to oidium. It has a good grafting affinity with the principal American stocks.

Practical information regarding the wine. — The Rossara grape generally makes a light wine, with little colour, rather acid. At the Institute of San Michele, the average composition of the must for 30 years was 15.5 % sugar and 8 % acidity. However, blended with Teroldigo or Lagrein or else with Schiave or Vernaccia, it can give good table wines

The Rossara vine grown on certain rather dry lands on the Upper Adige (specially in the neighbourhood between San Michele and Eppan) bears smaller bunches, but produces a wine which, blended with Schiavone, gives the well known and much esteemed " Überetschen " wine which has not much colour, but possesses body and flavour. Similarly, the famous wine of Lake Caldaro (" Kalterersee ") is made by blending Rossara with Schiave

However, among the number of Trentino vines with dark coloured grapes, Rossara is generally that which gives large quantity rather than wine of good quality.

II. — NOSIOLA. — This is one of the most cultivated and interesting of Trentino white grape vines. Outside of the Trentino this vine is distributed over Venetia where it bears the synonym " Durello " or " Durella " Another synonym applied to it in the Upper Adige (Meran) is " Spargelen. " The " Duraca " of Sicily and the white " Durello " of Cesena on the other hand are quite different.

On Monte di Calavino, near Castel Toblino, there are some Nosiola vines which known as " Spinarole, " with very small baby bunches but very numerous. This appears to be the original type of Nosiola.

Area of cultivation. — In the Trentino, the Nosiola vine is cultivated principally at high altitudes :— in the Val di Cembra, near Lavis, and in the Val del Sarca.

Description. — *Shoots* of medium size, sprouting early.

Leaves of medium size or smaller, generally trilobate, lateral sinuses shallow; defoliation medium.

Bunches of medium size, generally cylindrical, sometimes winged, crowded; swelling at end of pedicel, large; brush short

Berries of medium size, spherical; in colour green or light yellow, sometimes golden yellow, pulps hard, slightly crisp, sweet flavoured, fresh, pleasant. Stones generally 3; rather small, dark brown with reddish chalaza.

Maturation in the 2nd period.

Practical information regarding the vines. — The Nosiola vine is a strong growing variety. It requires a dry climate, because in regions where the autumn is damp the grape is likely to rot. On the other hand, cultivated in suitable places, it keeps for even a long time on the racks. It stands heat and drought well. As it sprouts early it is subject to injury from spring frosts In damp springs it is also liable to drop its fruit. It should be pruned long.

It can give a heavy yield, but it is of irregular fertility. As the Agricultural Institute of San Michele, it has given an average yield, for 30 years, of 75 hl. per ha, with a maximum of 168. It is rather sensitive to oidium, on the other hand it is very resistant to anthracnosis.

Practical information regarding the wine — In good situations the Nosiola vine gives a fairly full and pleasant wine, very acid, but inslightly years of heavy yield the quality is rather indifferent.

At the Institute of San Michele the must has given as the average for 30 years, 15.5 % of sugar, and 6.6 per thousand of acidity.

Altogether it constitutes a good type of table wine, not without character.

In the Val del Sarca a good " vino santo " is made from the Nosiola grape, which has acquired a certain reputation especially in the district round Castel Toblino.

729 - **The Malbeck Vine in Argentina and in Italy.** — SANNINO, F. A., in the *Rivista di Ampelografia*, Year II, No. 5, pp. 65-67 Leghorn, May 1, 1921.

The Malbeck vine produces a black grape for making ordinary table wine; it is very common in France, especially in the Bordeaux district, and in Touraine, where is is called " Côt. ". It has some good characters, such as maturation slightly retarded in the 1st period and the production of grapes rich in sugar and colouring matter, but not too rich in acids, so that the wine, not being very astringent while rich in colouring matter, matures rapidly. In Touraine, no doubt owing to the climate and unfavourable soil, it does not produce such a good or deep coloured wine and the vine becomes known as sour Malbeck.

In view of the great diffusion of this vine in France it is not surprising that it has also been introduced into other countries. The great vineyards of the province of Mendoza (Argentina) contain the largest plantations of the Malbeck vine. In the Argentina, this vine has given excellent results regarding the quality of grapes produced, and it is a grape very rich in sugar, which, however, reproduces the character of insufficient acidity in the must, so that the wine is " plat " to use the expression of RENDU. In Argentina that insufficiency of acidity is still more marked than in France, on account of the repeated irrigation necessary in vineyards in hot dry regions such as the two slopes of the Andes range. In Italy, the Malbeck vine has been introduced into several provinces. According to the very careful investigation made by MONDINI, it has been cultivated in 27 provinces but its diffusion has been rather limited on account of its smaller production compared with that of local vines. In the central provinces (Tuscany, Romagna, the Marches and the Abruzzi), the wine has been of good quality. The best Malbeck wine was no doubt the Collemaiino of vineyards planted at Giulianova (Teramo) by Senatore DE VINCENZI; when aged it acquired a delicious bouquet and possessed all the other qualities of a superior table wine, alcoholic, complete flavour, harmonious and extremely pleasant. It was given a gold medal at to the International Exhibition at Bordeaux in 1882.

After the plantations of Giulianova, the Malbeck vine was imported into the Provinces of Caserta (Mignano) and Avellino (Avellino, Sant'Angelo all'Esca). The yield was abundant, but the quality of the wine was not satisfactory, at least in the first few years. The grape was very liable to rot and the wine was not only badly affected by " Casse, " but was also liable to turn sour. These negative characters are very probably due to the climate of these localities, which is rainy during the month of September, especially at the time when the grape ripens.

Thus, whilst at Giulianova the Malbeck grape produces an infinitely better wine than that produced in the Bordeaux district, on the Tyrrhenenian slopes in the two provinces of Campania, on the contrary, inferior wines are produced owing to the difference of climate and soil, viz., a climate with a heavier rainfall and a loose soil in place of clay loam.

According to the author, it is not generally desirable to extend the cultivation of the Malbeck vine, unless experimental cultivation shows that it is advisable. As the vine sprouts late and ripens fairly early, it is consequently very suitable for cold places, both on account of its escaping damage from frosts and on account of the complete ripening of the grape. It stands rain badly as rain favours the development of mildew (to which this vine is too sensitive) and rot in the grapes; when rain falls, during the flowering season which is fairly early, it causes the dropping off of the fruit of vine plants obtained from cuttings taken from unfertile or slightly fertile plants. In Venetia, the Cabernet and Merlot vines are preferred to the Malbeck.

The damage which damp causes to this vine explains the good results obtained in Argentina.

730 - **Experiments on the Cultivation of American Vines on the Hills in the Province of Pisa, Italy.** — RACAH, V., in *L'Agricoltura Toscana*, Year XII, Nos. 5-6 pp. 85-48. Florence, May 15-31, 1921.

The author describes work he has carried out on his experimental vines at S. Marco (Colline Pisane) and he deduces from it that although the planting of 1 ha. of vines now costs from 20 000 to 40 000 lire, if carefully done and well kept, the cultivation of vines is none the less remunerative.

A vine planted in Feb. 24, 1919, using slips of " Trebbiano " grafted on " Riparia, " had grown to a good size and bore large bunches of grapes at the end of 18 months; this shows clearly that it is not always true, that grafted American vines take 6 or 7 years to come into bearing.

The same is the case for certain current ideas which are unfounded; such as, for example, that grafts on American vines grow at first with difficulty and yield insufficient produce, and that vines grafted on American stock do not live more than 15 years. From several hundred 5-year old plants of the "Grand Noir de la Calmette" vine grafted on "Aramon Rupestris No. 1," the author obtained in 1920 over 4 kg. per plant A 29-year-old "Chasselas doré" vine grafted on "Riparia da seme" covers an area of 7 hectares and produced, in 1920, 57 quintals of grapes which were sold at 145 lire a quintal. With abundant manuring (green manuring with beans and lupins every three years, with 6 quintals of superphosphate and 10 quintals of ashes per ha.), il continues to grow vigorously and luxuriantly and gives an abundant crop each year. This proves the accuracy of the statement made by GERVAIS, viz., that the duration of American vines depends, within limits. on the care given to them by the grower.

An American vine which is much estimed for its tolerance of calcareous dry soil is the "Berlandieri Riparia 420 A." It is true that it has the fault that the cuttings root badly but the bad effects of this may be avoided by using short (35 to 40 cm.) cuttings which should be planted very early, that is to say, before they lose their leaves, or very late, i. e., when they have commenced to sprout. It is not true that this vine grows slowly and fruits rather late: one of the authors' vines, 6 years old a "Chasselas d'Alexandrie" or Salamanna (a delicate vine which is subject, in the Tuscana climate, to fungoid disease), grafted on "Berlandieri Riparia 420A" and grown according to THOMERY's system, grows vigorously and gives a high yield.

Many vine-growers hesitate to plant nurseries while they are uncertein as to whether the demand for American stocks will lâst or continue to be remunerative. This is a mistake, for the old nursery plants can be profitably turned into grape-producing vines when it is no longer profitable to grow them for the production of wood. With this object owing to their size, it is not advisable to cleft-graft them, but they should be cut level with the ground and in the following summer only 2 of the numerous shoots given off should be allowed to grow. In the following spring the old vinestock should be cut through obliquely so as to shed rain well above the lower of the two shoots and that shoot can then be grafted.

The idea that vines grafted on American stock are unsuited for training on trees is unfounded; on the Basseto property near Certaldo there are about 80 000 plants of the "San Giovese" vine grafted on "Riparia Gloire" trained on maple trees and growing excellently.

The main thing is the correct choice of the stock. In the flat, moist, deep, fertile soils of the Valdelsa, and generally, in rich, fertile soils, "Riparia Gloire" is an excellent vine for planting over a large area.

On soils not so rich the author recommends the following varieties :— "Riparia Rupestris 101-14" for fairly good soils on plains and on hills; "Aramon Ganzin No. 1" for rather moist clay soils; and "Rupestris du Lot" for gravelly dry soils with permeable subsoil.

731 - **Vine Grafting and Sunstroke.** — RACAH, V., in *L'Italia agricola*, Vol. 58, No. 3, pp. 77-79. Piacenza, March 15, 1921.

Sunstroke or apoplexy of the vine, especially common in grafted vines, is generally due to incomplete union between the graft and the stock. Wounds result which prevent the circulation of the sap; necrosis sets in with the formation of tissues mostly with a spongy texture which are subsequently attacked by fungi.

In the case of slight sunstroke, the author has applied the following treatment successfully:— Laying the vine bare as soon as it commences to wither; watering for 2 or 3 consecutive days with 8 to 10 litres of water; the plants revives and succeed in ripening its fruit, but this treatment, which is only symptomatic and does not reach the origin of the disease, does not cure radically.

To get such a cure two cases must be considered:—

1) *Non-grafted vines.* — The plant should be cut below the lowest point which necrosis has reached and reconstituted with the most vigorous of the shoots, the others being removed, or better still, cut the vine back level with the ground, and graft it.

2) *Grafted vines.* — The plant should be cut below the graft and a new graft made, either on the same stock or on the most vigorous of the shoots. If the tip of the graft is sound, a new graft can be made 8 to 10 cm. above. It is best to cut the vine obliquely and to keep the surface of the cut smooth and clean; it is a good plan to cover the cut with a varnish, the recipe for which, as recommended by the author, is as follows:— Black pitch, Stockholm tar, linseed oil in equal weights; after melting the pitch and the tar and mixing them thoroughly, add the oil and mix the whole thoroughly.

732 - **Experiments or Growing Broad-leaved Trees in Denmark.** — HOLM, C. J., in *Det Forstlige Forsøgsvæsen i Danmark*, Vol. V, Part. 8, pp. 293-299, figs. 1. Copenhagen, 1920.

In forests where gravelly and sandy hills alternate with peat bogs, there is need of a broadleaved tree which will grow on the hills, whilst the pubescent birch (*Betula odorata*) is the most suitable forest tree for peaty soil. For re-afforesting, relatively high sandy and gravelly land spruce has hitherto been principally used; this tree however has the defect of giving too dense shade to the surrounding birches and when the latter are killed blanks ensue which allow free access to the wind and endanger the spruce. In these conditions the Danish Forest Research Station has found it desirable to experiment with a certain number of exotic broadleaved trees in the largest block of the State forests of Northern Seeland

The land on which the experiments were made covers 6 hectares, at an altitude of 40-50 m. in a place where peat bogs lie between hills of gravelly sand mixed here and there with a little clay. The trees most extensively grown are *Quercus rubra* and *Betula odorata*; experiments have also been made with *Quercus palustris* and *Q. coccinea, Betula lutea* and *B. Maximowiczii, Acer Negundo, Fraxinus americana, Cercidiphyllum japonicum.*

Acanthopanax ricinifolium and *Albizzia Juliprissin*. Some of these trees have proved incapable of standing the rigours of winter followed by spring frosts, but the three species of American oak have done as well as could be desired, although they also have suffered somewhat from the cold. Among the birches, the Japanese *Betula Maximowiczii* Rgl. has turned out a well grown tree with well developed leaves.

733 - **The Identification of Different Timbers** (1).—PICCIOLI, L. (Professore Ordinario di Tecnologia del legno nel R. Istituto superiore forestale nazionale di Firenze), in *I. I. I.*, *Rassegna settimanale illustrata della produzione italiana*, Year V, Gen. Ser. No. 16 Sect C., No. 4, pp. 13-15, figs. 3 Milan, April 1921.

All timbers can be placed in 2 classes:—

I) Gymnosperms, whose timber has no vessels;

II) Angiosperms, whose timber contains vessels which traverse it longitudinally.

The latter includes:—

1) Monocotyledons, without annual rings, with fibro-vascular bundles arranged irregularly (reed, butcher's broom, rattan, palm, bamboo, etc.).

2) Dicotyledons, with annual rings, vessels, tracheids, fibres, and parenchyma. The real commercial timbers belong to the Gymnosperms (more precisely to the family of the Conifers) and to the Dicotyledons; for this reason the timbers dealt with are limited to these. As a guide to the division of types, series and groups, the rules which the author gives in summing up his investigations should be borne in mind.

CONIFERS. — These are distinguished from Dicotyledons by the simplicity of their structure because the wood is formed of tracheids and contains no vessels.

They may have radial resin canals, but the annual rings are nearly always visible, because the cells of the autumn zone have always thicker walls and smaller cavities than those of the spring zone. The structure of these timbers can be subdivided into the following types:—

TYPE I. — Tracheids with wide spiral thickening inside.

(1) Timber without resin canals, very hard, sapwood yellowish white and heartwood red brown. Specific gravity of air-dried wood, 0.73. — Yew (*Taxus baccata*).

(2) Timber with resin canals, medium hardness, sapwood narrow and light coloured, heartwood brown — Oregon pine = Douglas spruce = red fir = yellow fir = sapin odorant = sapin américain (*Pseudotsuga Douglasii*).

TYPE II. — Tracheids without inside spiral thickening.

Section I. — Timber with resin canals.

(A) Heartwood of different colour to the sapwood; rays with transverse tracheids above and below.

a) Sheath of the resin canals thin walled;

α) Transverse tracheids of the rays with pitted thickening;

---

(1) L. PICCIOLI, *Selvicoltura* Turin, Unione tipografico-editrice torinese, 1915.— IDEM, *Tecnologia del legno*, Turin U. T. E. T., 1919. (*Ed.*)

β) Autumn tracheids with thin spiral stripes.

1) Fields of crossing of rays and tracheids with 1-2 large holes; rays composed 12 rows of cells; sp. gr. 0.67. — *Pinus Laricio.*

2) Fields of crossing with 2-4 large holes; rays of 10-25 rows of cells; sp. gr. 0.75-0.90. — Pitch pine (*Pinus palustris*).

3) Fields of crossing as above; rays of 5 to 12 rows of cells, sp. gr. 0.67. — *Pinus Pinaster.*

γ) Autumn tracheids without special stripes; rays of up to 18 rows of cells; sp. gr. 0.32. — Scots pine (*Pinus sylvestris*).

δ) Transversal tracheids without pitted thickening.

1) Fields of crossing with 2-3 areolae, rays of 6 to 11 rows of cells; sp. 0.67. — *Pinus Pinea.*

2) Fields of crossing with only 1 areola, rays of up to 20 rows of cells; sp. gr. 0.41 — White pine (*Pinus Strobus*).

b) Sheath of the resin canals with dense well lignified walls; rays of up to 20 rows of cells; sp. gr. 0.60. — Larch (*Larix europaea*).

B) Heartwood the same colour as the sapwood or nearly so; rays of 20 to 30 rows of cells; sp. gr. 0.44. — Spruce (*Picea excelsa*).

Section II. — Timber without resin canals.

A) Medullary rays without transversal tracheids.

1) Rays of more than 20 rows of cells; fields of crossing with 2-4 areolae; sp. gr. 0.62. — Cypress (*Cupressus sempervirens*).

2) Rays of 25 rows of cells; sapwood and heartwood very distinct; sp. gr. 0.75. — Juniper (*Juniperus communis*).

3) Rays of at most 8 rows of cells; field of crossing with 2-6 areolae; sp. gr. 0.46. — *Sequoia sempervirens*

4) Rays of 10 to 15 rows of cells. — *Araucaria brasiliensis.*

5) Rays up to 30 rows of cells; sp. gr. 0.44. — Silver fir (*Abies pectinata*).

6) Rays of 2 to 4 rows of cells; sp. gr. 0.42. — Ginko (*Ginkgo biloba*).

B) Medullary rays with transverse tracheids or special cells.

1) Fields of crossing with a single large elliptic hole. — *Sciadopitys verticillata.*

2) Fields of crossing with 2-4 areolae. — *Tsuga canadensis.*

3) Fields of crossing with 4-8 areolae in series. — *Taxodium distichum.*

DICOTYLEDONS. — TYPE I. — Vessels of the spring zone of the annual rings forming a porous circle; rings very distinct.

Section I. — Large rays (15-30 rows of cells), easily visible with the naked eye (0.6 to 1 mm. wide).

A) Vessels of the autumn zone arranged in radial lines.

a) Medullary rays, some large and some very small.

α) Sapwood of 15-30 rings.

1) Timber with fibres somewhat twisted; the smaller vessels and the tracheids of the autumn zone arranged in radial bands like a fan and not branched; sp. gr. 0.74. — Sessile flowered oak (*Quercus sessiliflora*).

2) Timber with straight fibre; small vessels and tracheids of the autumn zone in bifurcating lines; sp. gr. 0.75. — Pedunculate oak (*Quercus pedunculata*)).

β) Sapwood of 10-15 rings; rays smaller than in the 3 preceeding species; sp. gr. 0.74. — *Quercus Farnetto.*

b) Between the large medullary rays and the very small ones, are others of medium size (2-4 rows of cells); sp. gr. 0 73. — *Quercus macedonica.*

B) Small vessels of the autumn zone in irregular groups; sp. gr. 0.83. — *Quercus Cerris.*

Section II. — Medium rays (6-12 rows of cells), visible with the naked eye.

Series I. — Vessels of the autumn zone arranged uniformly.

1) Sapwood greenish white or grey, 30 rings, and heartwood brown; sp. gr. 0.75. — *Celtis australis.*

2) Timber yellow; rays undulating; sp. gr. 0.80. — *Koelreuteria paniculata.*

3) Shrub with yellow sapwood and bluish red heartwood; sp. gr. 0.75. — Berberry (*Berberis vulgaris*).

Series II. — Vessels of the autumn zone in tangential lines (circular) or forming hieroglyphics. Sapwood and heartwood more or less distinct.

1) Timber soft, porous, sapwood yellowish white and heartwood red brown; medulla with secretory canals; sp. gr. 0.57. — Persian lilae (*Melia Azedarach*).

2) Timber semi-hard, sapwood straw coloured and heartwood chestnut coloured; rings slightly undulating; medulla 5-6 mm.; sp. gr. 0.69. — Coffee tree (*Gymnocladus canadensis*).

3) Timber semi-hard; sapwood ample, yellow, brown and not very different from the orange heartwood; medulla with numerous peripheral secretory canals; sp. gr. 0.66. — *Ailanthus glandulosa.*

4) Timber semi-hard; sapwood yellowish white and heartwood red brown; sp. gr. 0.65. — White Mulberry (*Morus alba*).

5) Timber hard; sapwood yellowish white (3-8 rings) and heartwood brown; sp. gr. 0.74. — Alpine laburnum (*Laburnum alpinum*).

6) Timber hard; sapwood yellowish white, compact, and heartwood dark brown; sp. gr. 0.67. — Elm (*Ulmus campestris*).

Series III. — Vessels of the autumn zone in groups; sapwood cream coloured and heartwood brick-red; sp. gr. 0.81. — *Gleditschia triacanthos.*

Section III. — Rays small (3-4 rows of cells), invisible, or almost so, to the naked eyes.

α) Autumn vessels isolated; timber whitish, hard; medulla reddish; sp. gr. 0.66. — Judas tree (*Cercis Siliquastrum*).

b) Autumn vessels in radial lines; timber yellowish white, soft. — (*Styrax officinale*).

c) Autumn vessels in tangential lines or groups.

α) Sapwood yellow or straw coloured.

1) Heartwood brown; vessels tylose; parenchyma round the vessels; sp. gr. 0.70. — *Robinia Pseudo-Acacia.*

2) Heartwood brown; vessels without "thyllae"; parenchyma tangential, sp. gr. 0.68. — *Sophora japonica.*

3) Heartwood yellowish brown, stains orange with potassium hydrate and violet with hydrochloric acid; sp. gr. 0.92. — *Chlophora tinctoria.*

4) Heart wood dark or sooty, porous, light, fragile, odorous, aromatic; sp. gr. 0.49. — *Sassafras officinale.*

β) Climbing shrub; timber porous with large extremely tylose vessels. — Wistaria (*Wistaria chinensis*).

Section IV. — Rays very small, invisible to the naked eye, of 1-3 rows of cells.

Series I. — Autumn vessels isolated.

1) Tree with soft timber, yellowish white or reddish white; medulla white, 1 cm. broad; sp. gr. 0.43. — *Paulownia imperialis.*

2) Shrub with hard timber, sapwood yellowish white and heartwood violet-brown, medulla snow white, 1 mm. — Lilac (*Syringa vulgaris*).

Series II. — Autumn vessels in radial lines.

1) Tree with yellowish white sapwood and brown heartwood; rays of a single row of cells; sp. gr. 0.61. — Chestnut (*Castanea sativa*).

2) Shrub; rays of 2 to 3 rows of cells. — *Phillyrea variabilis.*

Series III. — Autumn vessels in short series.

1) Vessels very tylose; timber soft; sapwood whitish and heartwood olive and sooty; sp. gr. 0.45. — *Catalpa bignonioides.*

2) Vessels not tylose; timber hard; sapwood reddish and heartwood light brown; sp. gr. 0.74. — Ash (*Fraxinus excelsior*).

TYPE II. — One circle of porous spring wood (large vessels) wanting in the spring zone of the annual ring.

Section I. — Medullary rays large and easily visible with the naked eye.

Series I. — Vessels isolated or in irregular groups or in very short lines.

Group I. — Vessels distributed uniformly and of equal size throughout the ring.

A) Vessels visible with the naked eye, isolated, or in lines of 2-7.

α) Vessels isolated and numerous. — Climbing shrubs with spongy and very flexible timber.

1) Sapwood yellow brown and heartwood red brown; sp. gr. 0.65. — Vine (*Vitis vinifera*).

2) Timber yellowish green, no heartwood; sp. gr. 0.40. — Clematis (*Clematis Vitalba*).

b) Vessels rare.

α) Parenchyma in thin peripheral lines visible with the naked eye.

1) Timber heavy; sapwood yellowish white or light brown, 15-20 rings, and heartwood reddish brown often veined; sp. gr. 0.64. — Walnut (*Juglans regia*).

2) Timber soft, icterical yellow, no heartwood; sp. gr. 0.71. — Fig tree (*Ficus Carica*).

β) Parenchyma perivascular, not visible with a magnifying glass; sapwood yellowish white and heartwood red brown. Timber hard; sp. gr. 0.71. — Tamarisk (*Tamarix gallica*).

B) Vessels invisible to the naked eye.

a) Medullary rays large with 5-20 rows of cells.

1) Heartwood brown and sapwood reddish white, semi-hard, very rich in vessels and rays enlarged where they meet the annual rings; sp. gr. 0.61. — Plane (*Platanus orientalis*).

2) No heartwood; timber greenish white; very hard; sp. gr. 0.89. — Holly (*Ilex Aquifolium*).

b) Rays, some large (12-15 rows of cells), some very small; sapwood 50-80 annual rings; timber of medium hardness without real heartwood; sp. gr. 0.74. — Beech (*Fagus sylvatica*).

c) Apparently large rays (because they are formed by the crowding of a great number of small rays), small rays of a single line of cells.

1) Timber soft with many medullary spots; sp. gr. 0.55. — Alder (*Alnus glutinosa*).

2) Timber very hard, whitish, without medullary spots; medulla homogeneous. Tree; sp. gr. 0.82. — Hornbeam (*Carpinus Betulus*).

3) Timber fairly hard; medulla heterogeneous. Shrub; sp. gr. 0.65. — Hazel (*Corylus Avellana*).

d) Rays medium, but visible with the naked eye owing to the different colour of the wood.

1) Tree with medullary rays more compact than the tissue of the wood, 5-6 rows of cells. Timber whitish or reddish yellow, no heartwood; sp. gr. 0.66. — Sycamore (*Acer Pseudo-Platanus*).

2) Bushes or shrubs with rays as compact as the tissue of the wood; timber pale yellow, homogeneous, hard, sp. gr. 0.80. — Lemon (*Citrus Limonum*).

3) Shrub; rays of 10 rows of cells; timber whitish or light brown. — Trailing Dog-Rose (*Rosa arvensis*).

Group II. — Spring vessels more numerous than those of autumn, so that they form a less dense and lighter coloured zone; sapwood and heartwood.

1) Sapwood narrow (8-12 rings), yellowish white; heartwood very hard, violet or chestnut brown like mahogany, with veins; sections seen by transmitted light appear blood brown; sp. gr. 0.75. — Plum (*Prunus domestica*).

2) Sapwood reddish white with medullary spots and heartwood brown; timber semi-hard; sp. gr. 0.66. — Bird Cherry (*Prunus avium*).

3) Sapwood compact, yellowish white, heartwood red brown and veined, very hard; sp. gr. 1.00. — Almond (*Prunus Amygdalus*).

Series II. — Vessels in radial undulating series. Timber hard.

1) Small vessels and tracheids in irregular groups; timber red brown; very hard; sp. gr. 0.90-1.18. — Ilex (*Quercus Ilex*).

2) Small vessels in short series over the whole ring ; timber yellow brown ; sp. gr. 0.95. — Cork Oak (*Quercus Suber*).

b) Heartwood wanting; timber light yellow; bush with rays of up to 3 rows of cells. Medulla round or oval. — Laurel Cherry (*Prunus Laurocerasus*).

Series III. — Vessels in tangential (peripheral) lines; timber very hard.

1) Heartwood reddish brown, sapwood greyish white. Tree; sp. gr. 0.80-1.01. — *Casuarina equisetifolia.*

2) Timber yellowish. Shrub — *Anagyrus foetida.*

Section II. — Rays imperceptible, or nearly so, to the naked eye.

Series I — Vessels in radial lines.

1) Tree with very hard timber, rings very indistinct; sapwood yellowish white and heartwood brown with dark veins; sp. gr. 0.86-1.00. — Olive (*Olea europea*).

2) Tree with hard timber, whitish veins, sapwood ash-grey and heartwood brown; rings distinct, very irregular, with large canals in tangential lines ; sp. gr. 0.95. — *Avicennia nitida.*

3) Shrub or bush; timber soft, straw yellow or white, with distinct rings ; medulla triangular ; sp. gr. 0.56. — Oleander (*Nerium Oleander*).

Series II. — Vessels in tangential lines or bands ; timber hard

1) Tree with heartwood sooty chestnut ; rays of 1-2 rows of cells; sp. gr. 0.83. — *Astronium fraxinifolium.*

2) Shrub ; timber nut-coloured ; rays very thick. — *Myoporum debile.*

3) Shrub ; timber straw coloured or greenish white. — *Pittosporium Tobira.*

4) Tree ; sapwood yellow brown and heartwood red brown ; rings undulating. Rays of 4-5 rows of cells, with fine silky polished surfaces of 5-10 mm. height ; sp. gr. 0 70. — *Ceridium Torreyanum.*

Series III. — Vessels isolated or in small groups irregularly distributed.

Group I. — Vessels isolated.

(*A*) Timber hard or very-hard.

a) Heartwood or timber altogether lemon-yellow or dun ;

1) Timber lemon-yellow, very hard ; rays of 1-3 rows of cells; medulla 0.5 mm. ; sp. gr. 0.92. — Box (*Buxus sempervirens*).

2) Timber dun ; rays of up to 8 rows of cells ; medulla 2-3 mm. — *Garrya elliptica.*

b) Heartwood or timber altogether yellow brown, brown, reddish yellow or sooty.

1) Heartwood brown, sapwood yellowish white ; rays of a single row of cells; medulla white, quadrangular, 2 mm. Shrub; sp. gr. 0.68 Spindle-tree (*Euonymus europaeus*).

2) Heartwood yellow brown and sapwood reddish white ; timber hard ; rays of 1-3 rows of cells ; medulla angular, 1.5 mm. Shrub ; sp. gr. 0.93. — Wayfaring-tree (*Viburnum Lantana*).

3) Heartwood brown, compact, very hard; sapwood 5-12 rings; medulla 5-8 mm. reabsorbed when fully grown. Rays of 1-3 rows of cells; sp. gr. 0.80. — Upright Fly Honeysuckle (*Lonicera Xylosteum*).

4) Heartwood sooty and sapwood dun; rays very thick, lighter in colour than the wood; sp. gr. 0.65-0.80. — *Prosopis nigra.*

5) Heartwood reddish yellow or sooty, very close grain, hard, silky; rays lighter in colour than the wood; sp. gr. 1.07. — *Dipteryx odorata.*

c) Heartwood violet brown; sapwood straw colour; medulla snow-white, 12 mm. Shrub. — Privet (*Ligustrum vulgare*).

2) Heartwood greenish brown with dark veins; sapwood dun; timber very hard, with an acrid aromatic taste and a resinous smell; sp. gr. 1.27. — Guiacum (*Guajucum officinale*).

d) Heartwood or timber altogether reddish or red brown, compact, homogeneous, hard.

1) Timber reddish, no heartwood, rays of 1-2 rows of cells. Shrub; sp. gr. 0.81. — Myrtle (*Myrtus communis*).

2) Timber with reddish brown heartwood and yellowish white sapwood; rays of 1-4 rows of cells; medulla white, round, 3 mm. Shrub. — *Philadelphus coronarius*

3) Timber reddish, no heartwood; rays of up to 6 rows of cells. Timber of the roots (" bruyère ") is mottled. Shrub; sp. gr. 0.94. — Tree heath (*Erica arborea*).

4) Timber with red brown heartwood and pinkish yellow sapwood; rays of 1-3 rows of cells darker in colour than the wood; shrub, sp. gr. 0.96. — *Arbutus Unedo.*

5) Timber with reddish heartwood and light coloured sapwood of 20-25 rings; medulla snow coloured, 0.5-1 mm. Rays of up to 5 rows of cells; sp. gr. 1.03. — Cornelian Cherry (*Cornus mas*).

6) Timber without true heartwood, reddish brown; medulla white, round, and 1 cm. broad; sp. gr. 0.75. — Pear (*Pyrus communis*).

7) Timber without heartwood, light yellow; rays of 1-3 rows of cells; medulla round, white, and 1 cm. broad; shrub; sp. gr. 0.96. — Elder (*Sambucus nigra*).

e) Heartwood red brown or reddish, brick red, chestnut, umber, or dark purple, etc.; trees of foreign origin.

1) Timber red brown or reddish; vessels full of yellow-brown resin; rays of a single row of cells. — *Eucalyptus* spp.

2) Heartwood red brown alternating with yellowish parts, rose scented; sp. gr. 1.00. — Brazil rosewood (*Physocalymna scaberrimum*).

3) Heartwood red brown or wine colour, rich in red colouring matter, aromatic scent and sweetish taste; sp. gr. 1.01. — *Caesalpinia Crista.*

4) Heartwood brick red, sapwood dun or tortoise, rays of 3-4 rows of cells, with polished surfaces like those in beech; sp. gr. 1.20. — Mangrove (*Rhizophora Mangle*).

5) Timber brick colour, compact, easily polished; parenchyma is very dense in very fine peripherical lines of 2-4 elements; sp. gr. 1.10 — *Lecythis grandiflora.*

f) Heartwood chocolate, chestnut, umber or coffee colour, parenchyma in fine peripherical lines.

1) Heartwood chocolate. — *Pimenta officinalis.*

2) Heartwood chestnut, violet or blackish veins, smells of anise; sapwood narrow, grey or tortoise. Difficult to cut except when green on account of its hardness; sp. gr. 1.10-1.29. — Assam Iron wood (*Mesua ferrea*).

3) Heartwood umber or coffee colour, aromatic; sapwood narrow, whitish or light brown; rays of 3-5 rows of cells, vessels contain oleoresin; sp. gr. 0.50-0.93. — Teak *Tectona grandis*).

(*B*) Timber soft, light.

a) Shrub, sapwood light yellow 10 rings and heartwood reddish yellow; sp. gr. 0.62. — Alder Buckthorn (*Rhamnus Frangula*).

b) Trees.

1) Timber white, like tow, without heartwood; medulla white, quadrangular, 2-4 mm., sp. gr. 0.65. — Horse chestnut (*Æsculus Hippocastanum*).

2) Timber with cinnamon or tobacco-coloured heartwood and reddish white sapwood, aromatic, bitter; rays of 4-6 rows of cells; large vessels; sp. gr. 0.56. — *Cedrela odorata.*

3) Timber with light-brown heartwood and sapwood of 30-100 annual rings, yellow, straw yellow or light colour, resembling timber of willows and poplars; vessels very small and very numerous; rays very fine, white and shining; sp. gr. 0.65. — *Nyssa multiflora.*

4) Timber and heartwood reddish brown sapwood cream or dun; annual rings undulating and seen best by transmitted light; rays very dense, fine, with fine, graceful surfaces; sp. gr. 0.63. — *Liquidambar styraciflua.*

Group II. — Vessels partly in pairs, in lines or in groups of 3 to 10.

A) Timber bony or stony.

1) Heartwood black (the only part used commercially); sapwood narrow, yellow brown; sp. gr. 1.16. — Ebony (*Diospyros Ebenum*).

2) Heartwood bay or dark purple; sp. gr. 0.81-1.03. — White Quebracho (*Aspidosperma Quebracho*).

3) Heartwood red brown with blackish stripes; sapwood very narrow, grey, rose scented when green (rose wood); boiled with water it gives a yellow tint; with alcohol pink-violet; with ammonia dark brown, sp. gr. 0.86. — *Jacaranda brasiliana.*

(4) Heartwood dark red outside and light inside, pleasant scent and bitter taste. Large vessels isolated and joined by transverse lines of small vessels; sp. gr. 0.75.-1.04. — *Pterocarpus santalinus*

(*B*) Timber hard; heartwood reddish brown and sapwood light brown; vessels contain gum; rays of 2 rows of cells; sp. gr. 0.70-0.85. — Mahogany (*Swietenia Mahagoni*).

(*C*) Timber soft.

(*a*) Vessels partly arranged in radial lines of 3 to 11; timber yellowish or yellow brown; rays of 2-5 rows of cells; sp gr. 0.57. — Tulip tree (*Liriodendron tulipifera*).

(*b*) Vessels in groups or lines of 2 to 5.

(α) Timber bitter, straw yellow. — *Quassia amara.*

(β) Timber tasteless, light.

(1) Timber whitish without medullary spots and without heartwood; vessels with spiral thickenings; sp. gr. 0.58. — Lime tree (*Tilia europaea*).

(2) Timber without medullary spots, sapwood yellowish white and heartwood light in colour; vessels without spiral thickenings; sp. gr. 0.41. — Black Poplar (*Populus nigra*).

(3) Timber with medullary spots, yellowish white or reddish white; vessels without spiral thickenings; sp. gr. 0.73. — White Birch (*Betula alba*).

Series IV. — Vessels with reticulations, hieroglyphics, or slanting bands.

(1) Trees with yellowish white sapwood, 3 or 4 rings, and heartwood dark brown of coarse tissue, hard; sp. gr. 0.86. — *Laburnum anagyroides.*

(2) Shrub with yellowish white sapwood, abundant; heartwood reddish yellow; medullary rays of 1 to 3 cells; sp. gr. 0.81. — *Pistacia Lentiscus.*

LIVESTOCK AND BREEDING

734 - **Experiments in France on Milking Cows Suffering from Foot and Mouth Disease even when the Teats showed Lesions in Order to Maintain Milk Secretion Near to the Quantity obtained before the Disease appeared.** — PORCHER, *Ch.*, in the *Comptes rendus des séances de l'Académie des Sciences*, Vol. 171, No. 2, pp. 122-125. Paris, July 12, 1920.

The analysis of the milk during the course of foot and mouth disease reveals great discrepancies in the chemical composition. The author has demonstrated experimentally that, in cases where the percentages of the components of the milk were in deficit, the retention of milk, following suspended or restricted milking, acted in proportion of the extent to which the teats were affected by the disease.

In a milch cow affected by foot and mouth disease and in which the disease showed typical development, the teat *AL* (anterior left) which first showed lesions was not milked, whilst milking was done on the other teats ($A\ R + P\ R + P\ L$).

Milking was resumed on teat *AL* after 48 hours. The analytical data, recorded in a table, enable the following conclusions to be drawn: -

1) The retention of milk for two days in the quarter *AL* has furnished results which are in perfect agreement with those previously obtained namely:— Decrease of lactose, increase of salts, constant cryoscopic diminution, large decrease in the refractive index and notable increase in conductivity.

2) By retention in one quarter, milk secretion returns but slowly to its previous level.

3) On the other hand, by milking the teats affected by aphthae,

the quantity of milk obtained is little less than it was before the disease declared itself; this deduction is made from the fact that the cow in question, which gave 13.25 litres of milk on May 10, the day before the disease showed itself, gave 11 75 litres of milk of May 21, four days after retention in teat *AL* (which had lasted 48 hours) was discontinued.

According to the author the functional effort of the mammary gland during the disease, intensified by increasing the number of milkings up to 3, or even 4, a day, would cause the lactic secretion to come very nearly up to the quantity obtained previous to the disease and to do so more quickly.

735 - **Preservation of Aphthous Virus by Cold.** — LEBAILLY, C., in the *Comptes rendus de l'Académie des Sciences*, Vol. 172, No. 20, pp 1261-1262. Paris, May 17, 1921.

The author has tried the preservation of aphthous products in a freezing machine working between —4° and —8°C; 800 cc. of the blood of an ox at the height of an attack of foot and mouth disease was drawn off aseptically in a phial containing 50 cc. of a sterilised 10 % solution of sodium citrate in distilled water, and then distributed in small phials. The temperature not being sufficiently constant the virus was subjected to alternate freezing and thawing. However, it proved to be still active after 72 hours in 10 cc. doses injected subcutaneously. There is no doubt that by means of apparatus working regularly much better results would be obtained; the author is continuing his experiments with this object.

736 - **Efficiency of Chloroform and Thymol Against Hookworms (*Uncinaria polaris*) in the Silver Black Fox of Canada.** — ALLEN, J. A in *Journal of the American Veterinary Medical Association*, Vol LIX, No 1, pp. 62-72. Washington, April 1921.

In Canada, particularly in the province of Prince Edward Island, the raising of silver-black foxes in captivity has become an important industry and foxes are now also being bred in other provinces of Canada, the United States, Japan and some European countries.

During 1920, the approximate value of the foundation stock and of the pelts marketed that year is said to be $ 1 400 000 and this sum exceeds the revenue derived from all other classes of live-tock in this small province which has a population of less than 100 000 people. During 1920, there were over 2000 live foxes exported from the Island which has always been regarded as the principal breeding centre.

Investigations dealing with a considerable number of carcasses combined with further data obtained by the Fox Research Station have shown a large percentage of the animals harboring hookworms (*Uncinaria polaris* Loos).

It is the experience of practical fox farmers that a much larger percentage of foxes are now developing undesirable texture and colours. There are two conditions that have given fox breeders much concern: 1) Woolliness and 2) rust. In the first case the fur loses its silky texture, feels much like wool and the long hair (guard hair) does not grow to the required length. With rust, the fur takes on a reddish or brownish hue instead of the deep, glossy blue-black colour that characterises a prime pelt.

The fact that over 68% of the woolly and stunted animals used in this experiment harbored hookworms is significant.

The author has conducted a series of experiments on the most efficacious treatment of this disease with a view to reducing as much as possible the number of tainted furs. The results are summarised as follows:

1) *Uncinaria polaris* when present in large numbers undoubtedly influences the condition of the fur.

2) Chloroform is inefficient as an anthelmintic against hookworms in foxes and is also a dangerous drug, producing a mortality of 50 % in the present experiments.

3) Thymol showed a high degree of efficiency (87.8 %) when given to foxes on the basis of 0.13 gm. per kg. of body weight with this dose repeated in 2 hours. Before and after the anthelmintic given in capsule form, the animals received a purgative (magnesium sulphate).

From this dosage, a mortality of 18.7 % followed which makes it somewhat dangerous for universal application.

4) When thymol is used on the basis of 0.065 gm. per kg. of weight and the dose repeated in 2 hours, an efficiency of at least 33 % may be expected, and the mortality is reduced to about 6.8%; one dose given thus apparently has little or no anthelmintic effect.

737 - **Fattening Experiments on Pigs with "Maismastfutter" and Sweet Moist Lupins Respectively, in Germany.** — MÜLLER, K. (Director of the Experimental Farm at Ruhlsdorf (Teltow), for keeping, feeding and breeding pigs), in: — I. *Deutsche Landwirtschaftliche Presse*, Year XLVIII, No. 29, p. 221. Berlin, April 1921. — II. *Deutsche Landwirtschaftliche Presse*, No. 36, pp. 275-276, Berlin, May, 1921. — III. *Mitteilungen der Vereinigungs, Deutscher Schweinezuchter*, Year XXVIII, No 5, pp. 93 95. Berlin, May, 1921.

I and III. — Tests with "Maismastfutter," a fattening food placed on the market by the "Bezugsvereinigung Deutscher Landwirte G. m. b. H. Berlin," consists of maize and fish meal residues.

It contains: 18.3-20.8 % crude protein: 5-6.2% crude fats; 45.5-54.4% non-nitrogenous extracts and 5.4-9 % crude cellulose.

Four young castrated Large Yorkshire males with an average initial live weight of 75 kg. were selected for the tests which lasted from 2 to 4 weeks (2 periods).

First period. — The pigs were fed for 4 weeks on a mixture composed of 1 kg. of "Maismastfutter" and 8 kg. of steamed and mashed potatoes (starch content 16 %).

This mixture, given cold to the pigs, was eaten in considerable quantities; thus 10.7 kg. of the mixture per head per day was ingested during the first week, 14.7 kg. during the last and, on the average, 12.6 kg. containing 1.75 kg. of "Maismastfutter" and 10.85 kg. of potatoes.

Second period. — The quantity of "Maismastfutter" in the mixture was increased; the mixture then consisted of 2 kg. of "Maismastfutter " and potatoes as required. On an average, 12.05 kg. of this mixture, containing 2 kg. of " Maismastfutter " and 10.05 kg. of potatoes, was consumed daily by each pig.

The average increment in weight during the 4 × 7 = 28 days was 25 + 24 + 23 + 31 = 103 kg. for the first period and 20 + 18 + 25 + 22 = 85 kg. for the second period, corresponding to an average increment of 920 and 760 gm. per head per day respectively.

The production of 1 kg. live weight corresponded to a consumption of 2.27 kg. of " Maismastfutter " and 12.51 kg. of potatoes. No unfavourable influence on the meat was noticed. " Maismastfutter " in conjunction with potatoes is a good food for fattening pigs.

II and III. — EXPERIMENTS ON FATTENING PIGS WITH SWEET MOIST LUPINS.

(A) *The concentrates usually used are replaced partly by sweet moist lupins* (1). — The experiments were made on 6 pigs 8 months old of improved country breed with an average live weight of 60 kg.; the test lasted 6 weeks. The pigs were given 1 kg. of crushed barley, 100 gm of fish meal, 500 gm. of serradella husks, and 1.15 kg. of sweet moist lupins, mixed with steamed potatoes, per head per day. The increase in live weight per head per day was 834 gm., so that the production of 1 kg. of live weight required 1.2 kg. of crushed barley. 0.12 kg. of fish meal, 0.6 kg. of serradella husks, 1.4 kg. of sweet moist lupins, and 12.1 kg. of potatoes.

The author compares the experimental data of the two tests with the results of the previous test (2) and observes that the increase in weight per day per head was equal in the three tests and, further, that the ration containing only a portion of the concentrates in the form of lupins, proved in no way superior to the ration in which the lupins entirely replaced the concentrates

(B) *Semi-sugar-beet as a substitute for part of the potatoes in the ration.* — The experiments were made on 24 pigs of which 21 were of large Yorkshire breed and 3 half-bred pigs of the cross Improved country breed × Local Hildesheim breed. The initial weight per head averaged 73 kg.

The pigs were divided into three lots and were given the following mixtures: —

Lot 1: — 16 kg. of potatoes, 16 kg. of semi-sugar-beet and 3 kg. of sweet moist lupins (equal to 1 kg. of dry lupins).

Lot 2: — 16 kg. of potatoes, 16 kg. of sugar-beet and 4.5 kg. of sweet moist lupins (equal to 1.5 kg. of dry lupins).

Lot 3: — 16 kg. of potatoes, 16 kg. of sugar-beet and 6 kg. of sweet moist lupins (equal to 2 kg. of dry lupins).

---

(1) In the previous experiments the lupins entirely replaced the concentrates and were given mixed with steamed potatoes to the pigs. See *R.*, Feb. 1921, No 119. (*Ed.*)

(2) For the preparation of potatoes and lupins see *R.* Feb 1921. (*Ed.*)

The starch content of the potatoes was 14-16 % and the dry matter content of the sugar beet 15 %.

The tests lasted 8 weeks.

Quantities of food consumed by the 4 lots and quantities required to produce 1 kg. in live weight.

Lot	Food consumed	Mixture containing			Conversion of quantities of moist lupins into equivalents of dry lupins	Increase of weight per day per head	Quantities required for the production of 1 kg. of live weight			
		Moist lupins	Potatoes	Beet			Moist lupins	Dry lupins	Potatoes	Beet
	kg.	kg.	kg.	kg.	kg.	kg.	kg.	kg.	kg.	kg.
1	17.07	1.465	7.802	7.802	0.488	0.619	2 36	0.786	12 60	12.60
2	15.53	1.912	6.809	6.809	0 637	0 507	3.77	1.257	13 43	13.43
3	16.54	2 611	6.965	6 965	0.870	0.591	4.42	1.473	11 78	11.78

It appears from this table that the mixture eaten by Lot 1 gave the best results and this stands out still more clearly when the return is calculated. The author explains this by the fact that the protein content of that ration (0.257) was just sufficient (corresponding to KELLNER'S figure, 0.255 kg.) whilst the mixture fed to Lots 2 and 3 contained an excess of protein which could produce no favourable effect.

Further, the author, comparing these results with those of the test made last year, notes that the feeding effect of the ration containing semi-sugar-beet is inferior to that of the ration containing potatoes and sweet lupins only.

The increase in weight of the pigs of different breeds cannot be compared as they were unevenly distributed in the 3 lots; however, the cross-bred pigs in Lots 1 and 3 showed a smaller gain in weight than the Yorkshires

A later experiment with purchased sweet lupins showed the necessity of using lupins sufficiently sweet for rational fattening of pigs. As the trade lupins were not sufficiently freed from their bitter properties, the pigs only consumed 7.12 kg. per day per head and gained an average of 0.289 kg. in live weight.

738 - **Note on a French Fish Meal.** (1) DAHL, E., in the *Annales de la Société des Sciences Naturelles de la Charente-Inférieure*, Nov 1920; reviewed in the *Bulletin de la Société Scientifique d'Hygiène Alimentaire et d'Alimentation Rationnelle de l'Homme*, Vol IX, No 2, pp. 102. Paris, 1921.

Meal made at the Aytré factory utilising fish unfit for human food, edible species of fish which are unsaleable, and the heads of large fish. They are placed in driers in which they are simultaneously cooked, dried and ground.

---

(1) See *R.*, May 1921, No. 513 (*Ed.*)

After 4 hours an amber-coloured coarse powder containing quantities of bones, sharp bones and teeth, is taken out of the drier. This powder than passes into an electrically driven grinder, and is then sifted, reground, and again sifted very finely. The meal is then in the form of a yellow powder, smelling strongly of fish and having the following composition:— Protein 60 02 %; fats 9.68 %; mineral matter 18.90 %; moisture 14.40 %. The mineral matter contains:— Lime 7.60 %; phosphoric acid 7.08 %; sodium chloride 1.52 %. Its digestibility is 90 % and its nutritive value 72.9.

739 - **Correlative Variability in Domestic Animals.** — FEIGE, E., in *Landwirtschaft liche Zeitung*, Year 70, Nos. 3-4, pp. 61-69. Stuttgart, Feb. 1921.

Critical study of the method of calculating correlation from statistics of variations (1). The author explains that the biological conception of correlations does not agree with the usual procedure in the statistics of variations. Most comparisons between morphological characters, and between these and physiological characters, are not true correlations but functions of a third-degree magnitude that may give a positive or negative coefficient of correlation, which, on the contrary, does not enable a direct relationship to be deduced from it. All organs of an individual have, within their fixed limit of organisation, a deviation of variations, which is not in direct relationship of a correlative kind with all the other elements of the whole organism. All our calculations of variation are based on a supposititious average value of a series and correspond to that series, but for all that they are not expressions of an absolute fact and can only express a mathematical probability.

Consequently it is always possible from time to time to note that, in certain individuals, other bodily relationships appear, contrary to the average expectation.

Thus, it has been found, by calculation on 1828 Holstein cows ("Holsteiner Elbmarschkuh"), that regarding length of body, the "typical" average value was 159.973 cm., while the deviation of variation on this basis, accepting JOHANNSEN'S value $M \pm 30$ ($\varsigma = \pm 7.233$) varies between 138.304 and 181.624 cm. Actually there are variants above and below that deviation of variation which do not correspond in any way with the calculated type.

A single combination of the mathematical expressions of all the individual attributes might represent the bodily conformation of the maximum aptitude of a physiological attribute, such as the milking quality of an animal, but this method is not applicable, as a single extreme variant would upset the whole system of constancy of relationships, and also because each may constantly be displaced, so that it is impossible to find a standard generally valid for milk production by means of measurements and inspection of animals; that must be left to chance or zootechnical skill.

---

(1) Method used by AUSTIN with the object of introducing exact methods in estimating the relationship between bodily conformation and aptitudes of animals.

E. AUSTIN: Körperform und Milchleistung, 33. *Flugschrift der Deutschen Gesellschaft für Züchtungskunde.* Berlin, 1915. (*Ed.*)

This statement is not affected by the fact that a marked diposition to produce milk may be associated with a certain type of conformation which from a zootechnical standpoint does not represent any improvement, either because variation and copulation may always create new types, or because quantitative researches of the kind of the statistics of variation extending over several generations and taking biological analysis into account have not yet been made for domestic animals.

740 – **On the Cross between Jersey and Dutch Black Piebald.** — VAN DER PLANCK, G. M., in *Genetica*, Part II, No. 4, p. 300. 'S Gravenhage, July, 1920.

The author's experiments, provide no confirmation for KUIPER'S statement that the product of the cross Jersey × black piebald (" Zwartbont Vee ") should be more or less spotted in the F_1 generation.

It is precisely the white marks which are reduced to a minimum. Only a small white spot on the belly was noted. The coat of the calves is of a tint slightly more dark brown than the typical coat of Jersey. The zone of light hair round the muzzle and on the forehead which is characteristic of Jerseys is wanting.

741 – **Note on the Cattle of French West Africa.** — *Revue Générale du Froid et des Industries Frigorifiques*, year II, Vol. II, No. 4, pp. 137 Paris, April, 1921.

It has been said that the cattle of French West Africa, are of inferior quality, but veterinary surgeons who have stayed in those regions affirm that there is no truth in the statement. The meat is of excellent quality, and the yield, judging from the weights of cattle from Kaolack, is similar to that of French breeds, as will be seen by Table I.

TABLE I. — *Yield of Kaolack cattle.*

Live weight	300 kg	Feet (live weight)	1.7%
Yield	49.5%	Raw tallow	2.0
Hide	7.0	Bone	17.0
Head	2.5	Meat net of the weight in quarters	33.0

TABLE II. — *Number of cattle.*

Senegal	800 000 head
French Sudan and Upper-Volta	1 800 000 »
Guinea	400 000 »
Mauritania	500 000 »
Total	3 500 000 head

These figures are much below the true ones and ought certainly to reach 5 millions, including the cattle of Togo, the Ivory Coast, and the Niger Territories; 120 000 bullocks are available annually. Since 1912, peripneumonia has made great ravages. The losses were often 50 % and over, the average loss being 30 %. Cattle plague has caused a loss of 350 000 head.

The numbers of sheep and goats are indicated in Table III.

TABLE III. — *Number of sheep and goats.*

	Sheep	Goats
Senegal	250 000	700 000
French Sudan and Upper-Volta	2 500 000	3 000 000
Mauritania	2 000 000	3 000 000
Guinea	800 000	1 000 000
Dahomey	150 000	200 000
Ivory Coast	400 000	200 000

Among measures indispensable to the development of the flocks and herds may be mentioned:— Organisation and development of the Veterinary Service; increase in the number of wells so as to reduce the long journeys to water which fatigue the cattle; the improvement of cattle by selection.

742 - **The Reconstitution of the Cattle in Friuli, Italy.** — MURATORI, M., in *L'Italia agricola*, Vol. 58, No 5, pp. 129-134, figs. 3. Piacenza, May 15, 1921.

From a cattle-breeding point of view the Province of Udine should be divided into 3 regions:— 1) The mountains, where mountain breeds for milk production are kept; 2) the hills and the plains of middle and lower Friuli, where a local piebald breed is kept mainly for meat but also for milk and for work; 3) the hills and the plains of Western Friuli where is kept the grey breed in which aptitude for work while predominant does not exclude aptitude for the production of milk and meat (1).

According to data collected by Dr. P. ZANETTINI, ex-secretary of the Provincial Zootechnical Council, the total number of cattle, when the Province was invaded, was 216 000 head, of which only 19.5 % remained, that is to say about 42 100 head of cattle distributed as follows:—

13 500 in the mountains	against	48 000	before	the	invasion
23 000 in middle and lower Friuli	»	129 000	»	»	»
5 600 in western Friuli	»	39 00	»	»	»

Of the cattle left 85 to 95 % were cows. In the two years 1919 and 1920, private persons and the "Consorzio zootecnico provinciale" introduced about 52 000 cows and 10 000 bullocks into the Province of Udine; about 4000 of these cattle died of foot and mouth disease and a good part of the imported cows had to the replaced on account of permanent barrenness. Brown cattle chiefly were sent to the mountains; to hills and plains animals of northern Italian breeds were sent indiscriminately.

---

(1) Detailed information regarding the distribution of breeds of cattle in Friuli will be found in a Report by M. MURATORI published by the "Commissions di studio per la ricostituzione agraria delle terre invase." Rome, L'Union Editrice, 1919. See also *R.*, March 1921 No. 318; April, 1921, No 358. (*Ed.*)

The Zootechnical Commission, on recommencing work in the spring of 1919 proposed specially to re-establish the red piebald breed in middle and lower Friuli and the grey breed in western Friuli and to proceed with the gradual diffusion of the brown breed in the mountains, except for the Canal del Ferro and a few communes of the districts of Gemone (a land too poor for this breed), where it is proposed to reconstitute the small local red piebald breed, an offshoot of the Mölthal breed which is found in many of the alpine provinces of Austria. As the acquisition of such cattle in Austria presented difficulties, recourse was had to the Valdostana red piebald breed, akin to the Friuli breed.

In 1919, 350 bulls for public service were approved (about 60 % of the number which existed in 1916) distributed as follows: —

145 red piebald breed in middle and lower Friuli.
42 grey breed in Western Friuli.
123 brown breed in the Carnic Alps and Prealpes and in the mountain communes of the districts of Tarcento and Cividale.
40 Valdostana and Mölthal breeds in Canal del Ferro and in the mountain communes of the districts of Cremona.

The number of cows existing in the Province in 1919 represented about 60 % of the number in 1916, that is to say 70 000 as against about 120 000.

In 1920, the Zootechnical Commission placed 130 more young bulls, namely 13 Valdostana, 40 brown, 62 piebald and 15 grey, distributed in the regions mentioned above against each of these breeds. The number of approved bulls for public service was 462, or about 90 % of the number in 1916.

On the whole work accomplished by the Zootechnical Commission in 1919-1920 a total of 400 000 *lire* was spent, almost entirely used in the purchase and maintenance of the stud bulls.

In conclusion, the author outlines the programme of future work for restoring the cattle throughout the geographical area of each breed.

743 - **The Marsh and the "Procoio Bufalino" (1) in the Province of Rome, Italy.** — BIANCHINI, B., in the *Rivista Agricola Romana*, Vol. XLVII, No. 5, pp. 120-128. Rome, May, 1921.

In the low Maremma of Latium and in the Pontine Marshes buffaloes are bred on a large scale, making use of marsh land on which no other animals could live and which cannot be cultivated under any crop. The two principal centres of buffalo breeding are situated, one at Maccarese (Roman Campagna), the other, much more important, at "Foce Verde" in the commune of Cisterna. In that stretch of marsh and forest the buffalo gives a high return as the very inferior forage provided by the marsh grass suffices and the animals do not require any particular care while they furnish very rich milk, can be used for any kind of agricultural work and, like the ox, can finally be sent to the butcher. The idea that buffaloes give little profit is absolutely unfounded and it is a pity that their improvement has been neglected.

---

(1) "Procoio bufalino" = buffalo breeding farm. See *R.*, May 1921, No. 536 (*Ed.*)

Full grown buffaloes weigh from 4 to 5 quintals; the males reach even 7 quintals and over They are therefore fairly good animals for meat production; the meat, although darker in colour than that of oxen and cows and of a coarser grain, is just as wholesome.

Buffalo calves are reared exclusively on milk for the first 2 months and partly on milk until they are 8 months old. The second period is necessary, so that the cows may be milked as they will not give milk unless they are under the illusion that they are suckling their calves. This is the reason for the very original method of milking which is done at fixed times, generally 4 o'clock in the morning and 4 o'clock in the afternoon: At milking time the cows are collected in a " rimessa " (railed-off area) and the calves in a " rimessino " opposite; the " bufalari " provided with pails, are stationed between the two enclosures with the " paravanti " whose business is to keep the cows in order with their sticks. A " bufalaro " calls a cow by name; the calf, which has already learned to recognise its mother's name begins to low and comes to the rail of the " rimessino. " A man lets it out; the cow comes into the central space and the calf begins to suck. As soon as the cow begins to suckle the calf the latter is driven off by a blow of a stick on its muzzle and its place is taken by the " bufalaro " who starts milking. The cows after having been milked are driven into a " rimessino " apart, where are also driven the calves which, a short time before, had been prevented from sucking and which are now allowed to suck the small amount of milk that remains

With the buffalo milk various delicious milk foods are prepared, such as :— " provature, " " mozzarelle, " " marzoline, " " provoloni, " " uova di bufala " (buffalo eggs), " abote. "

The buffalo is wild and suspicious, but obedient to the orders of the " bufalaro, " the only person it obeys. They are stronger than oxen. In Latium they are yoked, and are well suited to drag very heavy loads over difficult roads.

Owing to the fact that buffaloes stay willingly in the water and do not suffer from rheumatism they are used for clearing the drainage canals in the marshy zones, which, having little or no slope, easily become choked by thick vegetation. Herds of buffaloes driven by the " bufalari " into the canal so as to occupy its whole width uproot the subaqueous bushes by the alternating movement of their powerful hoofs.

The " bufalari " go in small canoes, one in front of the buffaloes and two others behind them. Twenty four hours after their passing, the level of the water in the canals has sensibly fallen. The work done by the buffaloes is much more effective than that done by an underwater scythe, because the plants are uprooted.

The method of rearing buffaloes in the Roman Campagna is similar to that adopted for cattle (1). As a rule, castrated buffaloes and cows are kept on the farm until they are 12-16 years old when they are fattened for slaughter. The hides of these buffaloes are used in the manufacture of "soatto," the white leather from which the harness and special footwear, called "ciocie," used by the country people in the districts of Frosinone and Velletri are made.

With the horns are made various toilet articles, etc.

The author recommends:— 1) The selection of buffaloes so as to increase the dairy produce; 2) taming, so that more animals may be used on agricultural work for which they are marvellously suited; 3) the introduction, at least on a small scale, of stall rearing in localities near rivers.

744 - **Studies Made in the United States Concerning Variations in Length of Gestation Period and Other Factors with Special Reference to the Birth Weight of Pigs.** — CARMICHAEL, W. J., and RICE, J. B., in *University of Illinois, Agricultural Experiment Station, Bulletin* No. 226, Tables 22. Urbana (Illinois), May, 1920.

These records include 720 litters containing 5840 pigs, and were made during the years 1903 to 1916 inclusive under the management of the Animal Husbandry Department of the University of Illinois. The records are based on the influence of the following factors: 1) Length of gestation period; 2) size of litter; 3) age of dam; 4) breed; 5) time of year; 6) order of farrowing; 7) succeeding litters from the same sow.

1) LENGTH OF GESTATION PERIOD. — The records obtained from 549 litters, showed a somewhat wide range, 98 to 124 days, in the length of gestation period with an average of 114.58 days. However, 93.6 % of the litters were farrowed between the 111th and 119th days, and 73.8 % between the 113th and 117th days.

Although there may be a slight variation in length of gestation period due to age (see Table I), the general belief that older sows have a gestation period one to three days longer than younger sows seems to have no very sound basis.

There was a negligible, if any, correlation between the length of gestation period and the birth weight of pigs, but there was a tendency for some of the litters, which were carried longer than the average, to be smaller than those which were farrowed earlier than the average.

A study of the sex of the pigs in relation to the length of gestation period, shows no apparent tendency for either sex to predominate.

2) SIZE OF LITTER. — In this study the average size of litter was 8.1 pigs. The average weight of a litter is about 20 lb. This weight varies almost in direct proportion to the number of pigs in the litter.

The average weight of pigs in litters with fewer pigs than the average was 2.67 lb., and in litters with more pigs than the average it was 2.47 lb.

There is no noticeable correlation between size of litter and sex. It is, however, interesting to note that in a total of 5 657 pigs, 51.9 %

---

(1) See *R.*, May 1921, No 536. (*Ed*).

TABLE I. — *Relation of age of dam to length of gestation period.*

Age of dam (years)	Length of gestation period (*days*)																				Total number of sows of each age	Average length of gestation for sows of this age (*days*)

Average age (sows of known ages).	3.00	2.00	1.50	1.50	2.50	1.25	2.79	2.22	2.13	2.35	2.17	2.13	2.38	2.46	2.39	2.11	2.38	3.75	—	2.50	1.00	2.28	

	Average age of sows farrowing on or before the 114th day, 2.24 years (256 litters).	Average age of sows farrowing after the 114th day, 2.31 years (282 litters).	

were males and 48.1 % females. The litters larger than the average contained 10.5 % dead pigs, and the litters smaller than the average, 7.7 %. The proportion of males (56 %) among those farrowed dead was greater than the normal predominance of males over females.

3) AGE OF DAM. — On the whole, the belief that young sows produce smaller pigs than the older sows has been confirmed by these researches. The average number of pigs from sows 1 to 1 ½ years old was 7.5, and from sows 2 years old or more, 8.6, with average weights of 2.44 lb., and 2.61 lb., respectively. The older sows therefore farrowed a greater percentage of dead or immature pigs than the younger sows. The age of the sow appeared to have no effect on the proportion of males to females.

4) BREED. — Somewhat wide differences appear to exist among various breeds as to the length of gestation, size of litter, and birth weight of pigs. Berkshires had appreciably the longest gestation periods (115.4 days).

Results obtained in the experiments under consideration are shown in the Table on p. 885.

5) TIME OF YEAR. — Results lead to the conclusion that it is very doubtful whether any variations exist in farrow which can be attributed to the season.

Breed	Average age of dams *years*	Average length of gestation *days*	Number of litters	Number of pigs	Number of pigs per litter	Total weight lb	Weight Average weight per litter lb.	 Average weight per pig lb.
Berkshire	2.42	115.2	235	1 744	7.42	4 543.6	19.3	2.61
Chester White	2.52	113.1	29	278	9.59	719.0	24.8	2.59
Duroc-Jersey	2.04	113.1	57	498	8.74	1 122.0	19.7	2.25
Hampshire	2.75	112.5	2	14	7.00	35.0	17.5	2.50
Poland China	2.34	114.6	47	309	6.57	773.5	16.5	2.50
Tamworth	2.28	114.2	23	217	9.43	560.1	24.4	2.58
Large Yorkshire	2.85	113.5	24	278	11.58	722.2	30.1	2.60
Crossbred	1.93	114.0	40	320	8.00	780.1	19.7	2.44
	2.35	**114.5**	**457**	**3 658**	**8.00**	**9 261.8**	**20.3**	**2.53**

6) ORDER OF FARROWING. — Of the first farrowed, the proportion of males (59.4 %) was higher than the normal ratio of males to females. In comparing the averages of the same sex, as well as that of both sexes, it was found that the average weight of the former was somewhat heavier than the average of the latter.

7) SUCCEEDING LITTERS FROM THE SAME SOW. — In most cases, there was an increase in the number of pigs per litter and in the weight of individual pigs until the fourth litter, at which time the sows were 3 ½ years old. However, attention is drawn to the fact that to obtain the maximum and economical production, other factors than the number of pigs and their size should determine the age at which sows should farrow the first and succeeding litters.

[744]

745 - **The Present Position of Poultry Keeping in German Austria.** — WIENINGER, in the *Deutsche landwirtschaftliche Geflügelzeitung*, Year XXIV, No 26, pp 591-594 Berlin, March, 1921

The author shows, by the aid of statistics, that the customs receipts of the former Austro Hungarian Monarchy, so far as poultry and their products were concerned, were attributable less to well-developed poultry keeping with judiciously adapted methods than to the very extensive transit trade of poultry and their products originating in Russia and the Balkans and to the very restricted consumption, averaging 46 eggs, per inhabitant per annum, The production in the country itself was only 46 % of the total export.

Since the fall of the monarchy, the conditions of poultry keeping in German Austria have changed considerably, in as much as the scarcity has inevitably led to an extension in keeping poultry, to which must be added an increasing tendency to keep hens of selected breeds This interest in the keeping of special breeds of poultry is at present encouraged by the creation of numerous breeding Stations ("Zuchtstationen") or breeding farms ("Zuchthöfe"), composed of the best poultry farms possessing a number of good cocks and hens for breeding, which should be used for distributing the greatest possible number of young poultry selected with a view to good laying power. All the sitting eggs supplied by these stations are incubated in 24 industrial establishments and 304 incubation stations which now possess incubators with a total capacity of 200 000 eggs.

Of all the countries in German Austria, Lower-Austria has most poultry, but for hens it is beaten by Upper-Austria with 1-5 hens per inhabitant or 1.9 per hectare of cultivated land. The present production in these districts, owing to their mountainous character and also to the fact that the farms are chiefly in the hands of peasants, is not more than 70 eggs per hen per year

The total production is 248 736 180 eggs, a number which will not long suffice to meet the requirements of German Austria, the demand being for 736 748 160 eggs, so that there is a deficit of 488 011 980 eggs

The distribution of the poultry among the different regions is indicated in the Table. on p. 888.

The author considers the possibility of increasing the production of eggs and the number of hens and concludes that any considerable increase in production is unobtainable, owing to the lack of food, and that the best way of increasing the number of eggs, which are necessary for feeding purposes and especially Vienna, is a wide spread use of artificial incubation.

Regarding the increase of the number of hens, Carinthia, the Tyrol, Salzburg and Vorarlberg, which are for the most part mountainous, can only bear a very slight increase. Besides, in those countries the keeping of ducks for laying is making progress, ducks being specially prized on account of their resistance to inclement weather, their small consumption of grain and also for their habit of commencing to lay very early in the winter.

Number of poultry in Austria, present production of eggs and number of eggs required for consumption.

Country	Number according to the census of Dec. 31 1910				Cultivated Area	Number of inhabitants	Number of hens		Number of eggs required for a normal consumption of 120 eggs per inhabitant	Present production of the hens at 40 eggs per year	Deficit
	Ducks	Geese	Other poultry	Hens	(hectares)	on 1920 June 30	per inhabitant	per ha.

Salzburg	925	844	5 555	150 760	363 425	213 877	0.7	0.4	25 665 240	7 035 420	18 629 820
Voralberg	612	138	566	91 190	160 253	133 033	0.6	0.5	15 963 960	4 255 589	11 708 380
Austria . .	**50 734**	**60 636**	**304 396**	**5 330 067**	**3 979 997 ha**	**6 139 568**	**0.8**	**1.3**	**736 748 160**	**248 736 189**	**488 011 980**

The very developed river system provides extremely favourable conditions for keeping ducks. Pekinese ducks and runner ducks give very satisfactory results in these conditions and produce 100-120 and 150-160 eggs respectively.

746 – **Supplementary Note on Bee keeping in Morocco.** — JEAMMET, in *L'Apiculteur*, Year LXV, No 4, pp 94-95 Paris, April 1921

Infomation supplementing a previous account of bee keeping in Morocco (1). The author names some honey-bearing plants not given in his previous account, viz :— Cactus, Viburnum, Aloes, Asphodel, giant Cow-parsnip of the Caucasus or Heracleum; he proceeds to give the period and duration of flowering, the distribution of the principal melliferous plants, and furnishes some data relating to methods to be followed. Owing to the diversity of the climate, according to the altitude, and varying from the coastal region to the interior, methods have to be modified and lessons have to be learned from native practices. Thus, in the various regions of the Atlas (Middle-Atlas), the region of the Entifas or in the Souss, the hives are inside the kasbahs so as to protect the bees from the extreme temperatures which occur there :— 60°C in summer and –10°C, in winter in the Atlas.

In the regions of Casablanca, Meknès, Fez, the Dadant hive and the like give good results , in the hottest parts of the interior precautions have to be taken to prevent the wax melting in summer. In the Zaer districts, forest of Mamora, the native uses a hive about one metre long, made of the bark of the cork-oak which the bees like particularly on account of the non-conducting properties of the cork which shields them from the external temperatures. This hive is placed horizontally on the ground. This is also the position of other hives made of reeds plastered outside with mud.

At present, bee keeping in Morocco cannot be considered possible as the sole occupation, but it would be an appreciable auxiliary industry connected with a farm, especially where care is taken, when planting fruit trees or ornamental shrubs, to select those species which also produce nectar, e. g., the Judas tree, Robinia, *Grevillea robusta*, *Budleya*, and *Mioporum*.

747 – **The Saharan Bee.** — BALDENSPERGER P J , in *The British Bee Journal*, Vol XLIX, No 2031, p 235 London, May 1921

This bee found only south of the Atlas on the Saharan declivity is very rare in the places visited by the author. It resembles very much the Cyprian both in colour and in the well-marked crescent of a golden tint at the base of the thorax. The drones are rather darker with a few but very narrow bands.

The colour of the queen as seen by the author was of a dull yellow hue ; invariably the last ring of the abdomen is quite black while the next one is half black.

---

(1) See *R* May 1920, No 565 — Also see *R*. April 1919, Nos 413 and 498. (*Ed.*)

The bees are a little larger than the ordinary black bee of North Africa known under the name of " Kabyle " or Algerian and " Punic, " but the author considers the most appropriate name to be " Tellian " which thrives all along the Mediterranean coast from Tunis to south of Modagor, and inland up the Atlas to the limit where bees can thrive.

There is a sterile or half-sterile tract of country known as Hauts-Plateaux or Région des Steppes something over 200 km., in breadth, all over Algeria and part of Morocco of the Great Atlas serving as a strict separation between the two races of bees, yellow and black. The limit of the Saharan bee was found to be at Aïn-Sefra. The bee was first noticed by BERNARD of the Société des Apiculteurs Algériens. As regards its existence there the author considers the hypothesis plausible that the bees were probably imported into the Southern Atlas, then densely wooded, by Jewish settlers or persecuted tribes in the first century

748 - **The Mite *Tarsonemus woodi* Causal Agent for the Isle of Wight Disease in Hive Bees.** — I. *Journal of the Ministry of Agriculture*, Vol. XXVIII, No. 1, pp. 78-81. London, April 1921. — II. *The British Bee Journal*, Vol. XLIX, No. 2037, pp. 185-187. London, April 1921. — III. IMMS, A. D., in *Nature*, Vol. CVII, No. 2687, pp. 283-284. London, April 1921.

Investigations carried out at Aberdeen University by Dr. J. RENNIE (1) and his co-workers have demonstrated that the Isle of Wight disease and the disease caused by *Nosema apis* (2) are two quite distinct diseases. The causal agent of the Isle of Wight disease may be attributed to a mite of the genus *Tarsonemus* hitherto undescribed and named by RENNIE *Tarsonemus woodi*.

This parasite was observed first in December 1919 in a single example from a colony showing no signs of disease The symptoms were as follows :— Listlessness of the bees ; dislocation of one or both posterior wings, and distention of the abdomen ; the staining of the alighting board and combs with excreta of the consistency of putty ; crowding of the bees on the outside of the hive and in severe cases owing to their inability to fly crawling about in thousands on the ground or ascending upright objects, and at times collecting in small clusters eventually to die.

The mite occurs only in that part of the tracheal system which is connected with the anterior thoracic spiracle. All stages of the Acarine were found together (eggs, larvae and adults) which when present in large numbers entails the obstruction of the tracheae of the thorax, either partially or wholly, which leads either to sudden death or inability to fill the air sacs which permit of flight, and reduces the bees to crawling.

(2) Isle of Wight Disease in Hive Bees ; 1) " The Etiology of the Disease " by D. J. RENNIE, P. R. WHITE, and ELSIE J. HARVEY (pp. 737-758) ; 2) " The Pathology of Isle of Wight Disease in Hive Bees, " by P. B. WHITE (pp. 756-764) ; 3) Isle of Wight Disease in Hive Bees — Experiments on Infection with *Tarsonemus Woodi* n. sp., by ELSIE J. HARVEY, (pp. 765-767) ; 4) Isle of Wight Disease in Hive Bees, Acarine Disease : The Organism Associated with the Disease — *Tarsonemus Woodi*, n. sp. by Dr. J. RENNIE (pp. 768-769) pl. 1, figs. 2). — *Transactions of the Royal Society, Edinburgh*, Vol. LII, Pt. IV, No 29. Edinburgh, 1921.

In studying the pathology of the disease P. B. White points out that the mites perforate the tracheae and live on the body fluids of their hosts; the tracheae become darkened and ultimately black by the increasing deposition of chitin. In the examination of 250 stocks from different parts of the country, the parasite was discovered in all of them. Of 140 stocks, believed by the owners to be healthy, 50 (nearly 36 %), harboured the parasite *Tarsonemus woodi,* but *Nosema apis* was not always present.

Except in one doubtful case the brood was not found infected; the queens usually survive until the colony becomes extinct.

The usual symptoms of the disease have been produced artificially by blocking up the thoracical spiracles of the bee with wax. Many bees from different countries outside Great Britain have been examined and so far *Tarsonemus woodi* has not been found.

Dr. Rennie suggests that the name Isle of Wight disease should be changed to Acarine disease. Investigations connected with the appropriate control methods to be employed are in hand.

749 - **Experiments in Breeding and Feeding Silkworms in West Prussia.** — Lucks, R. (1), in *Biedermanns Zentralblatt,* Year XLIX, No. 5, pp. 190-196. Leipzig, May 1920.

As Director of the sericultural Station recently created by the "West-preussische Seidenbau-Studiengesellschaft" (West Prussian Society for sericultural study), the author, in 1917, proposed to establish a large breeding station of 30 000 silkworms. In these experiments in breeding silkworms in successive batches, owing to difficulties that caused considerable delay, the first worms were not hatched out until early in August. Between August 4 and 14, 9000 silkworms were hatched so that an experiment with 10 batches of 1000 silkworms in each could be started. The food consisted of mulberry leaves. Along with this experiment, a small comparative feeding test was arranged; 4 series of 390 silkworms in each were formed and fed as follows:—

Series I. — Mulberry leaves (M).
Series II. — Leaves of Viper's-grass (*Scorzonera hispanica*) (S).
Series III. — Mixture of leaves of mulberry and Viper's-grass (M. S.)
Series IV. — Mulberry leaves up to the fourth stage and leaves of viper's-grass during the fifth stage.

The experiments have shown that, in good conditions, the silkworm in West Prussia can be fed without risk up to the middle of September, since good mulberry leaves can be gathered up to that date, especially when it is considered that the best silk is obtained by feeding the silkworms on healthy full-grown leaves during the later stages.

In the experiment of breeding in successive batches, feeding with mulberry leaves, the period of growth of the silkworms was prolonged by

---

(1) *Bericht der Westpreussischen Seidenbau Studiengesellschaft, Versuchsstation Danzig.*

11 to 15 days; the weight of 7500 cocoons collected between September 17 and the end of the month amounted to 8.56 kg.

The comparative feeding experiments gave the following results:—

I. — FEEDING WITH MULBERRY LEAVES. — The growth of the silkworms was satisfactory. The first change commenced on August 10, the second on August 16, the third on August 21, and the silkworms began to form cocoons on September 8, so that on September 17 all the silkworms had pupated. No diseased silkworms were seen.

II. — FEEDING WITH LEAVES OF VIPER'S-GRASS. — A number of silkworms refused this food; altogether 21 % died. The beginning of moulting took place at the same time as in the first series for some of the silkworms but did not follows the same regular course. Moreover the commencement of pupation was irregular, but 60.3 % of cocoons were formed.

III. — FEEDING WITH THE MIXTURE OF LEAVES OF MULBERRY AND VIPER'S-GRASS (the chopped leaves were so treated that the sap from the two kinds was mixed to prevent the silkworms from choosing between them). — The food seems to have been eaten without difficulty. After the third change, the leaves were given alternately and unchopped. The consumption was regular at first but after the 4th change the leaves of viper's-grass were refused.

The formation of cocoons was delayed in a curious manner. On September 13 (38th day), 41 % only of the cocoons were finished; the maximum, 90 % of cocoons, was reached in September 16 (42nd day).

IV. — FEEDING WITH MULBERRY LEAVES UP TO THE FOURTH STAGE AND WITH LEAVES OF VIPER'S GRASS DURING THE FIFTH STAGE. — In spite of a prolonged fast, the worms refused the new food and had again to be fed on mulberry leaves.

The weights of the cocoons formed by the different series were as follows:—

100 cocoons of Series I and IV (M)	149	grammes
100 cocoons of Series II (S).	118	»
100 cocoons of Series III (M. S.)	157	»

The cocoons (dark yellow in colour) of series II were, on the average, larger, but on the whole weaker than the other cocoons. The cocoons of series III were the strongest and in point of size occupied a medium position. The moths from the silkworms fed on leaves of viper's-grass were darker in colour, and pairing and laying were done in a hesitating manner. Regarding the tenacity and elasticity of the silk, it was found that the silk made by the silkworms fed on mulberry leaves + leaves of viper's-grass differed but little from the silk made by the silkworms which had been fed on mulberry leaves only.

The author next selected a certain number of cocoons from the two experiments, for eggs.

The moths hatched from them were paired as follows: —

S ♀ × S ♂ — M ♀ × S ♂ S ♀ × M ♂ M S ♀ × M S ♂ — M ♀ × M ♂.

[749]

The eggs were collected separately. The silkworms hatched from these eggs, as well as some silkworms hatched from Hungarian eggs, were again fed on the leaves of viper's-grass. After the fourth stage the silkworms from the Hungarian eggs commenced to languish and, from May 6, dead silkworms had to be removed daily. The silkworms produced by the various pairings remained healthy up to May 20, but after that date they also died in large numbers. These experiments were repeated twice more. The results may be summed up as follows:—

The silkworms fed only on leaves of viper's-grass up to the time when they commenced to form cocoons, produced cocoons which were of little or no use; even when this substitute was only given up to the third stage the yields were not satisfactory. A yield of 55 % can be obtained by feeding with leaves of viper's-grass up to the third stage, and then replacing them by mulberry leaves.

When silkworms are reared industrially the latter method has small advantage, since it is especially during the fifth stage, when a large consumption of food takes place, that feeding with the leaves of viper's-grass as a substitute for mulberry leaves would have most value. The author, however remarks that for the creation of a family silkworm that would consume leaves of viper's-grass right up to the forming of cocoons, feeding with that substitute from the commencement up to the third stage might be of great importance; the silkworms hatched from eggs laid by the survivors would eat the leaves of viper's-grass with less repugnance and become accustomed to it from generation to generation (1).

The author emphasises the great advantages of breeding the silkworms in successive batches, a method which is much less liable to unforeseen accidents, owing to which the ordinary method of breeding generally fails; this has been shown by an experiment in breeding silkworms in successive batches in 1918, when the leaves of the mulberry were for some time lacking, and when, therefore, in the meanwhile leaves of viper's-grass could be given without fear of loss. Another advantage of this method is an even distribution of work.

750 – **Action of Concentrated Sulphuric Acid on the Eggs of *Bombyx mori*** (2). — LÉCAILLON, A., in the *Comptes rendus des Séances de l'Académie des Sciences*, Vol. 172, No. 11, pp. 718-721. Paris, March 14, 1921.

Fairly numerous researches had previously been made regarding the action of concentrated sulphuric acid both on fertilised and unfertilised eggs of *Bombyx mori*. It appears from the work of DUCLAUX (1876) and other writers that if the fertiliser eggs of univoltine varieties are submitted to that action for 1 or 2 minutes, just after they have been laid, they behave like the summer eggs, that is to say they produce silkworms at the end of 10 to 12 days, instead of producing them at the end of 9 or 10 months. But, on this point, some reservation is necessary since: — 1) Univoltine varieties fairly frequently give birth in a natural manner after 10 or 12 days, to casual bivoltine individuals; 2) the action in question appears to be inconstant.

---

(1) F. LAMBERT, Director of the Montpellier Sericultural Station, in his publication *La scorsonère dans l'alimentation du ver a soie du mûrier*, Paris, 1916, "Bureau de Revue de Viticulture," passing in review works on the substitutes for the mulberry and, using his own experiments as basis, arrives at the same conclusions and further remarks, that the results might perhaps even be practically applied in countries where climatic conditions are adverse for growing mulberry trees for silk production. See *R.*, Dec. 1917, No. 1195. (*Ed.*)

(2) See *R.*, Jan. 1918, No. 75; *R.*, May 1919, No 627; *R.*, July-Aug. 1920, No. 786. (*Ed.*)

In the course of researches made during the past 7 years, the author has made a series of observations on this subject from which he draws the following conclusions:—

1) It is true that the immersion of unfertilised eggs of *Bombyx mori* in concentrated sulphuric acid has an influence on certain of them which do not change their colour naturally. However, that influence affects not only freshly-laid eggs but also much older eggs (at least 20 to 25 days old). The aptitude for parthenogenesis persists therefore for a long time in eggs which have apparently remained in the condition in which they were laid.

2) In the conditions of concentration, temperature and time in which it acts on unfertilised eggs, concentrated sulphuric acid has no action on fertilised eggs whether freshly laid, laid 18 hours previously or laid 5 to 7 months previously.

3) When they are immersed in the sulphuric acid *Bombyx mori* eggs lose their yellow colour. It appears that the chorion undergoes some modification in structure and becomes more opaque. This fact would seem to support the theory of LOEB (1) However, it is not proved, that traces of sulphuric acid cannot penetrate into the vitellus and play the part attributed by DELAGE and GOLDSMITH, or some similar rôle to that of catalysts.

FARM ENGINEERING

751 – **Operating the Tractor Plough** (2). — REED C. O., in *Farm Implement News*, Vol. 42, No. 5, pp. 46-49 and 74, figs. 3. Chicago. Feb. 3, 1921.

The discussion is confined to ploughs of the two, three, and four bottom unit lift gangs type, though many of the principles are equally applicable to both these and the independent lift gangs also employed.

The true line of pull in a double drive wheel tractor may be considered to pass midway between the drivers as shown in Figs. 1 and 2. If the tractor has only one driving wheel or drum, for all practical purposes the true line of pull passes through the centre of that driver, and the true line of draft of small engine gang containing an odd number of bottoms passes through the centre of the middle beam (Fig. 1) or when containing an even number of ploughs, between the two middle beams (Fig. 2). An ideal working condition should therefore allow the true line of pull of the tractor to coincide with the true line of draft of the plough. In many outfits, however, this is not possible, because the tractor and the plough must each be run in a certain fixed relation to the open furrow, and their widths may not be such as to allow this coincidence of the lines of pull and draft. In such cases side draft to some extent is bound to occur either in the tractor or plough or both, according to the hitch.

---

(1) According to LOEB (1911) the action of sulphuric acid renders the membrane of the egg more permeable to oxygen. In his theory, aimed at explaining the experimental parthenogenesis, that writer assigns an important part to the phenomena of oxidation which are produced in the egg when the embryo begins to develop. According to DELAGE and GOLDSMITH on the other hand, it is the "dehydrating and caustic" influence of the acid which is the cause.

(2) Complete revision of former article on the Tractor Plough by the same author. See *R.* June, 1917, No. 575. (*Ed.*)

The method of procedure advised is as follows: — At the beginning of the second trip around new land, the tractor should be placed as near the open furrow as it is safe to run it, or actually in the furrow and the plough arranged carefully in its proper relation to the furrow. With a scratch of 2 marks on the drawbar of the tractor, — one to show the position of the true line pull, and the other to indicate where the true line of draft of the plough would cut the drawbar if extended ahead. The hitch bars from the plough to the drawbar of the tractor should then be attached at a point about midway between these 2 marks.

The sidedraft of the outfit will then be fairly well divided between the tractor and the plough.

Fig. 1 shows this condition with a 3-plough tractor when it has both drivers running on the unploughed ground. The true line of pull is on the left of the true line of draft. Fig. 2 shows a condition where a narrower, 2-plough tractor is running with one driver in the open furrow. The true line of pull is here on the right of the true line of draft.

With the hitch bars thus adjusted, the outfit should be started. If the side draft in the tractor proves troublesome, more of the sidedraft should be thrown on to the plough by removing pin *A*, and moving the clevis to the left on the drawbar of the tractor (Figs. 1) or to the right, (Figs. 2), thus attaching the load to the tractor nearer its true line of pull. Pin *A*. should then be replaced in the nearest hole in the hitch bars.

The fact that the sidedraft can be shifted at will from tractor to plough is important from the point of view of steering difficulties and plough troubles.

In making hitch adjustments to shift sidedraft, great care must be exercised not to destroy the proper width of cut of the front plough bottom, otherwise there results an uneven height of furrows. The cut of the front bottom should not be more or less than 14 in. for a 14 inch gang or 12 in. of a 12 inch gang.

If cutting too wide (Figs. 1) any one of 3 adjustments can be used to remedy the trouble: *a*) move the hitch clevis to the right on the drawbar of the tractor; *b*) move both hitch bars an equal amount to the left on the horizontal clevis on the plough beams; *c*) lengthen the right hitch bar in respect to the left by moving the latter forward at *A* one hole on the right bar. If the front plough is to be shifted to the right only an inch or two,

Fig. 2.

the length of one bar must be adjusted in respect to the other, — if it is only a matter of 2 or 3 in. too wide, either adjustment *a)* or *b)* can be used

If cutting too wide, (Fig. 2), the clevis may be moved on the drawbar to the right, or the right draw lengthened in respect to the left by moving the latter ahead on the former at *A*.

The principles of bar hitches described, are equally applicable to cross chain hitches still used in some sections on the larger tractor gangs.

For all practical purposes the centre of resistance of a 3-bottom plough may be taken to lie in the middle bottom at a point on the mould board about 2 in. from the shin and just above the share line. The hitch bars should be attached to the vertical clevises of the plough so that the bars lie as nearly as possible in the horizontal plane of the line of hitch (i. e. the imaginary line passing from the drawbar of the tractor to the above mentioned centre of resistance). Hitching higher will result in increased draft, and lower, in failure to penetrate properly.

Ordinarily in stubble ploughing, coulters should be set $^5/_8$ of an inch to land and from $1/2$ to $^2/_3$ the depth of the furrow. In sod ploughing, they should be set $1/2$ inch to land, set forward slightly from the stubble position and lowered to cut nearly the full depth of the furrow. The coulter is, as a rule, set on the beam so that its bearing is from 1 to 2 in. back of a vertical line from the tip of the share point (Fig. 3). These rules are however only general and cannot always be followed. Due attention should always be paid to the nature of the surface soil. If sharp shares and sharp coulters fail to penetrate properly and the trouble cannot be remedied by the coulter set, it is advised to raise the hitch bars on the vertical hitch plates, and as a last resort set the suck regulator so that the heels of the landsides are slightly raised. This adjustment will usually result in better penetration, but increased suck means increased draft and the operator should lose no time in going back to the original set recommended by the manufactures as soon as possible

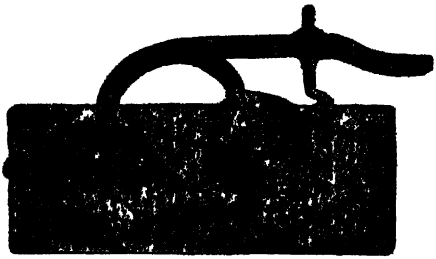

Fig 3 — Position of the coulter

Two fundamental principles should be understood with regard to failure to scour: firstly, the trouble is usually caused by the fine soil that breaks loose from the furrow slice, and, secondly, any adjustments that tend to increase the pressure of the slice upon the mouldboard will help to eliminate the trouble The following remedies are recommended.

1) Throw more of the sidedraft into the tractor;

2) set the coulters slightly wide or move the blades forward and set these wide

If these do not prove successful:—

3) Go back to the original set and then try raising the hitch bars a hole or two on the vertical clevises.

The so-called " winging down " (letting the front bottom cut a trifle deeper than the rear bottom) has often overcome the non-scouring difficulty, and its advantages outweigh its disadvantages.

An unsuspected cause of failure to scour in some instances is the speed at which the plough is run, and if a plough is employed which under normal conditions is too large for the tractor, all that can be done with the gang is to plough shallower unless one bottom can be detached. This should not however be confounded with the cause of slow speed due to excessive slippage owing to the soft friable condition of the surface of the fields. If there is no objection, however, to breaking into the subsoil to a greater depth, increasing the depth of ploughing may remedy entirely the non-scouring, because the pressure on the mouldboards will be increased.

By turning on the headland and leaving the plough at an increased depth until the point in the furrow is reached, where on the previous round the plough had reached its normal depth, and then bringing the plough back to its original position the depth may be maintained at the headlands at least for several trips. On a strip of unploughed land which is narrower than the plough, the whole outfit should be run so that the rear bottom is doing enough cutting to keep its point from hooking into and turning back the furrow slice on the left. The front plough will not do so much damage because it is the wing of its mould that hits the furrow slice on the right, and tends to keep that slice in its place. By dropping the plough a few inches on the land wheel to let it cut a small notch in the plough sole for the rear landside to work against and hold the plough in its correct position, the difficulties liable to arise may be overcome.

752 - **The " Mav " Cultivator for Rocky Land.** — MARRE, E (Directeur des Services agricoles de l'Aveyron), in *Le Progrès agricole et viticole*, Year 38, No. 19, pp. 455-458. Montpellier, May 8, 1921.

This new tillage instrument, designed especially for the rocky lands of the Causse, but which would be serviceable on all stony soils, even when not calcareous, has been thought out and constructed by M. BÉTEILLE, Matériel agricole et viticole (Mav), rue Pasteur, Béziers.

It has a rigid strong frame of special steel with rivetted joints. The working pieces, of cast steel with interchangeable parts of hard steel, can move out of the way on meeting abnormal resistance, such as that of a rock; they are kept in place or brought back into working position by powerful springs with a very small movement, which saves them from being bent or broken. The working pieces are fixed to the frame by means of bolted rings bearing the axis round which these pieces move

The penetration of the teeth into the soil is brought about by means of a crank axle governed through a screw by a flywheel, a chain, and a roller lifting the front at the same time. A seat, situated opposite the flywheel, enables a man to regulate the depth of digging while working.

The weight of the apparatus is about 500 kg. It can loosen a strip of ground 1.70 metres wide; in very favourable soil an average depth of 15 cm. can be reached, if necessary, by passing twice over the ground; but according as the difficulties, (hardness of the ground, the length of time it has been fallow, etc.), increase, it will obviously be necessary to pass more often over the ground to attain that depth. When that depth is reached, the soil is ready for sowing.

753 - **Penkala Press for Compressing Dry Pulp into Briquettes.** — BOUCHON, R., in the *Comptes rendus des séances de l'Académie d'Agriculture de France*, Vol. VII, No. 15, pp. 374-379, Paris, April 20, 1921.

R. BOUCHON, sugar manufacturer, Nassandres (Eure), has pointed out the advantage of compressing dry pulp into briquettes in order to reduce the cost of packing, as the pulp is relatively bulky owing to its low density.

The problem of compressing dry pulps, substances which are at the same time both powdery and elastic and difficult to compress by vertical pressure, is solved by the press invented by the Polish engineer PENKALA.

Its principle is that of a continuous press which agglomerates the substance molecule by molecule, or rather bit by bit by a series of compressions, whence the very remarkable homogeneity shown by substances pressed in this machine

The first experimental presses were constructed by la Compagnie de Fives-Lille. For a press with a capacity of 10 tons in 24 hours, about 10 HP. was required. As it was desirable to produce a division in the substance pressed and obtain briquetes of a given weight, each of which would represent the ration of an animal, a cellular distributor was added to the presses as first constructed. With the mass compressed in this way the animals can be given their food rations in ordinary form. Immersed in water these briquettes swell rapidly and, after 2 hours, the pulp immersed in plenty of water resumes entirely the appearance of ordinary pulp. This press has also been tried with success for compressing fuel (1) and for making electrodes.

Examples of rations used at Nassandres.

---

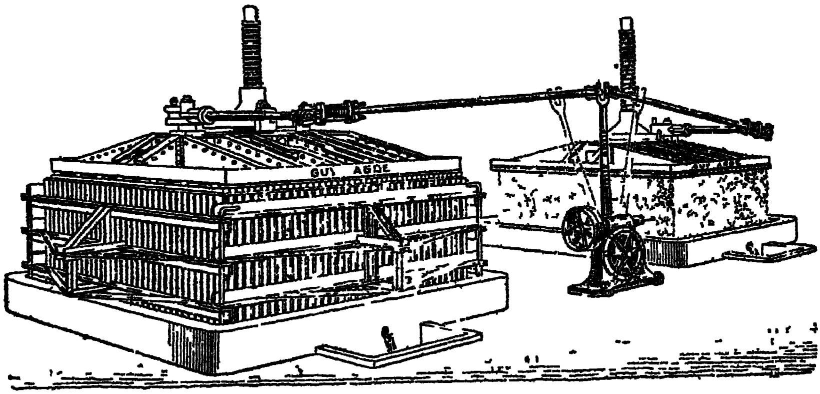
(1) See *R.* Feb. 1920, No. 247. (*Ed.*)

BOUCHON also gives some figures regarding the dry pulp from sugar factories, giving two analyses, as well as examples of the rations used on the Nassandres farms to which the sugar factory and refinery are attached.

The mixture is prepared 24 hours in advance and the pulp is steeped in plenty of water; the chopped straw is not added until the mixture is made and the pulp is thoroughly prepared.

754 - **The Guy " Motor-Press" for Applying Mechanical Pressure to Existing Installations.** — *Le Progrès agricole et viticole*, Year 38, No 18, pp 427-428, figs 1 Montpellier, May 1, 1921

The Guy Motor-Press has been made with the object of enabling wine-makers who make a medium, or even a small amount of wine, to benefit by the advantages of mechanical pressing, at the lowest possible cost of installation and making use of existing apparatus.



The Guy Motor-Press, on a base (without motor), working 2 presses

The Motor-Press is made in two patterns :—

1) Pedestal pattern, the more usual pattern, suitable when the presses are away from a wall and arranged about the middle of the cellar.

2) Wall pattern, used when the presses are arranged along a wall of the cellar.

DESCRIPTION. — The automatic system of constricting or pressing is essentially composed of an apparatus of the pedestal or wall pattern separate from the existing pressing apparatus and forming the Motor-Press properly so-called. The apparatus consists essentially of a cast-iron case, enclosing, protected from dust and accident, and in an oil bath, a *speed reducer of* 1/60 and a *transformer of circular movement into alternating movement.*

With the apparatus all the small high-speed motors (electric especially), can be connected directly, by a simple band, with an axle bearing pullies (turning at 300 revolutions a minute); an attachment can also be made of its large, very slow moving (4 to 5 revolutions a minute) arm, and by means of dynamometric connecting rods and cardan joints, to special bars fitting into the sockets of the existing presses.

A single "Motor-Press" (of the pattern made by GUY of Agde) can work 1, 2, 3 or 4 presses of any kind, arranged in any manner, together or separated and can do so with only 1/4 to 1/3 HP. per press according to the forms of the construction of the presses.

WORKING. — The press or presses being loaded in the ordinary way, and the charges and apparatus being brought to the required position by a small hand bar worked by one man, the man attaches the dynamometric connecting rod or rods which are hooked up in their position of disengagement, and then starts the Motor-Press.

The constriction or pressing takes place gradually, and, when the maximum pressure of the resistance of the press or presses is reached, that is to say the equivalent of the force of 4 men, a safety spring, by becoming compressed, shortens the stroke and owing to this the catches of the ratchet mechanism no longer fall into the recesses, the screw plate remains stationary and no longer presses, the Motor-Press still continuing to work, so to say, empty. This continues until the fresh or fermented grape husks becoming drained, the internal pressure decreasing and becoming less than that of the dynamometric safety spring, the latter relaxes, the normal length of stroke is re-established and the catches of the ratchet again fall automatically until a further period of maximum pressure occurs.

Automatic pressing is thus attained, and without attention, the Motor-Press can be allowed to go on working without stopping during meal times, and thus valuable time is saved compared with the time taken by ordinary pressing.

In case of possible breakdown of the motor, pressing can be continued by hand in the ordinary manner.

When pressing is finished all that has to be done is to turn back the catches and the Motor-Press commences to remove the pressure from the press or presses and the loads and apparatus are lifted in the ordinary way by hand, if the apparatus is not heavy, or by means of a special mechanism invented by the same constructor.

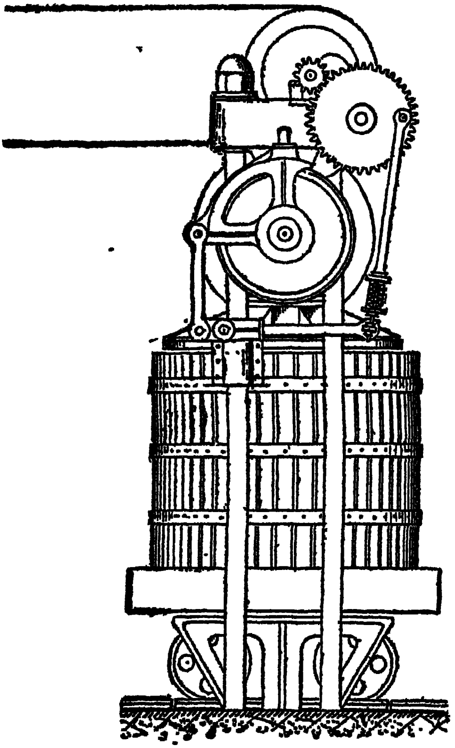
755 - **The Simplex Super-press with Movable Pan and High Pressure.** — VENTRE, J. (Professeur d'Œnologie à l'École nationale d'Agriculture de Montpellier), in *Le Progrès agricole et viticole*, Year 38, p. 327-334. Montpellier. April 3, 1921.

This apparatus, built to the design of P. PAUL, seems to fulfill the double object of producing great force and automatically exerting progressive pressure.

Like the hydraulic press, the new apparatus has a movable pan and the diameter of its sieves is about 1 m.; the pressing plate is supported and pressed down by two knee joints, the heads of which approach and recede from each other. These are controlled by a double threaded screw automatically pressed on a plate with catches.

As the angle between the knee joints decreases the pressure increases in the proportion of 1 to 10.

This mechanism has a total force of 100 tons, that is to say a pressure of 10 to 12 kg. per square centimetre. The pressing takes 35 minutes. It is regulated automatically, for, if the descent of the pressing plate is more rapid than the escape of the liquid requires, the catch ceases to fall so that pressure is not removed until the juice previously expressed is cleared.



Side view of the Simplex Super-press.

The raising of the pressing plate takes only 9 or 10 minutes so that one sieve can be entirely pressed and replaced by another in three quarters of an hour, or, allowing for clumsy working, in an hour

Only from 1 to 1.5 HP. is required, and can be supplied by a small electric or petrol motor.

The pressure is direct and this does away with the necessity for a regulator, the maintenance of which is always delicate. Stopping, both in raising and descending, (when the thickness of the cake is too little), is automatic so that no attention is required. Pressing by means of this apparatus is carried our under good conditions, for it is done by using the two most favourable principles for the clearance of the juice, namely:—

1) The pressure only increases gradually and slowly proportionately to the compression of the grape marc, so that felting of the sieves is prevented.

2) The pressure instead of being continuous, is obtained by a series of successive shocks leaving sufficient time between them to allow of the circulation and clearance of the wine enclosed in the marc.

The effect formerly obtained with percussion presses, which had the reputation of producing a much better draining of the grape marc than was obtainable with other kinds of presses, is therefore realised with less manual labour but with greater pressure.

756 – The Alexis Chaussepied Apparatus for the Rapid Production of Sparkling Wines.

Revue générale du Froid et des Industries frigorifiques, Year I, Vol. 1, No 12, pp. 399-401, figs 1. Paris, Dec 1920.

The process covered by the Alexis CHAUSSEPIED (of Saumur) patent makes it possible, using cold, to obtain, in the shortest possible time, sparkling wines of identical composition and quality to those obtained by fermentation in bottles according to the Champagne method.

The wine is composed precisely as if it was to be drawn to ferment in bottles, but the various operations; — Fermentation, dosing with the transport liquor, clarification, are not done in bottles, but in wooden vats containing from 10 to 40 hectolitres, which are enclosed in steel tanks sufficiently strong to hold the carbon dioxide produced by fermentation and whose pressure, under which it is dissolved in the wine, is capable of being regulated as desired by a valve.

After clarification, which is accelerated and made perfect by the action of cold, the deposit, resulting from the second fermentation in the closed vat, is got rid of; the clear sparkling wine is then bottled by means of isobarometric apparatus of the same kind as that used for bottling low gravity beers; the low temperature at which the bottling is done prevents effervescence and loss of carbonic acid gas

APPARATUS. — The apparatus is composed of a wooden vat 1, open at the top; the bottom 3 of this vat is pierced by a hole 4 in which is fixed by watertight washers, a metal piece 6 through which passes the tube 7, made of glass (or silver plated metal). This piece is covered, inside the vat, with a wooden cap 8 pierced with a hole through which passes the tube 7, intended to prevent contact between the wine and the metal piece 6.

The vat 1 is enclosed in a metal recipient capable of resisting the pressure of the gas produced by fermentation; the bottom 10 of this recipient is pierced by the piece 6 on which is screwed a nut 11 to form a watertight joint by means of washers. Tow packing is placed round the tube 7 and is pressed tight by the nut 12. On the nut 11 is screwed a piece 14 forming a solid piece with the tube 7 and which enables this tube to be raised or lowered. The piece 14 ends in a three-way tap 19.

The recipient 9, furnished with a thermometer 25 and spy-holes 26, has in its upper part an air-chamber 27 fixed with screws and a water-tight joint. The chamber 27 bears a metal tube 30 prolonged, at 31, by a glass tube 32, which is larger in diameter than the tube 7 which it protects against the fall of deposits.

The tube 30 opens out above into the feed bottle 33 with a tap 34 between them; it also communicates by a tube 35 with a pump 36, which draws out by the tube 37 the gas contained in the chamber 27 and drives it back by the tubes 35, 30 and 32.

The chamber 27 also has a tube 38 with a tap 39 communicating with the upper part of the feed bottle 33 and a tubing 40 carrying a manometer 41, a valve for regulating the pressure 42, and a tap 43, allowing communication by the pipes 51 with the arrangement for drawing off the wine into bottles and with a compressed air or gas container 57.

Inside the receptacle 9, and above the vat 1, is a coiled pipe 44, which communicates with a recipient 45 and through which can be made to circulate, as desired, heating or cooling liquids.

WORKING. — The wine is prepared in a big tun or in casks with all the necessary ingredients as in the Champagne method except that no tannin is added; the wine at this moment is a real culture broth of alcoholic yeast, fermentation having commenced regular action, the wine is introduced into the vat 1 through the feed bottle 33.

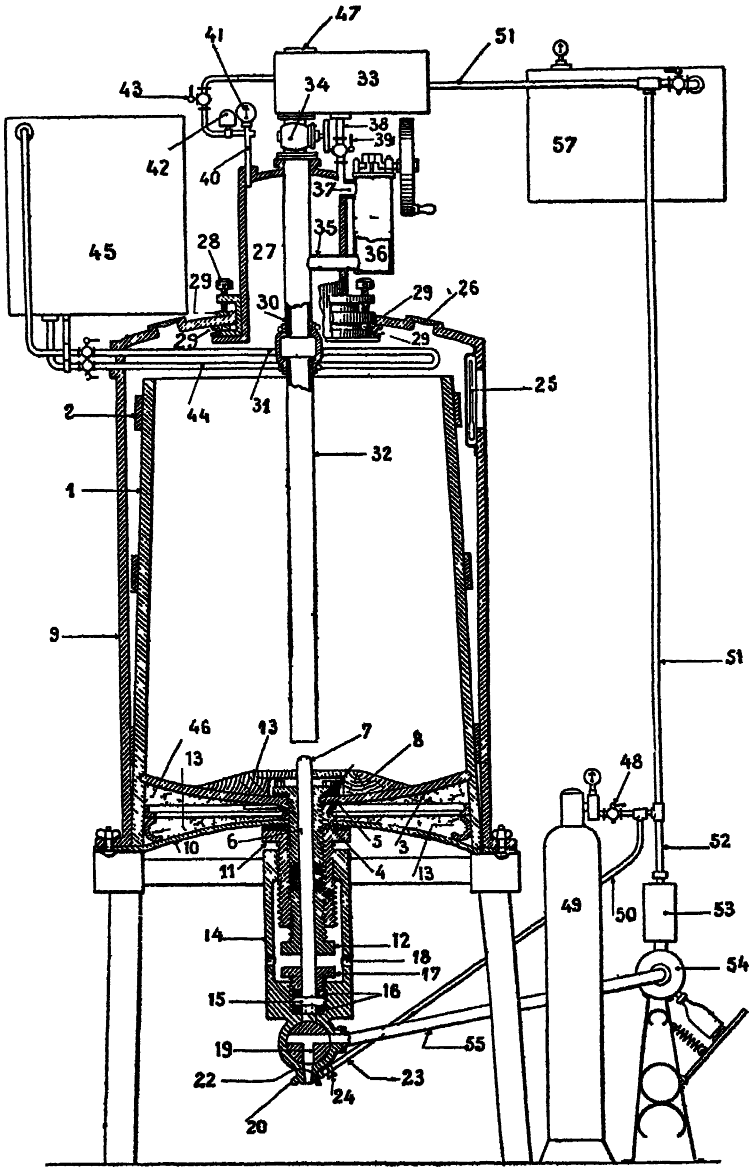
With this object, after closing the tap 19 and raising the tube 7 above the bottom of the vat by moving the piece 14, the stopper 47 is taken out and the taps 34 and 39 are opened; the wine runs through the tubes 30 and 32, the taps 34 and 39 are then closed and the stopper 47 is replaced.

Fermentation continues in the vat and it is quickened by starting the pumps 36; the gases drawn through the opening 37 are driven back through the tubes 35 and 32 causing continuous movement and mixing of all the ingredients in the wine.

When fermentation is finished (or, if it is desired to stop it, before it is complete) cooling liquid is made to circulate in the bent tube 44, and the pump is set in motion; the gases cooled by contact with the bent tube, are driven back into the vat, where they cause cessation of fermentation and the dosing is proceeded with.

The transport liquor — which contains the necessary dose of tannin (required to ensure the precipitation of all the albuminoids) and of glue — is introduced into the feed bottle, and, after the stopper 47 has been replaced it is run into the vat by opening the taps 34 and 39 which are then closed. This liquor is mixed with the wine by the pump which continues to work as well as by the circulation of the cooling liquid in the coiled tube to bring the wine as near as possible to its freezing point: at that moment the pump is stopped.

The wine, which is now effervescing and dosed, being at rest, clarification takes place by the action of the tannin on the albuminoids and by that of refrigeration; it is further facilitated by the presence of carbonic acid gas under pressure, which renders it absolutely perfect in a very short time the deposit is then collected, settled, at the bottom of the vat in a compact, solid mass above which the sparkling wine clear and liquid is led off by the tube 7 The low temperature is maintained by the circulation



The CHAUSSEPIED apparatus for the rapid production of sparkling wines

[756]

of the cooling liquid during the whole duration of clarification and bottling; owing to it, the latter operation is effected very easily without effervescence and without any loss of carbon dioxide.

The bottling is done by means of counter-pressure extractors like those used for bottling low-gravity beers; the pressure is ensured by compressed air or by carbon dioxide — coming from the vats under fermentation — contained in a tube 49, or in the container 57. The bottles are then corked and wired in the usual way and they are then ready for dispatch.

Each apparatus is enveloped in an isolating cover which shelters the contents from variations in the outside temperature and barometrical pressure as well as from draughts which have such a bad effect on the progress of fermentation. Owing to this isolation, which is as perfect as possible, each apparatus works independently of the others, which may be at different stages of the making, without affecting those which come near them, and it is thus possible to collect a fairly large number of apparatus in the same premises, the mean temperature of which is not of great importance provided it is not exaggerated one way or the other; it may vary between +10° and +30°C.

Each apparatus produces, in 1 month at most, its content of sparkling wine ready for dispatch.

The refrigerators required are of small power (600 to 3000 frigories an hour) and are only used during 3 or 4 days for each apparatus so that they can each work a fairly large number of machines.

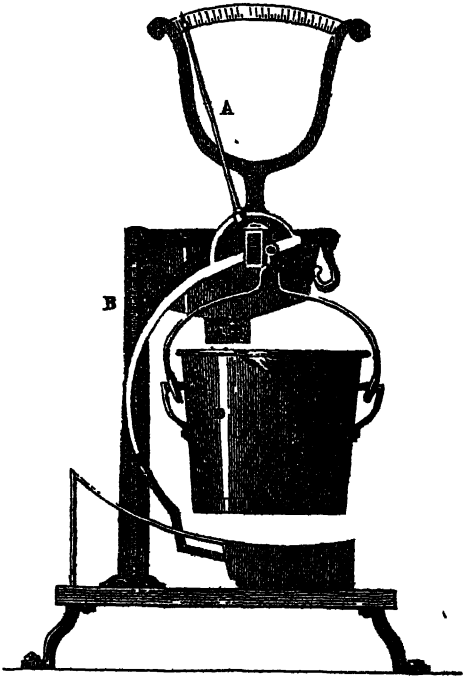
This process has proved its value in practice. Apparatus of 1000, 2000, and 4000 litres are working at present some of which have produced, under the conditions described alove, several charges of wine which have given complete satisfaction.

757 – **Milk-weighing Balance.** — GOUDOT, G., in the *Journal d'Agriculture pratique*, Year 85, Vol. 1, No. 19, pp. 379-380, figs. 2. Paris, May 14, 1921.

The author describes a good type of milk-weighing balance (illustrated in the figure below) used by cheese makers in Franche-Comté.

This balance is a steel yard the of which shorter arm supports the pail which holds the milk; the longer arm, bent in a circular arc, ends below in a weight calculated so that when the pail is empty the point of the hand *A*, fixed on the upper part of the arm, points to zero on the dial at the top of the apparatus. On this dial, starting from zero on the left, are marked large divisions each of which corresponds to 1 kg.; each of these divisions is divided into four parts corresponding to ¼ kg., respectively. Each kg. is reckoned as being equivalent to 1 litre of milk which in practice causes no objection. For weighing, the milk is poured into wire-mesh strainer designed to strain out impurities suspended in the milk. This strainer is fixed to the support *B* by means of an iron pin and is moveable round this support so that its lower aperture is over the pail while the milk is being strained and so that it can be moved to one side to lift the pail when filled.

The working of this weighing machine is therefore very simple. But in order for the balance to weigh accurately it must be quite vertical and the feet that support it should be firmly bolted to the floor of the room where the milk is received; otherwise the slightest disturbance may interfere with the accuracy of weighing. It is further necessary, for accurate weighing, that the axis of the beam should be kept dry, as rust would cause irregular weighing.

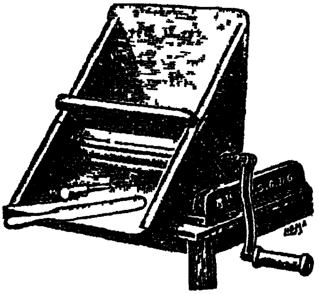


Front view of the milk-weighing balance.

758 - **Reciprocating Butter-worker.** — MAURIN, G., in the *Journal d'Agriculture pratique* Year 85, Vol. 1, No. 20, pp. 397-398, figs. 2. Paris, May 21, 1921.

With this new butter-worker, called " alternating, " it is possible to work up very small quantities of butter for which hitherto a spatula and a dish were used to get rid of the buttermilk and to work up the butter. This butter-worker, illustrated in the figure here reproduced, consists of a prismatic hopper with a triangular base, divided into two compartments by a partition below which rotates, in a horizontal plane, a grooved wooden cylinder worked by a crank handle outside. This handle can be placed either in the right or left of the hopper, the latter being able to rock backwards and forwards on two pivots below held in a frame which is attached to a table.

The butter is placed in the hopper which for the moment is uppermost, on rotating the grooved cylinder it draws and flattens the butter and removes the buttermilk in forcing the butter into the lower hopper, which slopes slightly so that the buttermilk and the water used for washing will drain away. Then the hopper is turned over on its lower pivots and the grooved cylinder is rotated in the opposite direction. The operation is repeated as often as is necessary, the butter being sprinkled with clean water After passing a few times the butter is thoroughly washed, worked up and separated from the buttermilk; it can be salted at the same time.



DAVID reciprocating butter-worker.

This butter-worker is made by the Firm L. DAVID, 56 Route d'Evreux, Vernon (Eure), France

RURAL ECONOMICS

759 - **Cost of Milk Production** (1) **in some States of the North American Union.** — *The Creamery and Milk Plant Monthly*, Vol X, No. 1, p 43 Chicago, Ill., January 1921.

The best way of estimating the cost of milk production is to determine it carefully in each administrative unit. The Dairy Division of the Department of Agriculture of the United States has instituted an enquiry for this purpose addressed to the groups of farms in 7 States of the Union. Data referring to 4 groups are now to hand. Each group consists of 20 dairies that are typical for their administrative unit.

The aim has been as far as possible to estimate the cost of production by quantity, rather than by price, in order to be able always to interpret the data by supplying the current price.

A summary of the data is given in the Table on p. 909.

AGRICULTURAL INDUSTRIES

760 - **Exhibition of Hybrid Wines at Mâcon, Saône-et-Loire, France** (2).— LAPRUGNE, in *Le Progrès agricole et viticole*, Year 38, No. 12, pp. 279-280. Montpellier, March 20, 1921.

The annual exhibiton of wines produced by hybrid bearers organised by the Agricultural Society of the arrondissement of Mâcon, was held on February 20, 1921. Over 50 samples of wine were shown, coming from Saône-et-Loire, the Côte d'Or, Haute-Marne, the Rhône, the Drôme, the Landes.

(3) Most dairy-farmers sell their milk retail, and this labour was for transport.
(4) By unit, 1 calf is understood.

In general, the opinion of the judges is that, under present conditions, when wine is made in too small quantities, the qualities of most of the samples cannot be judged and that a final evaluation would only be possible with wines made in a normal way in vats or casks. Nevertheless they summed up their valuations in the following notes:

1) *White wines.*

Bertille-Seyve 450. — Good wine, right flavour.
Seibel 880. — Vintage of 1919, good wine, pleasant, flinty taste.
Seibel 867. — Fairly pleasant, though very slightly foxy.
Seibel 4657. — Foxy wine.
Seibel 5061. — Insipid common wine.
Seibel 5213. — Shown as old, has a peculiar rancid flavour.
Seibel 5279. — Fairly good, alcoholic, slight peculiar flavour, rather pleasant.
Seibel 5409. — Peculiar unpleasant flavour.
Seibel 58-60. — Insipid wine, little alcohol, unpleasant aftertaste.
Seibel 1000. — Made as white wine, slightly rosy, interesting but badly shown.
Malègue 747-8. — Muddy wine, decidedly bad.
Le Brillant. — A wine which does not deserve the name of the vines which produced it.

Commerçon 2157. — Pronounced flavour of honey.

Baco-Thomur. — Wine with body and fineness; fairly mellow.

Baco Maurice Baco. — Peculiar flavour resembling the wines of Folle blanche, but much more pleasant.

Baco Dourion. — Fairly pleasant wine.

The wines made from mixed vines were not valued, not because they were despised, for possibly their mixing is a good operation, but, because the judges restricted themselves to observations on the characters of the hybrids, in order to bring out their respective merits later on.

2) *Red wines.*

Madone. — Vintage of 1919, full flavoured wine, deep coloured.

Couderc 4401, Buffet selection. — Insipid wine, common, but neutral, fine colour.

Couderc 162-97 (Drôme). — Indifferent wine, apparently badly made.

Couderc 7120 (Drôme). — Peculiar flavour, fine colour.

Baco No. 1 (Sologny, S.-et-L.). — Good wine, with body and colour.

Baco No. 1 (Haute-Marne). — Nice looking wine, which cannot be valued as it tastes of the cask.

Baco No. 1 (Montaguy-les-Buxy, S.-et-L.). — Made as a pink wine, "tender" wine, pleasant flavour, alcoholic.

Baco No. 1 (Landes). — Good wine, full bodied, deep coloured.

Baco-Estellat. — Wine with very good flavour, pungent, has fineness and bouquet, bright red colour.

Bertille-Seyve 872 (S.-et-L.). — Good ordinary wine, slightly earthy flavour.

Bertille-Seyve 872 (Drôme). — Foxy.

Bertille-Seyve 893 (S.-et-L.). — Ordinary wine, slightly acid.

Bertille-Seyve 893 (Drôme). — Passable, slightly peculiar flavour.

Bertille-Seyve 893 (Rhône) — Thin, with an earthy flavour.

Oberlin 595 (S.-et-L.). — Neutral wine, very deep coloured.

Siebel 1000 (S.-et-L.). — Vintage of 1919, very good wine in every respect.

Siebel 1000 (Drôme). — Vintage of 1919, neutral wine, thin, seems not to have been well made.

Siebel 4643 (Drôme). — Slight peculiar flavour; appears, like the last mentioned to have been badly made.

Siebel 4643 (Rhône). — Fairly pleasant wine, very slight special flavour, a little tart.

Siebel 4643 (S.-et-L.). — Fine wine, coloured.

Siebel 4643 (Hte-Marne). — Vintage of 1919, insipid and thin, special flavour, seems to have been badly cared for.

Siebel 4716 (Drôme). — Has fineness, colour rather yellow, alcoholic, flavour of old wine.

Siebel 5181 (Drôme). — Good wine, deep colour, slight special flavour.

Siebel 5181 (Rhône). — Made as a pink wine, light colour, interesting to see how it will mature.

On the whole, the red wines appeared more interesting and more successful than the white wines. The inequalities noted for identical hybrids are doubtless due partly to differences of soil and climate, but they appear to be due chiefly to the care taken in the gathering of the grapes and in the making.

761 - **Making Wine from Must of High Sugar Content.** — Mensio, C., in the *Giornale Vinicolo italiano*, Vol. 47, No. 12, pp. 112-114; No. 13, pp. 122-123. Casale-Monferrato, March 20 and 27, 1921.

The author describes an experiment which he made on a white wine of Castellammare del Golfo (Province of Trapani), with a high percentage of alcohol and also containing much unaltered sugar. The object was to ascertain the cause of its slow and difficult fermentation.

By fermenting musts very rich in sugar the author was able to get up to 19.5 % volume of alcohol, in laboratory tests, but he could never get more than 18 % under ordinary wine-making conditions. In the case investigated the wine contained 16 % of alcohol and 6.4 % of unaltered sugar; it therefore was made from a must containing 34 % of sugar, which, after complete fermentation, should have given a wine containing 19.7 % of alcohol.

The determination of the chemical composition of this wine and of the conditions under which fermentation took place led to the conclusion that the cause of the slowness and difficulty of fermentation was the excessive concentration of the must. The very small quantities of acetic acid and lactic acid found, proves that the fermentation of the wine in question did not reach too high a temperature. The author considers that it is practically impossible to get complete fermentation in such concentrated musts; nor does he consider it profitable, since such must could be used to greater advantage in making sweet filtrates, concentrated musts, or luscious, alcoholic, and sweet wines. The author thinks it would be more expedient to try to get a fairly rapid fementation, to produce 16 % of alcohol. without continuing it to the complete decomposition of the sugar. In a wine containing 16 % of alcohol a residue of sugar, even if fairly considerable, can do no harm. The best way of procuring this rapid fermentation is to inoculate a prepared yeast made with another less concentrated must (containing from 15 to 20 % of sugar) that has been fermenting from 24 to 48 hours. The quantity of that yeast should be from 2 to 3 % if the temperature is less than 20°C, and 1 % if the temperature is over 20°C. The fermentation will be governed by the same rules as those which regulate wine-making in hot climates (stirring the must so that the ferments spread throughout the mass; aeration repeated twice or more; moderate sulphuration; decantation according to the pace of fermentation).

Dilution of concentrated musts with water has been recommended, but in view of the present high cost of transport and casks and, on the other hand, the increasing demand for luscious sweet wines, the author doubts that such a method could be really better.

762 - The Alexis Chaussepied Apparatus for the Rapid Production of Sparkling Wines. See No. 756 of this *Review*.

763 - Balance of Nitrogen and Chlorine of Beetroot during the Manufacture of Sugar. — I. SAILLARD, E., Balance of Nitrogen during the manufacture of sugar. Precipitation of the albuminoids of beetroot by sulphuric acid, bisulphites and hydro-sulphites, in the *Comptes rendus de l'Académie des Sciences*, Vol. CLXX, No. 2, pp. 129-130. Paris, Jan. 12, 1920. — II. ID. The balance of chlorine during the manufacture of sugar and the chlorine content of beetroot. *Ibid.*, Vol. CLXXII, No. 5, pp. 283-284. Jan. 31. 1921,

I. — In a previous paper (1) the author has indicated what became of some of the elements from beetroot during the manufacture of sugar. In that paper the balance of dry material was shown as follows: —

---

(1) See *R.* 1918, No. 815. (*Ed.*)

		kg
Dry material from 100 kg. of beetroot		22.3
» » contained in pulp and diffusion water	5.6	
» » contained in the carbonatation cakes	1.2	
» » contained in the molasses	3.0	
» » contained in the white sugar	12.4	
Loss and sundries	0.1	
		22.3

Now the author notes that, from 100 kg. of beetroot about 50 kg. of dressed pulp, used as forage, and 40-50 kg. of press water are obtained. Its average composition may be represented as follows: —

	Per 100 of pressed pulp	Per litre of strained press water
Dry matter	8.5 – 10	8.5 gm.
Sugar	0.60	4.5
Ash	0.55	1.2
Total nitrogen	0.10–0.13	0.10–0.12

This means that the dry matter carried away in the press water is about 8-10 % of what remains in the pressed pulp ; the nitrogen is divided in approximately equal proportion between the pulp and the liquid. These figures, in conjunction with those of the first paper, show that in sugar factories which distil their molasses and incinerate the vinasses, the nitrogen from the beetroot is distributed on the average, per 100 of total nitrogen, in the following manner: —

In the carbonatation cakes	15
In the forage pulp	20
In the press and other waters	18
Given off in the form of ammonia during the process	17
Given off during the incineration of the vinasses	30

II. — When establishing the balance of chlorine, allowance was made for the chlorine contained in the well water which was used in the diffusion battery (0.02 gm. per litre). The following figures are average figures from ten sugar factories: —

Chlorine in the beetroot	0.016 %
Chlorine in the molasses	0.30
Chlorine in the beetroot contained in the residues of diffusion	19.00
Chlorine of the beetroot contained in the molasses	80.00
Undetermined losses	1.00

The distribution of the chlorine taken up in the soil by the roots among the various parts of the plant was, according to the following analysis made with beets containing 17 % of sugar: —

	Average weight of a plant	Moisture	Chlorine per 100 of dry matter
Blades of the leaves	127 gm	84.3 %	1.00 %
Petioles and principal rib of the leaves. .	296	85.9	1.80
Root collars	49	79.2	0.34
Topped roots	530	75.3	0.08

These figures show that the petioles have highest chlorine content; this remark applies also to mangolds. In the whole plant there is 1.2 of chlorine per 100 of sugar of the topped root, an amount which varies according to the conditions of growth.

764 - **Raw Materials for Industrial Alcoholic Production; Sugar Beet, Prickly Pear, Molasses, Potatoes, Sweet Potatoes, Maize, Acorns, Straw and Sawdust.** — I. JURITZ, A. C. Raw Materials for Industrial Alcohol Production, in *The South African Journal of Industries*, Vol. IV, No. 2, pp. 167-175. Pretoria, Feb. 1921. — II. BOAS, I. H., The Manufacture of Alcohol from Waste Wood or Sawdust, in *The Indian Forester*, Vol. XLVIII, No. 3, pp. 135-137. Allahabad, March 1921.

II. The raw materials possessing possibilities of being employed as bases for the production of industrial alcohol may be placed in 3 groups, namely, 1) sugar, 2) starch: 3) cellulose.

1) *SUGAR GROUP.* — a) *Sugar Beet.* — The juice derived by expression from sugar beet contains on an average about 15 % of sucrose. The yield may vary from 10 to 20 tons per acre; Germany showing the highest average in Europe. The yield of alcohol per ton of roots ranges from 11 to 24 gallons. If therefore, the average yield of beet be 12.5 tons per acre and the proportion of sugar therein 14 %, the consequent yield of 1.75 ton of sugar per acre will correspond to a theoretical yield of 237 gallons of absolute alcohol.

b) *Prickly-Pear Fruit.* — This is said to contain on an average about 10 % of sugar directly and completely fermentable into alcohol, and according to investigations carried on in the New Mexico College of Agriculture, a yield of 10 tons of fruit per acre was estimated, and it is estimated that 10 tons carrying 10 % of sugar, would yield 128 gallons of alcohol, and would bring in £ 6,5 s. per acre which is considered to be a good return for otherwise worthless land, entailing little or no cultivation.

c) *Molasses* (1). — This forms undoubtedly one of the cheapest raw materials for alcohol. At its highest value, the cost per gallon of alcohol thus obtained is 8d. It has however been estimated that the total raw material available for example in the United States and Cuba would produce only 162 million gallons of alcohol, or 5 % of the total requirements for motor fuel. The author gives details of the output of Natal in particular, and also quotes extracts from the paper read by HERIOT before the Scottish Section of the Society of Chemical Industry 1915 (1), showing the quantity and cost of production of alcohol from molasses in various countries.

---

(1) See "Molasses as a Source of Alcohol for the Production of Power", by T. H. P. HERIOT, in *Journ Soc. Chem. Ind.*, Vol. XXXIV, pp. 336-340.

II. *STARCH GROUP.* — a) *Potatoes.* — In a German potato distillery 100 kg. of potatoes are reckoned to furnish 20 kg. of starch, yielding 11.5 to 12 litres of 100 % alcohol. In Germany a particular variety of potato is grown exclusively for alcohol production, giving a specially large yield of tubers per acre, and containing a very high percentage of starch. Out of a total production of 4 ½ million hl. of alcohol (reckoned at 100 %), 3 ½ million hl. came from potatoes in 1918-19. The approximate yields per acre and corresponding potentialities for starch production for the various countries are tabulated.

b) *Sweet Potatoes.* — This contains approximately 25 % of starch and sugar. Assuming the yield to be no more than 4 tons per acre, the theoretical yield of the aforementioned elements would be about 2000 lb. per acre. Therefore from 1 acre of sweet potatoes, approximately 140 gallons of absolute alcohol should be obtained.

c) *Maize.* — The theoretical production per ton of maize may be estimated as 1360 lb. of starch (equivalent to 97 gallons of absolute alcohol), which compares well with the above crops. The amount of alcohol produced in actual practice bears the high proportion of 87 % to the theoretical yield, compared with the 77 % for potatoes. New Zealand apparently heads the list as regards the yield per acre of grain.

d) *Acorns.* — The author states that peeled acorns are said to contain about 40 % of starch together with some cane-sugar. At present, except for pig feeding, they are not much used, but once the difficulties are overcome there seems no reason why these should not be employed to advantage with regard to motor fuel.

3. *CELLULOSE GROUP.* — a) *Prickly Pear Stems.* — These of sections do not contain starch, but cellulose, and unless hydrolised by means of dilute acid, would possess no value for alcohol production.

b) *Straw.* — The same remarks apply to treatment of straw.

I-II (c) *Sawdust.* — The average yield of alcohol per ton of dry sawdust is about 20 gallons, but it should be remembered that the cost is nil, while that of other materials considered is considerable. Much research is needed to find methods of improving the yield, and it is also desirable to make a complete investigation of the sugars so formed. Methods may then be established to promote fermentation (1). In view of the importance in many countries of replacing petrol by another form of liquid fuel, this problem is extremely important.

The great obstacle in the way of the production of a larger proportion of alcohol from sawdust is the impracticability of completely converting the cellulose into sugar unless the material contains no more moisture than just enough to render it damp, and the hydrochloric acid used for hydrolysis is of at least 40 % strength. According to English Patent

---

(1) Research is now in progress at Berkeley University, San Francisco, with the constituents of the wood. (*Author's note*)

107,219, of May 23, 1916, by R. A. KOCHER of San Francisco, founded apparently on the researches of WILLSTÄTTER and ZECHMEISTER (1) maintenance of these conditions effects almost quantitative saccharification within 24 to 48 hours. Such a method would be a distinct advance on the processes hitherto in operation, as it effects the change at the ordinary temperature, in spite of the fact that the claim has been disputed (*Journal Chem. Soc.*, Vol. CXIII (1918), p. 181), where it is stated that it rested solely on polarimetric observations and the equally non-specific data of cupric reduction and was therefore inadmissible.

765 - **Contribution to the Knowledge of the Biochemical and Biological Qualities of Goats Milk.** — CORDES, F., in the *Zeitschrift fur Ziegenzucht*, Year XXII, No. 1, pp. 1-3. Hanover, 1921.

The author registered the milk production of goats (2) during one period of lactation, and determined the percentage of fat in the milk; in addition he determined the acidity, the catalase and diastase, and he made the alcohol test.

The milk production, which was 800 kg. per period of lactation before the war, has now decreased to between 500 and 400 kg., a quantity which is still equivalent to from 10 to 13.5 times the live weight. The fat content was variable. The average figures of the percentage of fat in the milk of the different goats varied between 2.72 and 4.11 %. The morning milk was, on the average, poorer in fats than the evening milk and the latter poorer than the mid-day milk.

The fat content of the morning milk is recorded as 3.29 %, that of the mid-day milk as 4.19 % and that of the evening milk as 3.94 %.

The alcohol test for ascertaining the freshness was of no use as the milk co-agulated every time.

The degree of acidity was determined by the SOHXLET-HENKEL method. The values obtained showed great variations; the average figure was 4.7 degree of acidity. The determination of the catalase gave results showing considerable differences. Thus treating 15 cc. of morning milk with 5 cc. of $H_2 O_2$ gave a lowest value of 0-5 catalase and a highest value of 7; the average was 2.25. The figure of catalase increased with the age of the goats.

The estimation of the diastase in goats' milk was made with KONINGS' method; here also a marked difference was recorded between the morning and evening milk; the smaller milkings showed the higher figure of diastase; 10-30 mgm. of starch were decomposed in 30 minutes by 100 cc. of fresh raw milk (3). No influence of the period of lactation on the diastase content was noticed.

766 - **Freezing Broken Eggs** (1). — I. MONVOISIN A. (Chef des travaux de physique et de chimie à l'École d'Alfort; chargé de l'enseignement de la conservation des denrées périssables à l'A. F. F.), in the *Revue général du Froid et des Industries Frigorifiques*, Year I, Vol. I, No. 12, pp. 397-398. Paris, Dec. 1920. — II. Organisation de la production des produits d'œuf à Shanghai, *Ibid.*, p. 398.

The author describes the freezing of liquid eggs as an industrial means of preservation. The frozen eggs of commerce (hen's eggs and sometimes duck's eggs) are prepared in China, Japan and North America.

The plant required includes: — 1) Cold storage to preserve the eggs, before they are broken, at a temperature of 0° to +4° C; 2) a testing room kept at a temperature of +10° to +13° C.; 3) a well-lit breaking room at a temperature of +15° to +18° C.; 4) a freezing chamber with a temperature of between —12° and —18° C.; 5) a room for washing and sterilising the utensils. All the apparatus is in non-rusting metal and capable of standing daily sterilisation without deterioration.

Eggs freeze at about —3° C.; the shell cracks and lays bare the membrane inside the shell, which renders the egg very vulnerable and easily invaded by microbes when thawed. To avoid these defects it is better to get rid of the shells of eggs to be frozen.

The worker breaks the eggs one at a time by striking the egg against the sharp edge of a metal blade. The egg is emptied into a glass, so that a bad egg which has escaped the test con be eliminated. An experienced worker can break and empty 12 to 16 eggs a minute. The yolks are mixed with the whites, or they are kept separate; the yolks can have sugar (1 %) or salt (0.7 %) mixed with them. The liquid eggs are placed in tins which usually contain 13.5 kg., the tins are soldered and then taken to the freezzing chamber, where, they remain for about 36 hours at a temperature of from —12° to —18° C. Preservation is subsequently effected in cold storage, with or without ventilation at —6° or —8° C. Preservation can be prolonged for a year or more; it is, however, noticed that in this case the product thickens slightly and sometimes a slight oily film forms on the surface.

REDFIELD has made a detailed study of the variations in the composition of frozen eggs produced under various conditions; from his paper are taken the figures reproduced in the Tables below. The results are indicated in gm. per 100 gm. of fresh material.

The ammoniacal nitrogen is expressed in milligrammes per 100 gm. of fresh material; the acidity of the fats in cubic centimetres of alcoholic soda N/20 per gramme. The counting of the bacteria was done after 5 days' culture at 20° C.

II. — An American company, the "Amos Bird Co." at Shanghai deals daily with one million eggs. The yolks and whites are dried and frozen, or frozen only. These products are sold in America. The factory employs 700 workmen and the processes of manufacture are kept secret.

---

767 - **The Frozen Meat Industry in Brazil** (1). — *La Revue générale du Froid et des Industries frigorifiques*, Year II, Vol. II, No. 3, pp. 87-81. Paris, March, 1921.

The frozen meat industry in Brazil is of quite recent date, since it began in 1914; the first consignment to London, 1415 kg., was made in December of that year by the Osasco and Barretos packing houses in the State of São Paulo.

During the war the enormous demand for frozen meat required for the Allied armies gave this industry a remarkable impetus; the following statement shows the total shipments from Brazil each year up to 1920:—

	Tons shipped	Values in thousands of paper *milreis* (1)
1914	1 415	—
1915	8 514	6 121
1916	33 661	28 192
1917	66 452	60 233
1918	60 508	60 755
1919	54 094	60 183
1920	63 600	67 213

(1) 1 paper *milreis* = 16 *pence*.

From an examination of these figures it would seem that the demand due to the war resulted, as principal effect, in the sudden creation of the meat industry and that this industry, which has now reached the stage of regular production, shows a tendency to develop normally, the price of Brazilian meat tending at the same time to keep level with those of other similar markets.

Statistics of 1913, based on an official census of cattle in the various States of Brazil, gave a grand total of 30 705 080 head. The States which had most cattle were:— Rio Grande do Sul, with 7 249 000 head; Minas Geraes, with 6 861 000 head; Bahia, with 2 683 000; Matto Grosso, with 2 050 000 head; and S. Paulo, with 1 322 000 head.

These figures are no longer accurate, the cattle in certain States in Brazil having considerably increased since 1913. Thus, according to recent information, Rio Grande do Sul has at present more than 8 million cattle, Minas Geraes about 7 500 000, S. Paulo 3 803 205. These are the three States in which cattle breeding has been specially developed and improved by the introduction of well bred bulls.

These would be no exaggeration in fixing the present number of cattle at 35 million head (2).

In 1913, the total number of cattle in Brazil and other cattle breeding countries in decreasing order of importance were as follows, in millions of head: — United States 63; Russia 37.3; Brazil 30 705; Argentine 29; Germany 20.15; Austria 17.8; France 14.5; England 11.8; Algeria and Tunis 11.3; and Canada 10. In the same year the average price of an average steer was:—

---

(1) See *R.*, May, 1915, No. 530; June, 1915, No. 623; August, 1915, No. 733; March, 1919, No. 339; Feb., 1921, No. 213. (*Ed.*)

(2) An estimate made in 1918 gave: — 37 500 000 head of cattle, 7 205 000 sheep and 17 320 pigs. (*Note by the Ed. of the Revue Générale du Froid*).

United States	300 to 350 *milreis*
Argentina	225 to 250 »
Brazil	120 to 130 »

It cannot be said that any breed properly speaking is found in Brazil, and all efforts of breeders are directed towards the creation of a breed by crossing and selection.

The cattle in Rio Grande and Minas Geraes are generally cross-bred with imported cattle on one hand and with indigenous " caracu " (1) and " zebu " (2) (the latter chiefly in the State of Minas Geraes).

The weight, height and yield are small. An average steer does not weigh more than 300 to 500 kg.; the bones are much developed and scarcely 220 to 250 kg. of meat net are obtained.

Up to the present the efforts of breeders in the south have been generally very scattered. The want of concentration and especially the mistake formerly made, notably in the State of Minas, of mixing the breeds of " zebu " and " criolla " (cattle of foreign origin living almost wild) has been one of the chief obstacles to the production of a fixed type.

For several years the Federal Government (3) has been making greater efforts to introduce well-bred bulls into the country. It has instituted bonuses for breeding, allowed duty-free importation of bulls, and encouraged cattle shows and fairs. The Minister for Agriculture has recommended the following measures as capable of giving good results:—

1) *Restriction in the importation of bulls to two or three breeds at most* (Shorthorn, Polled Angus, Hereford) with the object of improving the live weight of the cattle. On its part the Union of Breeders of Rio Grande do Sul recommends, for cattle intended for slaughter, that after experimenting, one or other of the three breeds should be definitely adopted so as to create a fixed breed by the introduction of a single strain in the indigenous cattle.

2) *Generalising the practice of keeping cattle in pens.* — Up to date Brazilian breeders have been content to import bulls and let them run free among the herds in the open all the year round. It was soon discovered, and this was notably the case with cattle belonging to the Brazil Land, Cattle and Packing Co., that these bulls, imported into Brazil at great cost, could not stand the diseases which raged in the country:— foot and mouth disease, red water, anthrax, etc.

---

(1) See *R.*, Nov. 1917, No. 1044.

(2) See *R*, Jan. 1915, No 80. (*Ed*)

(3) See No. 700 of this *Review*. (*Ed.*)

The Union of Breeders of Rio Grande do Sul considers that the present methods of keeping cattle must be brought up to date, recourse had to preventive measures (arsenical dips or injections of trypanoblue against ticks or " carapatos „), shelters provided for the animals where they can be visited, cared for, or placed under observation.

3) *Gradual elimination of the " zebu " breed.* — The breeders of Southern Brazil have pronounced clearly against cross breeding between imported cattle and the " zebu " breed, the produce so obtained being inferior in yield and degenerating more and more.

The question of natural or artificial pasturage is secondary.

There is no doubt that in this matter Brazil is particularly fortunate. Enormous stretches of land, selling at very low prices, are found in the north of Parana and Rio Grande do Sul, or the borders of Parana and Paraguay, as far as Matto Grosso, abundantly watered and situated at a sufficient altitude to furnish excellent pasture although the grass there is, apparently, fairly hard.

The frozen meat from Brazilian cattle has been recognised as capable, as regards quality, of comparison with the best Argentine, Uruguayan, Australian or Canadian meat on the English and French markets.

Argentine cattle yield on an average 500 kg. of meat per animal, whereas in Brazil the average barely reaches 250 kg.

Consequently the 30 million head of cattle in Brazil only represent in utilisable weight, compared with the 29 million head of Argentine cattle, some 15 million head actually.

As, on the other hand, the home consumption is greater in Brazil than in La Plata, the first deduction to be drawn from these facts is that the present condition of the Brazilian herds is a long way from showing a potential annual export equal to that of the Argentine, which amounts to about 600 000 metric tons. With the generally primitive methods of keeping cattle in Brazil and the mortality which is thus caused, it is not possible to estimate a higher average annual production than 10 % (1).

The possible export would be about 700 000 head, which at an average weight of 250 kg. per head, would give a total of 175 000 tons of meat. At 1000 *reis* a kg. this tonnage would represent a value of 175 000 *contos de reis*.

At present the capacity of industrial production is far from reaching this amount. At the present moment, there are in Brazil 12 undertakings engaged in the production and preservation of frozen meat, of which 10 are working, distributed as indicated in the table on p. 921.

The first nine establishments in working are controlled by the Federal Government and the last by the Municipality of Rio de Janeiro, During

---

(1) This percentage seems too low, for many Brazilian cattle breeders state that they can count on a production of 20 % and even 25 % for those who use the more rational methods; 18 % would seem to be an accepted average which corresponds to an export of of 1 260 000 head and 315 000 tons of dressed meat. (*Note by the Ed. of the Revue Générale du Froid*).

Designation	Number of cattle killed in 1918
State of São-Paulo :-

Federal District : —	
Companhia brasileira britanica de carnes, near Rio de Janeiro (connected with the British and Argentine Meat Co., Ltd. capacity :— 6000 tons)	43 836
Grand total.	**434 847**

the first half year of 1919, 93 250 head of cattle were slaughtered at the Swift cold storage at Rosario alone. For the year 1919 the export of chilled and frozen meat was as follows, for the 3 great ports of shipment :—

Rio de Janeiro	15 260 tons	54 094 metric tons.
Santos	32 034 »	
Rio Grande do Sul	6 800 »	

The following is some supplementary information (1) regarding the refrigerating establishments in the State of São Paulo (not including that of Armour and Co.) for the year 1918 :—

---

(1) This information and part of that given previously is due to M. Paul WALLE, Councillor for foreign Commerce, General Secretary-Treasurer of the Franco-Brazilian Chamber of Commerce, at Paris. (*Note by the Ed. of the Revue Générale du Froid*).

	Number of animals killed	Dead weight in metric tons
Cattle	204 011	42 400
Pigs	31 215	1 706
Sheep	2 526	35

Production of dressed meat (in tons).

	Factory at Osasco	Factory at Barretos	Factory at Santos	Totals
Frozen meat	18 501	9 489	1 705	29 695
Chilled »	1 046	4 209	—	5 255
Fresh »	—	—	—	4 372
Preserved »	2 751	44	—	2 795
Value in *contos* *	34 000	15 189	6 985	56 174

* 1 *conto de reis* = 1000 *milreis*.

For the State of São-Paulo, the exports of chilled meat, from 1916 to 1920, were as follows:—

Years	Metric Tons	Value in *contos*
1916	18 689	15 717
1917	29 315	26 388
1918	32 655	32 757
1919	30 731	33 805
1920 (11 months)	34 000 about	35 917

There is still a great difference between the actual figures and what might be expected. The problem of improving the breed is well on the way to being solved but the problem of shipping remains to be dealt with before this industry can be fully developed in Brazil.

As the best breeding areas are certainly Rio Grande do Sul followed by Matto Grosso and Minas Geraes, for which the port of shipment is Rio de Janeiro, it is not expecting too much to anticipate that the export from these three States will quickly reach 100 000 tons, but on condition that this quantity can be transported to the European markets by regular and sufficient lines of ships with cold storage. There, apparently, lies the kernel of the matter for, at present, the transport capacity for frozen meat is certainly not adequate to the production.

PLANT DISEASES

DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS.

768 – **On the Identity of *Spirospora Castaneae*, a Hyphomycete Observed on Chestnuts in France — and *Acrospeira mirabilis*** — PEYRONEL, B, in the *Bulletin trimestriel de la Société mycologique de France*, Vol XXXVII, Part 1, pp 56-61, Paris, April 15, 1921

A short time ago, MM. MANGON and VINCENS described, under the name of *Spirospora Castaneae* n. gen. and n. sp, a hyphomycete found in France on Chestnuts affected by black rot » (1). They thought that the perfect form of *Spir. Castaneae* might be a member of the genus *Melanospora.*

The author states that this hyphomycete is not a new species, for it was discovered and accurately described, at least under its chlamydospore form, as long ago as 1857, when it was found, also upon chestnuts, at Bristol (England) by BERKELEY and BROOME, who gave it the name of *Acrospeira mirabilis.*

The author adds that this fungus cannot be very uncommon, seeing that since 1916 — when he began to study the diseases of chestnuts — he found it frequently every year in Rome during the autumn and winter. In any case, it is very widely spread, for according to BERKELEY and BROOME, many mycologists have met with it in other European countries, and in South America.

Spirospora Castaneae Mangin and Vincens (1920) should thus be regarded, according to the author, as a synonym of *Acrospeira mirabilis* B. and Br. (1857), as well as of *Polycystis italica* Sacc. and Speg. (1879) *Urocystis ? italica* (Sacc. and Speg.) De Toni (1889), and *Stephanoma italicum* (Sacc. and Speg.) Sacc and Trav. (1911).

775 - **The Smut of Italian Millet (*Ustilago Crameri*) in the Presidency of Madras, India.** — SUNDARAMAN, S., in *Agricultural Research Institute, Pusa, Bulletin* No. 87, pp. 1-11, pl., 2 map, 1 Calcutta, 1921.

Italian millet (*Setaria italica*) is one of the most important food crops of the Presidency of Madras, where it is grown in all the districts, except Malabar and South Canara. This cereal is subject to several cryptogamic diseases, but the one that does it most injury in Madras is smut (*Ustilago Crameri* Koern).

In 1917, this disease assumed serious proportions in the « taluk » of Siruguppa (Bellary district). The loss due to the fungus was estimated at more than one quarter of the whole crop.

According to the author, of all the preventive measures so far known, copper sulphate is the best, being both the cheapest and surest.

It was found by his experiments, that in distilled water the chlamydospores of *Ustilago Crameri* germinate in the proportion of 50 % in six hours ; 95 % germinate in twelve hours, and 100 % in twenty-four hours. If placed in a 0.5 %, or stronger, solution of sulphate of copper for fifteen to thirty minutes, none of these spores germinate.

As regards the effect of copper sulphate upon the germination of the millet seed, the author's experiments proved, that it was hindered by immersion for thirty minutes in 5 % copper sulphate solution, and for fifteen to thirty minutes in a stronger solution.

Practically, all that is needed to protect the seed from the attack of smut, is to place it for half an hour in a 2 % solution of copper sulphate.

Only seed in good condition should be used, old millet is liable to be injured by the treatment. The disinfected grain should be immediately dried, to prevent its germinating, and planted at once.

776 - **Diseases of Sweet Potato in the United States.** - - See No. 719 of this *Review*.

777 - **Diseases of Cotton in Brazil.** — See No. 700 of this *Review*.

778 - ***Alternaria Nelumbii* n..sp., a Hyphomycete Injurious to the Nympheacea, *Nelumbium speciosum* in the United States.** - ENLOWS, E. M. A., and RAND, F. V., in *Phytopatholo y*, Vol. XI, No. 3, pp. 135-140, figs. 1, pl. 1. Lancaster Pa., March 1921.

A cryptogamic disease of the leaves of the Egyptian lotus (*Nelumbium speciosum*), was first observed in 1913, at Kenilworth (District of Columbia), and later, at the New York Botanical Garden The disease begins as very small, smooth, reddish-brown spots, which increase in size, until they reach 5 to 10 mm. in diameter. They may be roundish, or somewhat irregular in shape, with a tendency towards the formation of concentric bands of alternately lighter and darker brownish tissue. The margin is definite. In some cases, the spots are surrounded by a lighter green halo. When the spots are very numerous, many of them coalesce, and the leaf gradually dries from the margin inward.

Since 1913, the disease has been seen at Riverton (New Jersey), again at the New York Botanical Gardens, and Kenilworth, at Arlington (New Jersey), and at Pittsburgh (Pennsylvania).

The same fungus, which from its characters appears to belong to the genus *Alternaria*, was isolated several times from diseased leaves collected in the above-mentioned localities. The results of numerous inoculations carried out upon detached leaves in the laboratory, as well as on plants of *N. speciosum* under normal conditions, in the greenhouse and out of doors, leave no doubt of the pathogenicity of this species of *Alternaria* to the Egyptian lotus.

No perfect stage of the fungus has yet been discovered, but the fact that its conidia are able to germinate after remaining dry in the laboratory for as long as 2 years, would certainly indicate, that the conidia are probably carried over winter on dead leaves, and other débris. This micromycete grows well saprophytically, so it is also possible that it might continue growing on fallen leaves during the warmer periods of the winter.

The fungus in question is considered to be a species new to science, and is described under the name of *Alt. Nelumbii.*

779 - ***Trichothecium roseum*, a Hyphomycete Producing " Marciume amaro " (Bitter Rot) or " Marciume del cuore " (Core Rot) in Apples and Pears, in Italy.**

— PEYRONEL, B., in the *R Stazione di Patologia vegetale e R Osservatorio fitopatologico per la provincia di Roma e gli Abruzzi, Bollettino mensile d'informazioni e notizie*, Year II, Nos 1-4, pp. 23-27, figs 3. Rome, 1921.

Many of the apples and pears sold in the markets of Rome are found every year to be affected by a disease Although the fruits look perfectly normal and healthy externally, the pulp surrounding the loculi is brown, soft and rotten. During the first stages of the disease, a kind of spider's web, which subsequently gives place to a pink efflorescence, is seen on the interior of the loculi, and on the surface of the pips

Microscopic examination has shown this spider's web and efflorescence to be, respectively, the mycelium and conidial fructifications of a very common hyphomycete, *Trichothecium roseum* Link (= *Cephalothecium roseum* Corda) which frequently occurs on all kinds of dead and decaying plant matter, and usually behaves as a saprophyte. The fibrous tissue bounding the cavity of the style and connecting the loculi with the cavity of the calyx, is also altered and brown, and the rot gradually extends to the surrounding pulp. In the end, the entire fruit can become affected, and if the surroundings are not excessively damp, it is mummified. The diseased pulp is very bitter. Fruits attacked by this malady have been frequently sent from different places in Italy to the Station of Plant Pathology in Rome.

In the case of the fruits in question, it is clear that the fungus finds its way into the interior by way of the cavity of the calyx; it probably at first lives as a saprophyte; afterwards making its way along the hollow style, it reaches the core, and thence passes to the pulp. Sometimes, however, in the case of apples, the fungus reaches the loculi by way of the peduncle, following the course of the fibro-vascular bundles of the latter. According to the author, it is most probable that the germination of the conidia and the penetration of the mycelium are assisted by the habit of placing the choicest fruits — which are most often attacked — on a horizontal plane with the cavity of the calyx turned downwards. In this way, if the fruit is not perfectly dry, an actual moist chamber is made, in which any spores present on the skin can grow under excellent conditions. Piles of fruit also are easily attacked by the hyphomycete, especially if they are damp. The fruits should be kept perfectly dry, in dry rooms, and spread out, not piled one upon another.

780 - ***Phoma citricarpa*** **a Deuteromycete Parasitic on *Citrus sinensis* and *C. nobilis* in China.** — LEE, H. A., in *The Philippine Journal of Science*, Vol. XVII, No. 6, pp. 635-643. Manilla, 1920.

The same disease which was recorded in 1899 as occurring on the fruit of certain citrus trees in New South Wales (Australia), and attributed to the parasite *Phoma citricarpa* Mc. Alp. has recently been observed on the fruits of *Citrus sinensis* and *C. nobilis* in China, at Canton, Hongkong, Swatow, Amoy and Foochow. Infected specimens coming from Shanghai were intercepted at Nagasaki (Japan), and Chinese fruits severely affected by the disease have been collected on the market at Manila (Philippines). Citrus fruits grown in the Philippines have, however, so far, not been found to be infected

Small reddish-brown spots first appear on the surface of the diseased fruit, with increasing age, these spots become darker, and sometimes turn completely black. The spot may be 1 or 2 mm. in diameter, but can subsequently spread to from 7 to 9 mm. in diameter. As the spot matures, a reddish-brown, raised margin forms round the outer edge, while the centre sometimes becomes depressed and assumes a light-tan or brownish colour. Pycnidia occasionally show in this light-coloured area; they are black and extremely small (only a fraction of a mm. in diameter).

The lesion occurs not only on the surface of the fruit, but extends into the skin-tissue for 1, or at most, 2 mm In this internal tissue, the lesion is usually reddish-brown; it has never been observed to extend into the fruit, although, rarely, secondary rots emanating from a lesion due to the fungus in question may spread into the pulp. The disease is not widespread on fruits in the orchard, but seems to develop while they are in storage, or in transit to market. The presence of the spots on the fruit lessens its selling value.

Isolation experiments were first made at Nagasaki, and a fungus was invariably obtained. Subsequently isolations were also made from Chinese fruits found on the Manila markets, and in this manner, a fungus was isolated, which proved to be identical with the one obtained at Nagasaki, and answered closely to Mc Alpine's description of *Ph. citricarpa*.

Inoculation experiments carried out at Manila with a pure culture on sound, ripe oranges resulted in the reproduction of the disease. Control punctures with tap-water remained entirely negative The fungus has been re-isolated from positive lesions. Inoculation experiments have been repeated several times, and a reasonable percentage of positive results produced, thus proving that *Ph. citricarpa* is the cause of the disease recorded in China.

There are no experimental data regarding the control of this disease in an infected orchard The inoculations made have shown, that fruits are only susceptible when approaching maturity; unripe fruits yield negative results when inoculated.

It is possible, that the disease could be easily controlled by spraying. For countries where the malady is not yet present, the best control is, of course, to exclude it by quarantine measures.

The situation in the Philippines with regard to this disease is peculiar; as has already been said, it has not yet been seen on Philippine-grown oranges. Those imported from China, and found everywhere on the markets, are sometimes severely attacked by the fungus, and afford a source of infection for Philippine citrus fruits just at the period when the latter are ripening. The absence of the disease in these islands is therefore probably due to climatic conditions, or possibly to the fact, that ordinarily the rind of the Philippine citrus fruits does not mature and turn yellow, but remains green up to picking time. This point may be cleared up in future experiments.

INJURIOUS INSECTES AND OTHER LOWER ANIMALS

781 - **Indigenous *Gossipium* spp. in the Philippines Resistant to *Anthonomus grandis*.** — See No 722 of this *Review*

782 - **Insects Injurious to the Sugar Cane in Cuba.** — BARRETO, B T, in the *Revista de Agricultura, Comercio y Trabajo*, Year III, No 10, pp 371-374, figs 5 Havana, 1920

On an estate at Jagueyal (Commune of Ciego de Avila), all the sugar-cane fields contained small patches where the plants had been destroyed. These patches seemed to increase in size from one year to another. On the sugar-canes being examined, a large number of *Pseudococcus sacchari* and of *Ps. calceolariae* were found on the lower surfaces of the leaves, and on the roots

Practically the whole field was infested with these insects, but only about 15 to 20 % of the canes had been attacked. In places where there were most insects, the plants appeared to have succumbed to the attack of both species. The chief injury had been done in the case of canes that had been planted, to fill up the gaps. The small pieces of cane, on removal from the ground, were found to be infected with *Pseudococcus* which covered all the buds and shoots; the insects were probably already present on the canes before they were planted. On inspecting those that had not yet been used, many *Pseudococci* were found clustering round the buds.

It is probable however, that the death of the plants was due to other causes also. In some cases, indeed, the plantations had been cut over twelve times, and the stems were almost at the level of the soil, and weakened by the frequent action of fire.

Other insects had also been observed in the diseased plantations and in some of them large numbers of the eggs and larvae of Scarab beetles were found, as well as other intruders.

In certain of the sugar-cane fields on the same estate, great quantities of termites were also discovered; these insects, however, do not seem to have been responsible for the death of the plants.

The best means of controlling the sugar-cane scale-insects is to burn the field, and plough it thoroughly; this should, however, only be resorted to in extreme cases, when the plantation is infested.

Periodically cleaning the ground, in order to prevent the spread of likely host-plants, is also an excellent way of ridding the field of the pests.

A field that has been burnt should not be replanted under two months, and it is wiser to wait a year.

Further, only canes completely free from scale-insects should be used for planting and if there is any doubt about the matter, they should be disinfected by immersion for half-an-hour in a solution of whale-oil soap.

Aspergillus flavus, one of the natural enemies of *Pseudococcus* in Cuba, was not present in large numbers on the estate in question. It was not possible to determine how far species of *Polistes* were useful in controlling scale-insects. In some fields that were infested with the latter, numerous larvae of the coccinellid *Cryptolaemus montrouzieri* were liberated by way of experiment, but little faith is placed in their efficacy.

For the control of scarabs, the soil should be worked from January to March; the larvae uncovered can be picked up, or left for the birds, which devour them readily. The adult beetles, which feed on the leaves of the fruit trees at dusk, in May and June, ought to be shaken down into cloths spread below, and then collected and thrown into vessels containing petroleum.

When it is known which trees are visited by the adult coleoptera, they can be sprayed with a solution of lead arsenate, so that the insects are poisoned on eating the leaves.

Light-traps can also be used for adult scarabs; if these are suitably arranged, great numbers of the insects are attracted and caught in the early spring.

783 – ***Pyrausta ainsliei*** **a Microlepidopteron Parasite of** ***Polygonum*** **spp. in the United States — Closely Resembling the Maize Pyralid (*Pyr. nubilalis*)** (1).

— Ainslie, G. G., and Cartwright, W. B., in *Journal of Agricultural Research*, Vol. XX, No. 11, pp. 837-844. Washington (D. C), March 1, 1921.

Observations made since 1912 in Tennessee, and the neighbouring States, have shown, that the Smartweed Borer (*Pyrausta ainsliei* Heinrich), is of no importance as a pest. At present, however, the insect is of considerable interest because of its resemblance, both in habits and appearance, to the maize pyralid (*Pyr. nubilalis* Hübner). Until recently, it has also been confused with *Pyr. penitalis* Grote, which feeds on *Nelumbium luteum.*

---

(1) See *R.* Oct.-Dec 1919, No. 1289; *R* April 1920, No 471. (*Ed*)

The Smartweed Borer is known in the following States: Massachusetts, New York, Pennsylvania, Ohio, Illinois, Tennessee, Kentucky and South Carolina. It is possible that its geographical distribution is still more extensive.

Polygonum pennsylvanicum is the chief plant upon which its caterpillars feed, though they have also been found inside the stems of other related species The larvae have also been reared upon the leaves of the curled dock (*Rumex crispus*) and buckwheat (*Fagopyrum fagopyrum*), which are close relatives of *Polygonum.*

The stems of many other species (maize among the number), afford shelter to the caterpillars during the winter, but they obtain no food from these plants.

The article analysed contains much information regarding the life-history and habits of *Pyr. ainsliei.*

The latter varies greatly in abundance from year to year; this seems to be due, in Tennessee at least, to variations in the natural enemies of the microlepidopteron.

The most important of the latter appears to be (*Panzeria*) *Pyraustomyia penitalis* Coq. Other parasites found on the Smartweed Borer are *Cremastus facilis* (Cresson), and three apparently distinct hymenoptera, one of which has been determined as *Microbracon* sp. The larvae of *Callida decora* Fab. and of *Chauliognathus pennsylvanicus* de Geer are predatory insects, that have been mentioned as attacking it.

784 - **Insects Injurious to Medicinal Plants in the Crimea.** — PARFENTJEV, I., in the *Bulletin de la Société de Pathologie exotique*, Vol. XIV, No. 3, pp. 614-167, figs. 5 Paris, 1921.

The results of entomological researches made from 1919-1920 on crops of medicinal plants cultivated at the Fruit-Growing Experiment Station of Salghir, which is situated in the vicinity of the town of Simferopol.

Atropa Belladonna, unlike *Ricinus*, is much injured by insects. The adult forms of *Epithrix atropae* and *E. pubescens* make small, more or less round holes in the leaves of the former plant, which finally look like sieves. These beetles also attack plants of belladonna growing wild in the forests of the Crimea. The females of the genus *Epithrix* deposit their eggs during summer directly on the ground, and the larvae hatch out after seven, or eight, days and remain in the soil, where they pupate, the adult insect appearing on the 6th or 7th day after pupation.

Psylliodes hyoscami, which is sometimes seen on *Atropa Belladonna* occurs more frequently on the common henbane (*Hyoscyamus niger*).

The leaves and flowers of *Atropa Belladonna* are sometimes attacked also by the caterpillars of *Mamestra brassicae* and *Heliothis peltigera.*

The adult form of *Ceuthorrhynchus macula-alba* perforates the capsules of *Papaver somniferum* which are arrested in their development, and bend over. The larvae of this insect live inside the capsules.

Podagrica malvae bores small, irregular holes in the leaves and flowers of the marsh-mallow and the holly-hock. The reproductive organs of the marsh-mallow are devoured by *Oxythyrea funesta.* The holly-hock is also attacked by *Baris nitens, Apion longirostre,* and *A. validum,* the larvae of the two last insects living in the seeds and the stems of the plant respectively.

The flowers of the fennel are attacked by several Hymenoptera, Diptera, and Coleoptera. *Graphosoma lineatum* does considerable injury by sucking the fruits.

The adult forms of *Cassida viridis* and *Cryptocephalus ocellatus* perforate the leaves of balm (*Melissa officinalis*).

The flowers of wild plants of *Adonis vernalis* are often injured by *Amphicoma vulpes.*

785 - *Rhagium lineatum*, a Coleopteron Injurious to Pines in North America.—

HESS, W. N., in *Cornell University, Agricultural Experiment Station, Memoir* 33, pp. 367-381, figs. 6, pl. 1. Ithaca, New York, 1920.

Rhagium lineatum Oliv. is one of the commonest and most widely distributed species od Cerambycides in North America

It has been reported from Canada, twelve States of the North American Union, and Mexico.

In the state of New York, and in Pennsylvania, all species of pine are attacked by this beetle, although it most frequently chooses *Pinus Strobus, P. rigida,* and *P. resinosa.*

Although the attack is limited to the region of the inner cortex, and outer sapwood, there is no doubt, that the insect does great damage to the recently dead wood. It generally makes extensive galleries, which lead to the bark becoming detached, and the damp gaining access to the interior of the tree Once the moisture has succeeded in effecting an entrance, it is retained by the large mass of wood fragments produced by the excavations of the beetle, the growth of fungi is thus promoted, and the decay of the tree hastened.

The tree attacked dies after the second or third year; the exits made by the adult insects permit of the entrance of large quantities of water, as well as of other insects, and fungi, which soon render the wood useless for commercial purposes.

The author gives a full morphological and biological account of the different stages in the development of *Rh. lineatum.*

As regards the control of the latter, a wet season, not only hinders its work of destruction, but is also favourable to the growth of fungi which attack the beetle at every stage, and especially the larvae. Individuals surviving until the winter often succumb to frost. The larvae on hatching out, while seeking an easy way to reach the inner cortex, often fall a prey to other insects, or to birds.

Atanycolus simplex Cresson, a parasite of the larvae of *Rh. lineatum*, was reared in Pennsylvania, the number of larvae attacked by it being estimated at 5 % In the State of New York, this parasite is extremely rare, and only attacks about 1 %.

The pest could be artificially controlled by felling all the pines recently killed, and removing the bark before March 1. The larvae and adult insects would thus be destroyed, and this would contribute greatly to reducing subsequent attacks Trees lately felled can be protected against *Rh. lineatum* by putting them into water. The attacks can be greatly decreased by placing the trunks in damp surroundings, but this may also hasten the decay of the wood The application of repellent substances, like carbolineum, in May, as a rule prevents oviposition on the part of the females of this beetle.

Only a few years ago, these pests were extraordinarily plentiful in the environs of Ithaca (New York) ; recently however, *Rh. lineatum*, and many other insects which were most injurious to forest trees, have almost disappeared. This is due in a great measure to the fact, that all dead, or dying trees, have been at once felled and removed.

786 - ***Neodiprion lecontei*, a Hymenopteron Attacking Pines in the United States.** — MIDDLETON, W, in *Journal of Agricultural Research*, Vol. XX, No 10, pp. 741-760, figs 3, pl. 5 Washington, D. C, February 15, 1921.

A very detailed morphological description of the various stages of Leconte's sawfly (*Neodiprion lecontei* (Fitch) — a hymenopteron belonging to the family Tenthredinidae, sub-family Diprioninae — followed by a short acount of the life-history of the insect.

The latter has hitherto been found in the following States of North America North Carolina, Conneticut, the District of Columbia, Florida, Louisiana, Maryland, Michigan, Mississippi, New Hampshire, New Jersey, New York, Pennsylvania, Virginia, West Virginia, Wisconsin.

The hymenipteron appears to have three primary, or preferred, hosts : Jack pine (*Pinus Banksiana*), red pine (*P. resinosa*) and scrub pine (*P. virginiana*). Its secondary, or possible hosts are white pine (*Pinus strobus*) Scotch pine (*P. sylvestris*), loblolly pine (*P. Taeda*), shore pine (*P. contorta*), silver pine (*P. monticola*), mugho pine (*P. mughus*), *P. eldarica*, western yellow pine (*P. ponderosa*), longleaf pine (*P. palustris*), Austrian pine (*P. austriaca*), and American larch (*Larix americana*).

The larvae of *N. lecontei* do considerable damage to both natural reproduction and nursery stock by defoliating the trees. The complete, or nearly complete, defoliation before late summer usually kills the part stripped, and since these insects show a very decided preference for young trees, the larvae are often numerous enough to entirely deprive the tree of all its leaves ; many young pines are killed by this means' alone. Trees not completely denuded frequently die because, in their weakened condition, they are attacked by secondary insect enemies. Where there is incomplete defoliation and the tree recovers, it is often stunted, or misshapen, and of little commercial or ornamental value.

Four species of Hymenoptera and four species of Diptera have been reared from the cocoons of *N. lecontei*, but neither egg parasites nor parrasites that emerged from uncocooned larvae have been obtained. The hymenopterous parasites observed were: *Exenterus diprioni* Rohwer, *Lagorotis diprioni* Rohwer, *L. virginiana* Rohwer and *Perilampus hyalinus* Say Of these parasites, *L. diprioni* Rowher is much the most abundant species, and *Perilampus hyalinus* Say is probably a hyperparasite. The dipterous parasites of *N. Lecontei* are: *Phorocera claripennis* Macquart, *Adomonita demylus* Walker, *Neopalus maera* Van der Wielp, and *Spathimeitenis spinigera* Townsend.

From what was observed, in 1912, at Wisconsin, the larvae of *N. lecontei* are also subject to a disease which is probably of bacterial origin, but it appears that none of the insect parasites were abundant enough, nor was the bacterial disease sufficiently distributed or infectious, to allow of the neglect of artificial control measures.

In large areas of either natural or artificial conifer reproduction, control cannot be generally practised on account of its expense, but rangers and lumber men should systematically destroy the colonies of this sawfly, whenever they are found. The easiest plan is to knock the larvae from the trees, and crush them with the foot.

In nurseries and parks, the control, in case of heavy infestation, can best be carried out before the larvae are full-grown, and should consist of thorough spraying. An arsenate of lead spray is very efficacious; if the larvae are quite young, nicotine sulphate is a fairly satisfactory spray. Since however, conifers are very resistant to arsenical sprays, and arsenical treatment gives the best result , the first treatment should be employed almost exclusively. In scattered infestations, hand-picking, or knocking the larvae down from the trees and crushing them, will be found more economical, and at least as effective.

Whenever these insects are observed in any locality, and control measures are practised against them, it is important that the territory should be carefully surveyed for the following 14 months, since it is possible, that some of the larvae may have survived, and have spun cocoons. This possibility makes it necessary to watch carefully throughout the entire colony-period of this sawfly, in order that an emergence of adults from the cocoons may not give rise to a new infestation.

GENERAL INFORMATION

787 - **Note on the Mountainous Regions of North Annam.** — POILANE (Chargé de prospection forestier), Official Statement from the Laboratoire de Botanique de l'Institut Scientifique de l'Indochine, in *Bulletin Agricole de l'Institut de Saigon*, Year III, No 6, Saigon, June 1921

The note begins with a short preface from the Botanical Laboratory of the Scientific Institute of Indo-China, describing the considerable amount of work which the author carried out in collecting, preparing, preserving and transporting nearly 3000 numbers (respresenting at a low estimate 30 000 botanical specimens) of woody and herbaceous species regarding each of which he patiently collected information such as could obtained from the natives themselves in each district visited It is to be hoped that this material, which has been sent to the Natural History Museum in Paris, will soon yield much scientific information regarding the less-known regions of Indo-China.

The itinerary of the journey through North Annam was approximately as follows: — Thanh-Hoa, Phu-Quan, Phong-Y, Hoi-Xuan, Hua-Tau, Ban-Inh-Dam, Na-Ham, Sam-Neua, Tam-La, Xieng-Khouang (Province of Tran-Ninh to Laos), Cha-Mung, and Muong-Sen.

The author gives much information on the indigenous flora, the forests, cultivation in the high regions with relatively temperate climate, where a fairly large number of European fruit trees (apple, pear, peach and cherry trees) are often found, and on various other natural sources of wealth (minerals, etc,). and on the manners and customs of the inhabitants of various races (Annamites, Moïs, Muong, Méos, Thôs and Laotiens).

All the mountainous zone of North Annam and Laos will have a fine future when means of communication are constructed to open it up.

788 - **Influence of the Size of Plots on the Accuracy of Field Experiments.** — KRISTENSEN A. K., in *Tidskrift for Planteavl*, Vol. XXVII, Part 4, pp. 681-692. Copenhagen, 1921.

The author continues his examination of the technique of field experiments relating to the researches of SCHNEIDEWIND and VAGELER (1). He discusses their results and draws certain general conclusions.

If fields bearing crops treated in a similar manner are divided into plots, the produce of which is weighed separately, it is found that small plots give much more accurate results than large, when the latter are obtained by reducing the number of duplicate plots Even if the area of the plots is increased thus increasing proportionately the total area, whilst the number of duplicate plots remains the same, the small plots still give more accurate results, and this is particularly noticeable for cereals.

In the case of weeded crops (red cabbage), the results were not so favourable with very small rectangular plots. These remarks, based specially on VAGELER's data, are equally applicable to those of SCHNEIDEWIND.

CORPS AND CULTIVATION

789 - **The Degree to which Plants can be considered as Integral Factors' Capable of Measuring the Complex Effect of Climatic Factors.** — I. LIVINGSTONE, P. A., in *Physiological Researches*, Vol. No. 5, pp. 217-288, figs. 4, 1914. — II. LIVINGSTONE, B. E., *Ibid.*, Vol. 1, No. 8, pp. 399-420, figs. 4, 1916. — III. HILDEBRAND, F. M., *Ibid*, Vol. 2 pp. 341-405, figs. 8. Baltimore, May 1921.

I. — LEHENBAUER has undertaken a series of very interesting researches concerning the effect of temperature on the growth of young maize plants. The results obtained by previous writers suggest thet the growth curve of plants, in relation to temperature, is very irregular, since it has two distinct apices instead of one. On the other hand, the data concerning the technical optimum vary considerably according to different authors, perhaps because the very important factor time of has not been sufficiently taken into account in this kind of research.

In the course of the experiments in question arrangements were made to obtain, as far as possible, uniform conditions; the young maize plants were kept in the dark and at a constant temperature, the re.ative humidity was always about 95 %, and lastly the time factor, in relation to the rate of growth at different temperatures, was taken into account. The biometric data were, in many cases, recorded every hour and the period of observation lasted from 12 to 39 hours, at temperatures of 12° to 43°C.

The chief conclusions may be summed up as follows: —

---

(1) See *R.*, March 1921, No. 243. (*Ed.*)

1) There was only one thermic optimum. For maize in liquid cultures and for a period of 12 hours it was equal to 32°C.

2) Under these experimental conditions, the thermic optimum varies with the change of duration of exposure (see Table I)

3) At high temperatures the initial rate of growth is not maintained but diminishes considerably when the period of experiment is prolonged beyond a certain limit.

4) The decrease in the rate of growth, which is noticed at high temperatures makes it necessary, in every case, if the period of exposure is prolonged, to take into account the length of the periods which have served to determine that rate. The term *optimum temperature* has no meaning, at least in the case investigated, if the duration of exposure of the plant to that certain temperature has not been established with accuracy.

5) On the contrary, with temperatures which approach the minimum (12-14°C), even in the case of long experimental periods, no decrease in the rate of growth is noticed.

6) At intermediate temperatures the rate of growth obeyed the law of VAN T'HOFF, i. e, the rate was doubled by raising the temperature by 9 or 10°C.

II. — On the basis of the results obtained by the previous author giving exposures of young maize plants for a period of 12 hours at temperatures of 12° to 43°C., LIVINGSTONE was able to calculate a series of "thermo-physiological indices" which considerably facilitate the study of the growth of plants in relation to climatic conditions

LEHENBAUER'S data have been entered on a table of abscissae and ordinates, for drawing the corresponding curve; this curve was corrected later by LIVINGSTONE and prolonged by extrapolation to 2° and 48°C. These two values are considered as the extreme temperature of growth.

For each degree of temperature (both in the Centigrade and Fahrenheit scales) the corresponding ordinate, is measured (which gives the measure of growth per hour in hundredths of a millimetre), and the numbers thus obtained are divided by the value of the growth corresponding to 4.5°C. (40°F). The quotient represents exactly the "thermo-physiological index" of growth at the given temperature. Each index thus expresses the different growth for a given temperature, taking as unity the growth obtained by exposing the plant for 12 hours to a temperature of 4.5°C. Table II contains all the indices for temperatures in degrees C, from 12 to 47, and for temperatures in degrees F. from 36 to 118.

III. — Results of a series of parallel observations on the growth of soya beans and the course of meteorological factors. Th se observations were made simultaneously, during the summer of 1914 at 9 stations: — Oakland, Chewsville, Monrovia, College Park, Baltimore, Darlington, Coleman, Easton, and Princess Anna. The object of the observations was to establish in what degree and to what extent plants could serve as integral factors to give an idea of the course of the climatic factors, temperature, light and evaporation, as a whole. The same type of soil was used in every case, which unified the agrogeological conditions, and humidity was always maintained at 10-11 %, by means of a special automatic irrigator, so as to exclude the effect of rainfall, by placing constantly at the disposal of the plant the quantity of water necessary to the processes of growth.

Biometrical data recorded: — 1) Length of the stalk; 2) area of the leaf surface; 3) leaf product (length multiplied by breadth); 4) dry weight.

Two weeks after sowing determinations were made of: — 1) The average daily relative increase in length of the stalk for each plant (in mm.); 2) the average daily relative growth of the leaf area for each plant (in sq. mm.); 3) the average daily relative increase in dry weight for each plant (in grammes). (Sowing was carried out regularly every two weeks during the period of observation).

Meteorological data: — Temperature was expressed by means of thermo-physiological indices; for this purpose average daily temperatures are replaced by the corresponding index (see Table II), and the sum of the indices is divided by the number of days (14 or 28). Besides the thermo-physiological indices, the sums of the residual temperatures are calculated. The residual temperature is obtained by subtracting 3.89°C., from the average daily temperature.

Light: — The assumption is made that in a week there are *two* fine, *three* mixed and *two* overcast days. If the respective values 2, 1.5 and 0, are added up they give 3.5 the number equal to the total of fine days in the period considered. Now 3.5 is equal to the half (0.5) of the total number of days. The latter value, 0.5, which the author calls " coefficient of clear weather " is finally multiplied by the average intensity of insolation expressed in gramme calories per sq. cm.). The product obtained gives a fairly adequate idea of the phenomenon during the period considered.

Evaporation: — This is determined with an atmometer with a porous tank. The average daily evaporation in cc. is calculated for each period of 2 and 4 weeks.

The average daily growth of plants, as well as all the other biometric and climatic values, are expressed in the form of relative averages, with reference to the general average of all the data, and for all the stations for each period of 2 and 4 weeks. Directly comparable figures are thus obtained

To obtain the unit for each factor all the corresponding values (for example, all the daily averages of growth for two weeks at the 9 stations) are added together and then divided by th number of readings. This quotient serves as a comparative unit.

The daily averages, both climatic and biometric, are divided by this unit and the quotient is multiplied by 100 to avoid decimals.

The following are the units as calculated: —

2 weeks after sowing:—
Average daily increase in the height of the stalk per plant = 3.56 mm.
Average daily increase of the leaf product per plant = 112 sq. mm.

4 weeks after sowing:—
Average daily increase in the height of the stalk per plant = 3.20 mm.
Average daily increase of leaf area per plant = 122 sq. mm
Average daily increase of dry weight per plant = 6.29 gm.
Temperature = 13°50C.
Light = 442 gramme calories per sq. cm. of horizontal surface.
Evaporation = 16 cc

TABLE I. — *Data relating to the Station of Oakland for a period of 2 weeks*

	Iay 25 to une 5	June to June	June to July	July to July	July to July	July to Aug	August to August	August to Sept 1	Sept to Sept	verag

Relative average increase in the length of the stalk .	76	96	124	84	96	98	101	53	42	**86**
Relative average increase of leaf product	—	81	87	71	81	78	82	40	—	**77**

The tables relating to the 4 week periods are worked out in the same way; only instead of leaf product, leaf area is taken into account, and, further, the data relating to the increase of dry weight are entered.

The data of the tables are graphically shown in a series of diagrams.

Table IV shows the average values of each biological index for the whole period of observation at each station.

From an examination of Table IV it appears that: —

1) During an observation period of 2 weeks the formative power of the climatic conditions as a whole is found to be the same both for the the growth of the stalk and for the increase of leaf product The former

43	12	9	7	6	5	(1)	—	—	—	—	—	—	—

value passes from a minimum of 79 at Monrovia to a maximum of 125 at Baltimore. According to that measure it may be said that the average intensity of the climatic conditions as a whole at Monrovia is equal to 63 % of that at Baltimore

2) In an observation period of 4 weeks the data obtained are much more uncertain and less defined just as if the plant, considered as an instrument, was exhausted from too long exposure. The length of the observation period is therefore a factor of capital importance, of which the optimum value must be recorded with the greatest possible accuracy

The efficacy of the climatic conditions as a whole, that is to say the power of producing growth of the typical plant chosen for the purpose may be considered as a product of 2 factors viz., intensity and duration. For the former the average of 5 biometric values dealt with in Table IV,

TABLE III. — " *Thermo-physiological indices* " *of plant growth based on data established by* LEHENBAUER *by exposing young maize plants to various temperatures during a period of* 12 *hours* (see Table II).

Princess Anna	181	105	19 005

These products of climatic efficacy represent more or less approximately the relative values of climatic conditions (of the different stations), so far as they influence plant growth, and furnish points of reference for the comparative quantitative study of climatic conditions as a whole.

One of the objects of ecological climatology is precisely that of valuing climates, like hydraulic force, mineral deposits and other sources of riches which have a well-defined geographical distribution.

The importance of these researches is considerable, both for agriculture and for sylviculture, and the results obtained by the author constitute a new step towards the solution of this important problem.

790 - **Effect of An Extraordinarily Hot April on the Progress of Phenological Phenomena in East Prussia, in 1918.** — KNÖRZER, A., in the *Phaenologische Mitteilungen* 1919, year, 37, No. 26, pp 26-30. Darmstadt, 1920

Normally the mean April temperature becomes lower in proceeding further from the south-west towards the north-east, so much so that between the extreme north west corner of Prussia and the hottest zones of Rhineland there is a difference of 5.5°C. The following data give an idea the distribution of April temperatures in different sectors of Central Europe, — Lugano 11.4°4C.; Bozen-Gries, 12.7; Montreux, 9.6; Colmar, 10.6°; Heidelberg, 10.0°; Berlin, 7.7°; Bromberg, 6.9°; Königsberg, 5.4°; Marggrabowa, 5,0°; Memel 4.8°C.

In 1918, on the other hand, there was an exceptional April and the distribution of the temperatures is almost the inverse of the one preceeding — Lugano, 9.4°, Bozen Gries, 11 2°; Montreux, 8.7°; Colmar, 10.9°; Heidelberg, 10.4°; Berlin, 11.4°; Bromberg, 12.1°; Königsberg, 12.2°; Marggrabowa, 11.0°; Memel 11.0°C There are the following differences from the means: Lugano — 2,0°; Bozien-Gries, — 1,5°; Monticux, — 0,90°; Colmar, + 0.3°; — Heidelberg, + 0.4°; Berlin, + 3.7°; Bromberg + 5.2°; Königsberg + 6.8°; Marggrabowa + 6°0.; Memel + 6.2°C.

Such high positive differences had never been recorded in Prussia; at Königsberg and Memel the temperature reached a maximum of 9.8° and 9.2° C. respectively.

TABLE I. — *beginning of the flowering season in East Prussia in the spring of* 1918.

	Botanical Garden of Konigsberg	Pillau	Allenstein	Losgehnen (Fredland)	Sensbrag	Johannisburg	Gerwiscken (near Gumbinnen)
Prunus spinosa . . .	April 21	April 20	—	April 21	April 21	—	—

» *Cerasus* . .	» 22	» 26	» 22	» 24	» 25	April 22	» 24
» *Padus*	» 22	» 22	» 22	» 22	» 26	» 21	—
Pyrus communis . . .	» 22	» 24	» 22	» 25	» 25	» 22	—
» *Malus* . . .	» 24	» 26	» 25	» 27	May 4	May 1	May 13
Aesculus Hippocastanus	» 26	» 28	» 28	» 25	—	April 30	—
Syringa vulgaris . . .	» 27	» 29	» 29	May 1	—	May 11	May 14

The extraordinarily high temperatures in April helped to accelerate considerably the revival of spring growth. Table I reproduces the data of the flowering season for certain trees in different parts of East Prussia.

Striking the general average of the given phenomena, and considering it as data for the begining of spring, April 21 is indicated for East Prussia in 1918.

Normally, according to IHNE, for various places in the region under consideration, the dates are: –

Födersdorf	17	May	Ibenhorst	22	May	Arys	19	May
Königsberg	17	»	Dingken	21	»	Grabnik	19	»
Fritzen	24	»	Brödlauken	17	»	Kurwien	23	»
Neustemberg	18	»	Sadlowo	18	»			
Pfeil	16	»	Rothebude	19	»			

The general average for East Prussia is May 19. In 1918 it was, therefore, more than 3 weeks in advance.

791 – **Effect of Late Spring Frosts on the Vine.** — NÉGRIER, A., in the *Revue de Viticulture*, Year 28, No. 1400, pp. 315-326. Paris, Apr. 1921.

The effect of late spring frosts is shown in various ways, and the following cases may occur: —

1) The buds may be frozen before they open.

2) The young shoots may be frozen.

3) The clusters may be destroyed without injury to the branches.

4) The ends of the branches may be affected while the clusters are unharmed.

5) Branches that are already strong and partially lignified at the base may be frozen up to just below the clusters.

In the first four cases cutting back is quite useless. In the fifth case on the contrary it is recommended to cut the branch at 2.5 cm. from the base, 3 or 4 days after the frost

The author does not recommend pruning the shoot back to the false bud (called " bourrillon ") of the previous year, because of the loss of sap which would result and because of the great development of adventitious branches which would ensue.

792 – **Effect of Late Spring Frosts on the Geographical Distribution of Forest Trees.** – RUBNER, in the *Forstwissenschaftliches Centralblatt*, Year 42, Part 2, pp. 41-49 and Part 3, pp. 100-114, Bibliography of 32 publications. Berlin, 1921.

The annual temperature and its distribution during the growing period, the rainfall and its distribution in each season, the hours of sunshine, the frequency of winds, are phenomena which are modified according to altitude and latitude, but in a gradual and steady manner,. Sharp limits of the area of distribution of a given forest species cannot therefore be constituted In considering the meteorological phenomenon of spring frosts, the question presents itself quite differently. When these frosts take place only occasionally, wood already formed (especially in young trees) although more or less damaged by them, easily survives the crisis; but when frosts are frequent and regular every year, their action must be felt from a geographical standpoint, in relation to the species which resist and those which do not resist cold.

This resistance depends on many factors.

PERIOD OF GROWTH: — Species which come into leaf late such as the oak and ash, are much less exposed to the retarding effect of frosts than early species, such as the beech

Quercus pedunculata var. *tardissima* is a good example of this order of phenomenon. In the district of Agram, at altitudes of 100 to 150 mm. it forms pure stands, whilst at higher altitudes mixed stands of the common *Q. pedunculata* and *Q. racemosa* appear This distribution is in relation with the last spring frosts. *Q. p.* var *tardissima* grows in damp places, most exposed to frosts, from which it saves itself owing to its late production of leaves whereas the two other oaks, which begin to shoot in the second half of April, would be inevitably damaged. They appear at higher altitudes and in drier and more open places, where the intensity and frequency of late frosts are very much reduced.

The mean dates of foliation are as follows:—

Quercus racemosa:— April 15-18.
Q. pedunculata:— April 25-30
Q pedunculata var. *tardissima*: — May 23-28.

The retarding effect of frosts, in so far as it affects the geographical distribution is exerted most evidently on the inflorescences, at the flowering stage, and on the newly-formed tissues. Silver fir, beech, and oak exposed to frosts do not always manage to produce their seeds regularly, whilst on the other hand, young plants are always liable to be frozen until they have reached a height of 1 to 2 metres.

CAPACITY FOR RECOVERY. — The alder, ash and, oak stand first, especially the last named owing to its foliation called after St John, as new buds make their appearance to replace those which might eventually have been destroyed by frost. The beech, however, is less apt to recover and conifers still less.

RATE OF GROWTH DURING THE FIRST STAGES OF GROWTH. — The shorter the duration of these stages, when the trees are most sensitive, the less is the probability of damage caused by frost.

Among deciduous trees, the alders, oak and ash are distinguished by their rate of growth, while the beech is much slower; among conifers the larch and Scots pine grow rapidly in the earlier stages, while the silver fir and *Pinus Cembra* grow slowly.

WEIGHT AND MOBILITY OF SEEDS. — In places subject to frost, heavy seeds do best; when ripe they fall in the immediate neighbourhood of the tree in the middle of the wood, so that young trees grow up under the shelter of full grown trees.

The relationship existing between frosts on the one hand and topographical conditions, on the other, the depth of snow, the date of the melting of the snows, and that of the last frosts, are explained by the author by means of the average data of foliation for the beech, oak and silver fir. A period without snow before the last frosts, constitutes a danger, the consequences of which increase as the period is prolonged.

[792]

Data concerning certain regions of Central Europe.

Some German forest species, such as the silver fir and mountain maple, do not grow outside the mountainous region of Central Germany, and the limit is at approximately the same latitude both in Poland, and Prussia The eastern limit of copper beech is bounded by the line Königsberg — Allenstein — Kalische, that of *Quercus racemosa* by the line Königsberg — Ossoweicz — Brest-Litowsk, whilst *Quercus pedunculata* reaches, in latitude, as far as southern Finland, and to the east as far as the Ural mountains. How are the late spring frosts distributed in these districts ?

For Germany the author comments on the data, collected during 15 meterological forest seasons, and shows that the date of the last frost is not so much in direct relation with the altitude, as with the general conditions of the climate, the character of which becomes more rigorous and continental further to the east. Towards the first fortnight in May the plains of Russia are generally swept by a succession of cold waves, which are even felt in the eastern parts of Germany. Thus at the station of Kurrvien (East Prussia) the last spring frost happened, on the average, on June, 18, whereas at Melkerei in the high Vosges, at 934 m. altitude, the last frost took place on May 22. The geographical distribution of the beech is intimately allied with the distribution in frequency and intensity of spring frosts, and as these increase towards the east, the northern limit of the beech traces a curve towards the east.

The species which withstand cold best are the Swedish *Pinus sylvestris* the birch and the mountain alder, which can form forests up to 69-70° north latitude Of the two species of birch, *Betula pubescens* and *B. verrucosa*, the former reaches higher latitudes than the latter, probably because of its greater resistance to frosts, as may be deduced from the fact that this species flourishes also on peaty soils, more exposed to the action of frost. It might be thought that these species, which are capable of growing in the extreme north, could also grow at very high altitudes. This is not the case; as a matter of fact: —

The Scots pine reaches 1600 metres in the Bavarian Alps, and only in small stands; it reaches 1000 m. in the Black Forest, and only 800 m. in the Giant mountains.

Betula alba reaches 1400 m. in the Alps, 1028 in the Bavarian Alps, and only 500 m. in Central Germany.

The mountain alder reaches 1400 m. in the Bavarian Alps and 650 m. in Saxony.

On the other hand, the beech and silver fir, of which the former does not grow further north than Southern Sweden, and the latter beyond the mountainous zone of Central Europe, reach respectively, 1420 and 1500 m in the Bavarian Alps, 1200 and 1300 m. in the Black Forests, and 750 m. in Thuringia

The author suggests the following reasons for this phenomenon: — Pine, alder, birch, which are light demanding trees struggling with beech and silver fir, which are shade enduring species, endowed with greater growth and longer lives, are completely overcome, surrounded and choked by the last two which hinder their normal growth Moreover the Scots pine owing to the brittleness of its branches, is badly suited for the mountains, where the heavy snowfall increases the risk of broken branches. The author thinks that other similar facts can be explained in the same way. thus, the hornbeam (*Carpinus betulus*) extends much further north and east than the copper beech which, however, grows, to a higher altitude.

The importance of frosts as regards the distribution of forest trees has not yet been appreciated at its true value. Some writers attribute to rainfall a dominant effect on the geographical distribution of the silver fir; the author refutes this statement, and adduces numerous data, which make the effect of frost conspicuous Spring frosts should therefore be included among the most effective phenomena which determine the area and limit of the distribution of numerous forest trees.

793 – On the Lateritic Nature of Italian Soils and Researches on the River Silts. —

DE DOMINICIS, A., (Laboratorio di chimica agraria della R Scuola Superiore d'Agricoltura, Portici), in the *Annali della Regia Scuola Superiore di Agricoltura in Portici*, Sect II, Vol XV, pp 23, Portici, 1920

VAN BEMMELEN's method consists in the separation of decomposed silicates, insoluble in mineral acids, decomposed silicates of kaolinic nature, soluble in sulphuric acid, and decomposed silicates, soluble in hydrochloric acid, when in the last named the ratio $\frac{\text{molecules Si O}_2}{\text{1 molecule Al}_2\text{O}_3}$ is greater than 3, the soil colloids are composed of true agricultural clay; on the contrary, if this ratio is less than 3 it is laterite or gelohydrate of aluminium which prevails. By means of this method or suitable modifications of it, lateritic soils were identified in localities of southern and central Italy such as the provinces of Lecce, Foggia, Bari, Potenza, Naples, Caserta, and Teramo, as well as the arid zones of Tripolitania. These researches are so interesting that the utility of extending them systematically to all soils of southern and central Italy is indisputable. With this object, it is clearly, useful to examine river silts, of which the general diagnostic value enables entire regions, drained by the water carrying the earthy particles, to be included in a single survey. The finest compounds of a colloidal order, the chemical nature of which, disclosed by VAN BEMMELEN'S method, may serve as a guide for a more detailed examination in the drainage area of the river found largely in deltas. If the ratio is lateritic it would be possible to deduce that the clay nature does not predominate in the soils which constitute the entire basin. With this object the collection of silt from the rivers and streams of Italy has been undertaken and this work should be completed as soon as possible. The samples examined belong to the following rivers:— Tagliamento, Po, Foglia, Cecina, Tiber, Ofanto, Cozzelli, Belice. Physical and chemical analyses have been made of them, using SCHLOESING'S method for sandy matter, colloidal matter, calcareous matter, humus, hygroscopic moisture, and for the analysis of silicates VAN BEMMELEN'S method.

To sum up, whilt the investigation of lateritic soils is especially important in dry climates, because of their behaviour in the presence of water, with reference to the lack or bad distribution of rainfall, and the fertility of these same soils, in such dry climates the products which are derived from the process of laterisation all remain *in situ* without dissolving. It is therefore difficult in a chemical analysis, to separate and identify them; they are more easily separated by means of the artificial operation of levigation; this occurs naturally under the action of running water in the streams, and the examination of muds is interesting because it can serve as an indication of the nature of the soil of entire regions. The results obtained up to the present in this direction represent an experimental contribution to theories relating to the lateritic nature of the soil of Southern Italy, and give an entirely new direction to study and technique.

794 – **Physico-Chemical Investigation on the Power of Absorption of Soils and on the Way in which Plants Absorb Nutritive Matter in the Soil.** — CASALE, L. (Lecce, Scuola Agraria), in *Le Stazioni Sperimentali Agrarie Italiane*, Vol. LIV, Parts 1, 2, 3, pp. 65-113. Modena, 1921.

Theoretical and experimental contribution to the study of the phenomenon which governs the power of absorption in the soil and absorption by plants; this phenomenon would take place both in the soil and in the plant independently of vital action which only intervenes to regulate and control it according to the requirements of the protoplasm.

The author recapitulates the data concerning the colloids and electrolytes of the soil and, in view of the importance of the ionic velocity in the phenomena of absorption, he sums up as follows the principal factor which may cause it to vary: —

1) The velocity of the ions decreases with an increase in the viscosity of the solvent. The nature of the salts in solution or the suspended colloidal matter has an influence on the viscosity of the solvent in the sense that the more abundant the suspended colloidal matter and the smaller the colloidal granules, the greater will be the viscosity.

2) The velocity of the ions increases with the temperature and tends to become the same for all the ions. The velocity increases with the temperature either because the viscosity of the solvent decreases with the temperature, or because the mass of the ion decreases with the temperature. It should be noted that the mass of the ion does not mean the atom or group of atoms which constitute it, but the ion and the molecules of the solvent which surrounds it to form the hydrate. These hydrates are unstable and become less complex with an increase in the temperature. With an increase in temperature, the mass of the ion becomes less and can move more easily in the solvent.

3) With great dilution, the hydrate formed by the ions is more complex and its velocity decreases sensibly. The effect of the temperature in increasing the velocity of the ions is more marked with great dilution, because the complexity of the hydrate formed by the ions undergoes greater variation.

4) All ions have not the same hydrating power. It may be stated that, in general, calcium and magnesium have greater hydrating power than ammonium, potassium, and sodium. The ion with the greatest hydrating power undergoes the most marked variation of velocity for an equal increase of temperatures.

5) Pressure also acts by increasing the velocity of the ions. From various experiments made with this object, from consideration of the data of other writers (PETERS, BRETSCHNEIDER, PRATOLONGO, WAY, ULPIANI, BERNARDINI) and their theoretical discussion, the author passes to the principal conclusion: — The causes which determine, the power of absorption of soils are the same as those which regulate the phenomena of absorption by the colloids.

The colloidal constituents of the soil receive a positive or negative charge according as they give out to the liquids which moisten them, anions or cations. Their charge will therefore be proportionately greater when the number of ions given out is greater. As the simultaneous presence of negative and positive colloids in a colloidal solution is inconceivable, it must be admitted that the positive colloids are absorbed, in the ground, by the mass of negative colloids. Each granule of negative colloid exercising an attraction on the ions charged with electricity of the opposite sign, determines around it the formation of a zone of concentration of cations. The absorption of the cations by the granule of the colloid takes place when the necessary difference of potential is established between it and the zone of concentration. The greater the number of cations present in the zone of concentration the more easily is that difference of potential reached.

It follows therefore that the degree of absorption and coagulation of a given electrolyte is highest when its ionic concentration is greatest. Different electrolytes have not the same coagulating power; but this, all other conditions being equal, is highest when the tension of solution of the cation of the electrolyte is lowest and when its relative velocity is greatest. Iron and aluminium have greater coagulating power; next in decreasing order come magnesium, calcium, potassium, ammonium, and sodium. Sodium is an exception to the rule, inasmuch as it unites a high tension of solution with a low relative velocity and because its salts are feebly dissociated.

It is not only the cationic nature of the added electrolyte which influences the coagulating power and the quantity of cation absorbed by a given quantity of soil, but also the anion, in the sense that while the coagulating power increases with the relative velocity of the anion, the quantity of cation absorbed decreases. Absorption by the colloids is not effected on each cation but on the whole of the zone of their concentration. Hence the anions which, existing in the zone of concentration, give rise to insoluble compounds on the colloidal membrane, are able to remain fixed.

The complex soil solutions give up a greater quantity of the swiftest cations. For this reason potassium and ammonium are most absorbed, followed by calcium, magnesium, and sodium.

The different cations are retained on the colloidal granule by electric action and are deposited on its membrane in order of arrival, so that the last to be neutralised form the outer layers. The most-easily soluble ions form the outside layer of the colloidal membrane, and this is why they are more easily replaced by other bases. However the phenomenon of substitution is not due to a chemical action of double decompositon, as has been maintained by WAY since 1850 and confirmed by more modern chemists, but it also is due to electric action.

The difference of potential between the granule of the colloid and the solution which moistens it, is the factor which governs the phenomenon of absorption and substitution. All factors which may cause variation in the difference of potential and the surface tension, help to cause variation in the composition of the products of absorption.

To cause the production of the phenomenon of absorption it is necessary that the colloid should receive a negative charge and send positive ions into solution. Thus basic silicates and humates, treated with boiling hydrochloric acid and freed from the substances formed by continual washings, lose their power of absorption, because they cannot drive the cations in solutions.

The behaviour of the organic colloids may be summed up as follows: — 1) They have a smaller negative charge than that of inorganic colloids; 2) to coagulate them, considerably greater quantities of electrolytes are required than in the case of inorganic colloids; — 3) they act as protectors to the coagulation of inorganic colloids so long as the latter have a concentration below a certain limit; beyond that limit they on the contrary, facilitate coagulation; 4) they absorb both the cation and the anion of the salt which determines their coagulation; 5) they behave in an absolutely identical way to inorganic colloids when they are treated with metallic salts at a lower tension of solution than hydrogen.

Regarding the manner in which the plant absorbs the nutrients in the soil, the author, after having recalled the opposite points of view of EHRENBERG and ROHLAND and the opinion of ULPIANI, describes some of his expements and considers the mechanism of absorption, to which he applies considerations relating to the action of manures with special regard to the views of the American school of WHITNEY and his followers. Finally, comparing these considerations with the conclusions mentioned above on the subject of the power of absorption of soils, the author sums up the manner in which plants absorb the nutritious substances in the soil as follows:— The ectoplasm of the absorbing cells forcing the hydrogen ions into solution acquires a negative charge. This charge is less than that of the soil colloids so that there is a difference of potential between the plant and the soil. By virtue of this difference of potential the granules of the colloid are attracted by the absorbing zone to which they adhere tightly. The colloids of the soil tend to equalise their negative charge with that of the ectoplasm and drive the cations towards the latter. A kind of continuity is thus established between the plant and the soil colloids. The nearest colloids give up ions to the plant, those further off to those which are nearer. The passage of ions from one granule to another would go on until the charges of the ectoplasm and the colloids of the soil are equalised; but this equality is unattainable, since the ions absorbed by the ectoplasm do not remain on it; but, by an identical act, they are attraced by the tonoplasm. They must therefore pass through the protosplasmic mass and can thus be utilised.

Absorption by the absorptive cells is effected in the same way as with the colloids, that is to say, it does not take place for each cation, but for a whole zone of concentration which is formed round the cell. In that zone there are also anions which can be utilised in passing through the protoplasm.

The phenomenon of absorption commences with a demand for moisture on the part of the plant, which according to its requirements and by the help of the production of substances with osmotic activity regulates the circulation of moisture. The moisture demanded by the interior of the plant brings to a higher degree of saline concentration the liquid layer nearest to the absorbing zone and thus facilitates absorption. Cultures made in nutrient solutions acquire an acid reaction due to the hydrogen ions driven into solution by the ectoplasm. The hydrogen ions, which, are at a low tension of solution, hinder absorption. Cultures made in nutrient solutions containing colloids, on the contrary, have not an acid reaction because the hydrogen ion is absorbed by the colloids, and they can, consequently support greater dilution than simple nutrient solutions. Absortion also proceeds more regularly, because the granules of the colloids can absorb the cations not used by the plant instead of those given up to the plant.

[794]

In the soil, absorption is more intense when the difference of potential between the plant and the colloids of the soil is greater. The latter offers the plant substances absorbed by the solutions which are the same as those required by the plant. The plant thus profits by the substances which it needs, while the colloid profits by the elements which the plant rejects. If these elements are already abundant in the soil the plant must use them.

The exchange of nutritive substances between one cell and another, determined by a need of the protoplasm, is governed by the same factors as those which determine absorption. The moisture, circulating in the plant, permits and helps the circulation of nutritive substances.

The beneficial action of fertilisers is explained by the influence exerted by their cation in lowering the negative charge of the colloids, which increases the difference of potential between them and the plant Fertilisers are therefore not so useful on account of the need of the plant for their constituents as on account of the influence which they exert in increasing the difference of potential between the plant and the soil.

The author himself remarks that the experimental work is not yet complete and he proposes to renew the investigation with this object in view.

795 - **Mechanism of Flocculation in Soils.** — A Contribution to a General Discussion on "Physico-Chemical Problems Relating to the Soil," held by the Faraday Society on Tuesday, May, 31, 1921, in *The Chemical News*, Vol. XXII, No. 3192, pp. 279-281. London, June 17, 1921.

The structure of the soil, so far as the mineral part is concerned, is determined by two principal factors: — The dimensions of the soil particles and their arrangement.

In practice the dimensions of soil particles, evidently remain permanent and unaltered; these dimensions are measured conventionally, in England, with reference to particles which pass through a 3 mm. sieve, as follows:—

	Diameter in mm.
1. Stones and gravel	3.00 - 1.00
2. Coarse sand	1.00 - 0.20
3. Fine sand	0.20 - 0.04
4. Silt	0.04 - 0.01
5. Fine mud	0.01 - 0.002
6. Clay	less than 0.002

The finest particles are separated by levigation, the coarsest by sifting.

On the other hand the arrangement of the soil particles is by no means permanent; and is even subject to rapid changes. Besides modifications caused by mechanical actions, there is the phenomenon of aggregation of the finest particles, which renders the soil more friable.

The phenomenon of flocculation is influenced by several factors such as freezing, thawing, insolation and the presence of electrolytes; the phenomenon is reversible, for deflocculation is produced as soon as the factor which produced the flocculation disappears, and the author considers precisely the process of floculation, due to electrolytes in general and to lime in particular.

Custom has fully confirmed the effect of certain fertilisers on the structure of the soil; thus the prolonged use of nitrate of soda induces an increased tenacity in the soil; it deflocculates clay so much as to cause it to be carried away in considerable quantities by drainage water. However, the most remarkable and important fact in practical agriculture is that of the improvement of the structure of the soil produced by liming; the experience of numerous generations has confirmed that liming, in the proportion of 1 to 2 tons per acre, greatly reduces the tenacity of clay soil and makes it easier to plough and drain. However, variations may be found and this comes from the fact that clay is easily flocculated by lime whereas silt is not.

The flocculation of the soil particles seems to correspond only to the flocculation of suspensoids, which is based on the theory of the isoelectric point, there is, therefore, *grosso modo* a norm between the flocculation power of electrolytes and the valency.

The flocculation of clay by lime is a most important exception, because it does not agree with the electric theory, if it was so, the hydroxyl ion would have stabilised the suspension To explain this anomaly the transformation in the soil of the lime into bicarbonate, and the action of the latter as flocculant, would have to be admitted but this explanation is not very plausible, and note should be taken of:—

1) The different effect on clay and on fine silt

2) If two similar suspensions of clay are treated with calcium hydrate and bicarbonate, in equivalent quantities, flocculation is much more rapid with the former, the contrary occurring with fine silt.

In studying the effect of alkalinity on flocculation by means of a calcium salt, in clay and fine silt suspensions it was found that the flocculation of clay by calcium nitrate is greatly intensified,even as regards the volume of coagulum, by the addition of a small quantity of ammonia, whereas the flocculation of fine silt is retarded by the alkaline addition; the anomaly of the flocculation of clay by means of lime, which is favoured by the hydroxyl ion, is thus confirmed.

To explain the mechanism of flocculation in the soil it is therefore necessary to take into account two important characters of clay.

1) It reacts easily, with exchange of bases, and of solubility in acids;

2) The clay particles do not present in water a well defined solid surface to the liquid, but colloidal and silicious matter passes.

On the basis therefore of power of reaction, and on the protection which clay enjoys, three cases of flocculation may occur:—

a) Direct flocculation, in which the flocculant acts as on non-reactive and unprotected particles, the action being even more or less retarded by the protection of the clay particle, but this case occurs but rarely and then only under the action of salts or colloidal hydrates of iron and aluminium.

(*b*) *Indirect flocculation*, where the products of a preliminary reaction such as exchange of bases or solution, act as flocculants ; there is no doubt that when using neutral salts, this kind of flocculation is brought about to a certain degree by the exchange of bases : flocculation of the clay by means of acids also appears to be due largely to the indirect action of aluminium in solution.

(*c*) *Abnormal flocculation*, in which the flocculant reacts with the emulsive protective matter, and forms a coagulum, which carries the particles with it ; this kind of flocculation of clay seems to be of the greatest agricultural importance because it gives a plausible explanation of the abnormal flocculation of clay due to lime.

To sum up ; although the mechanism of flocculation in soil does not appear to be fundamentally different from that of flocculation of suspensoids alone, the flocculation of clay by lime constitutes a process of a distinctly different type ; it is an emulsoid phenomenon which is due to the reaction between calcium hydrate and colloidal silica, on the one hand, and, on the other, to a special colloidal condition of clay, different from that of other fractions of the soil, and of kaolin itself.

796 - **Formation of Nitrate in the Cultivated Soils in Illinois, U. S. A.** — WHITING, A. L. (Chief in Soil Biology), and SCHOONOVER, W. R. (Associate in Soil Fertility), in the *University of Illinois, Agricultural Experiment Station Bulletin*, No. 125, pp. 1-63, Urbana, Ill. March, 1920.

The aptitude of a soil to produce a large amount of nitric nitrogen, sufficient to satisfy the requirements of growing crops, except for leguminous crops, and this in spite of washing by rain, constitutes one of the principal factors of a greater and more economic production of food, whence the importance of systematic study of nitrates in cultivated soils. A series of observations, which lasted a year, was undertaken with this object on expertimental plots at two farms of the Agricultural Station of Illinois. It was thus possible to measure systematically the percentage and rate of formation of the nitric nitrogen in the soil, up to a depth of 15 cm., in soils treated and cultivated in different ways, and it was possible to determine their influence as well as that of the season and rainfall.

The principal factor which favours the production of nitrates in the soil is the manner in which the soil is treated. Climatic factors govern the course of the formation of nitrates, but the quantity produced depends on the treatment of the soil; crude mineral phosphate is an important element for increasing the production of nitric nitrogen, and this effect is greater with good rotations of crops than if the latter are inadequate, but a complete application of organic matter (plant debris and farmyard manure) of phosphate and lime causes a greater and more rapid formation of nitrates than if organic matter and lime, or organic matter alone, are used. This application will satisfy the requirements of abundant crops, and, at the same time, dispense with the purchase of commercial nitrogenous fertilisers.

It is proved that the nitrogen of clover and of sweet trefoil, dug in during April and May, furnishes nitrates for the subsequent rotation crop, and although farmyard manure is equally efficient for nitrification, especially if it is applied with phosphate and lime, it does not nitrify to the same extent and with the same speed as the above mentioned leguminous plants. Active organic matter also greatly increases the provision of nitrogen in dark sandy silt soils. The best rotation for the formation of nitric nitrogen is that in which leguminous plants are used as green manure and where two crops, consuming large quantities of nitrogen are not planted in succession.

The maximum production of nitrates is noticed generally in June, with maize and soya beans and in May, with wheat and oats. The rate of formation of nitric nitrogen varies according to the season in the following manner: —

a) At the end of spring and beginning of summer, the period of greatest formation and accumulation; the optimum of temperature and humidity is found at this season;

b) at the beginning of autumn there is often a second period of activity in the production of nitrogen, which constitutes a second degree of optimum for nitrification;

c) at midsummer, small production of nitrates, unless the weather is cool and there is a sufficient amount of humidity;

d) in winter the formation of nitric nitrogen has never been recorded.

The most efficient cultural treatments which reduces the losses of nitrogen by lixiviation, is the presence of vegetable debris; a growing crop also decreases these losses.

The greatest consumption of nitric nitrogen, estimated by the corresponding dimunition of nitrogen in the soil coincides for maize with the period of greatest visible growth, which takes place generally between June 25 and July 15; for wheat and oats, the greatest consumption takes place earlier, towards the middle of May or the beginning of June, and, in the cases investigated, earlier with wheat. The period of greatest consumption of nitrates, as well as the rate and percentage of their production, are directly connected with the treatment of the soil; thus according to the author, plots suitably treated gave earlier and greater quantities of nitric nitrogen, than those not so well treated, and in the former the renewal of the formation of nitrates took place also earlier and more abundantly.

797 - **Chemical and Biological Researches on the Soil of a Wood of Hypertrophied Spruce trees' in Denmark.** — WEIS, F. and BONDORF, K A., in *Det Forstlige Forsgraesen i Danmark*, Vol V, No. IV, pp. 343-352, fig. 1, Copenhagen. 1920.

The chemical analyses of soil on which some hypertrophied spruce trees were growing showed that this soil was very rich in nitrogen both absolutely and relatively to the fertilising mineral matter. The reason for hypertrophy of the spruce trees should therefore doubtless be found in this lack of balance in the assimilable fertilising matter, causing an exclusively nitrogenous nutrition of the trees.

The nitrogen contained in the soil examined, under favourable conditions, easily assumed a nitric form, but the cause of this intense nitrification cannot be explained except by considering that it is produced in a very acid soil. That this is due to biological factors is proved by the fact that on sterilising the soil in question, nitrification ceases. In investigating the influence of different substances on this nitrification the remarkable fact has been noted that peptone hinders it and that sulphate of ammonia becomes nitrified very incompletely or not at all, unless calcareous matter is added.

The attempt made by the authors to isolate the forms of nitrifying bacteria were not successful; soil cultures in WINOGRADSKY's solution were always negative; it may be that the nitrifying bacteria are not the only active ones in very acid and humiferous forest soils (1).

798 – **Soil Protozoa.** — CRUMP, L. M., (Rothamsted Experimental Station), I. Numbers of Protozoa in certain Rothamsted Soils. *The Journal of Agricultural Science*, Vol. X, Part. 2, pp. 182-198, figs. 20, bibliography of 23 works Cambridge April, 1920. — II. CUTLER, D. W. (Rothamsted Experimental Station), A Method for Estimating the Number of Active Protozoa in the Soil. *Ibid.*, pp. 135-143, bibliography of 10 works. — III. CAUDA, A., and SANGIORGI, G (Istituto d'igiene della R. Università di Torino), Untersuchungen über die Microfauna der Brohen aus Reisgegenden, *Centralblatt fur Bakt.*, *etc.*, II. *Abt*, Vol 42, No 15-16, pp. 393-398, 6 figs Jena, Oct 30, 1914 — IV. CAUDA, A. La microfauna del suolo in rapporto alle colture, *Il Coltivatore*, Year LXVII, No. 12, pp. 357-359. Casale Monferrato, April 30, 1921 (2)

I. — Determination of amoebae and also, in certain case, of ciliates and flagellates in samples of soil taken from different fields at Rothamsted; the conclusions arrived at are that flagellates, amoebae, and thecamoebae are usually present in the soils in the trophic condition, that is to say feeding, and in comparatively large numbers so that here is an extensive population actively in search of food. The protozoan fauna is practically confined to the top 15 cm. of the soil. There is a definite inverse relation between the numbers of bacteria and amoebae present in the soil. The amoebae are insensible to variations in the moisture and temperature of the soil and to rainfall; the richer the soil in organic matter the more abundant are the protozoa, especially amoebae and thecamoebae.

II. — Up to the present most methods of determining protozoa in samples of soil give their total number, but what is required to be ascertained approximately is the number of those in an active condition and not encysted. With this object, the author proposes a fractional method of determination, by which the total number of protozoa is first ascertained by means of a dilution process; a fresh portion of soil is then treated with 2 % hydrochloric acid for a night; in this way all active forms are killed; the number of encysted protozoa is next ascertained by the dilution method and the number of active forms is ascertained by subtraction.

III and IV. — Investigations made on 6 types of soil from Vercelli (Novara) and Mortara (Pavia) show the constant presence of amoebae; the following are the numbers of different forms of protozoa per cubic centimetre of culture fluid (average of 4 dilutions of the 1/10 soil extract diluted in nutrient solution in the proportions $^1/_{100}$, $^1/_{1000}$, $^1/_{10000}$, $^1/_{100000}$. —

(2) See *R.*, 1913, Nos. 14, 167 and 646. (*Ed.*)

Soil	Amœbæ	Flagellates	Ciliates	Total
Clover.	370 000	120 000	16 000	506 000
" Marcita " (artificial meadow).	70 000	200 000	45 000	315 000
Irrigated meadow	150 000	37 000	absent	187 000
Submerged rice-field.	125 000	absent	»	125 000
Wheat after rice	17 000	»	»	17 000
Dry rice-field	10 000	»	»	10 000

Clover in rice-field soils grown twice in succession does badly and the clover fields soon show signs of exhaustion ; the " marcite " and irrigated meadows rich in organic matter have also a rich micro-fauna.

To prevent damage caused by a rapid increase of protozoa in the soil, the author recommends the application of potash salts, phosphates, calcareous compounds, as well as special tillage of the soil, special rotations of crops which serve to correct and modify the condition of exhausted soils, that is to say which tend to the " marcescenza, " in place of disinfection ; but the best results will be obtained by an intelligent change in the system of cultivation.

799 – **Production of Mineral Phosphate in the United States in** 1920. — I. *Engineering and Mining Journal*, No. 22, p. 908, New York, May 28, 1921. — II. *The American Fertilizer*, Vol. LVI, No 10, p. 54. Philadelphia, May 7, 1921.

According to data collected from all the producers at the commencement of April, 1921, by the United States Geological Survey the production of phosphates in the United States in 1920 greatly exceeded that of any previous year. The quantity mined and sold was 4 103 982 long tons, that is to say about 1 million tons more than in 1913 when the production was exceptional. The total sales amounted to $25 079 572 that is to say more than double those of any other year.

The average sale price of the whole output was £6.11 per long ton as againt $5.10 per long ton in 1919.

The production in Florida was more than doubled, the quantity of pebble extracted having increased by more than 1.5 million tons South Carolina produced 27% less than in 1919 ; Tennessee increased its production by 100 000 long tons, or 18 % and an increase of 223 % is reported in the production from Idaho and Utah. The production of the Western States of the Union (chiefly due to Idaho), amounting to 17 000 long tons in 1919 rose sharply to 55 000 long tons or more in 1920.

TABLE I. — *Mineral phosphates exported from the United States in* 1920.

	Quantity		Value

800 – **Phosphates of Nauru and Ocean Islands.** — STEEL T., in *Journal of the Society of Chemical Industry*, Vol. XL, No. 6, pp. 59,61 T. London, March 31, 1921.

Detailed analyses of the different kinds of phosphates from the island of Nauru and Ocean (1) are rare ; therefore the author gives in a Table, complete results of analyses of 16 samples of phosphates, 2 of which(Nos 6 and 16) are from the Ocean Island.

Some samples contained but traces of iron and alumina and a good many of them contained varying. but always small, quantities of fluorine. The appearance of the samples would suggest that it was a case of guano accumulated over the years Of the phosphoric acid, a part only was found in the form of tricalcium phosphate and the proportion of tetracalcic phosphate was variable, as in other natural phosphates.

801 – **The Physical Chemistry of Basic slag.** — DESCH, C. H, (Professor of Metallurgy in the University of Sheffield, (Transactions of the Faraday Society, Dec. 1920), in *The Chemical News*, Vol. 122, No 3177, pp. 102-103. London, March 11, 1921.

Complete physico-chemical knowledge of basic slag, is still lacking, in spite of the many excellent researches made regarding it. Chemical analysis has, indeed given the proportions of oxides of the metals and metalloids contained in it, and the sulphur content is also known, but there are many discrepancies regarding the nature of the phosphates and silicates and also, among the minor constituents, regarding that of the sulphides. The fact that perfect crystals have been isolated gives no assurance that they are identical with the ordinary constituents of the mass of the slag or that they are substances that are mineralogically homogeneus.

The essential constituents of basic slag are the oxides of iron, manganese, calcium, magnesium, silicon and phosphorus, whilst the sulphides of calcium and manganese and the fluoride of calcium should be considered as accessory; a state of oxidation only is considered although the iron may be found both in a ferric and ferrous state.

In basic slags containing more than 40 % of lime, the latter is found chiefly in the form of orthosilicate (Ca_2SiO_4) which may produce by excessive fusion, glass, in which are incorporated small crystals of phosphoric mineral; and this structure complicates the determination of the constitution or the slags. Regarding phosphorus, it should be remembered that anhydrous phosphates of iron (ferrous or ferric) that are stable at high temperatures are unknown on the contrary for calcium phosphates. Be that as it may, many writers have shown that the silico-phosphates are the principal constituents of phosphatic basic slags.

The first of these compounds has been described by CARNOT (1883; formula $Ca_3 (PO_4)_2 . Ca_2SiO_4$); STEAD and RISDALE next describes crystals of another compound containing phosphate and silicate (1887 ; formula $4 Ca_3 (PO_4)_2, Ca_3SiO_5$) ; other similar compounds were also described and in 1911, KROLL added to them another Thomasite ($Ca_3 (PO_4)_2$, 3 Ca.O

Ca_2SiO_4) Previously (1883) HILGENSTOCK had described the tetraphosphate (4 $CaO. P_2O_5$), which had long been considered as the essential component of agricultural slags, but it is no longer probable that the silicophosphates are most valuable for that purpose. Generally all the compounds are described externally, but little is known of their mineralogical individuality. It should be remembered that, as a rule, in these compounds calcium may be replaced more or less by iron or other metals, and that slags can be found with such an analysis that they will come under the formula of Thomasite It does not follow that these slags should be considered as individualised compounds, but rather as entectic mixtures simulating pure crystals; the fact that phosphorus can pass in solid solution in silicates of iron should not be overlooked. A micrograpic examination of the surface generally gives more information then the examination of sections, although the use of polarised light on the latter may be a good way to identify the minerals.

The sulphides enter into solid solution, but not to any extent; they remain partly in the form of insoluble globules. The fluorides are combined with phosphates to form minerals of the apatite class, which is the reason for the non-assimilability of fluoriferous slags.

This is about all that can be really definitely said regarding the constitution of basic slag and further research is absolutely necessary.

802 - **The Ash of the Green Husks of Almonds as an Industrial Product.** — DE DOMINICIS, A. (Laboratorio di chimica agraria della R. Scuola Sup. di Agricoltura, Portici), in *Annali della R Scuola Superiore di Agricoltura in Portici*, Sect II, Vol XV, pp 11. Portici, 1920

The production of almonds in Italy is developing greatly; among tree fruits it comes immediately after that of the citrus plants in point of yield, so that, for almonds also, Italy holds the first place, its average production for 1909-1916 being 1 564 000 quintals of almonds, that of Spain was less, 993 200 quintals, that of France and other countries was still less again.

A few years ago the whole value of almonds consisted almost entirely in the kernel; the shell, which burns easily was used for fuel; the green husk was used chiefly as green food for sheep who eat it greedily. It is only during the last few years, and especially in Sicily, that the industrial utilisation of the ash of the green husk of almonds has commenced. The ash is rich in potash and is sold to soap manufacturers.

As soon as the almonds are gathered, the green husks are separated from the rest of the fruit, and reduced to ashes in the fields in ovens made with circular stones ; when cold the ashes are ready for sale. A few years ago the price of the ashes was 8 to 12 lire per quintal, but after the commencement of the war it went up to 177 lire in 1916 and in 1920 it was more than 100 lire per quintal.

Analysis of the ash dried at 105° or 110° C gave the following results: —

	Per cent.		Per cent.
Sand and carbon	3.06	Phosphoric acid	3.15
Ferric oxide	2.03	Sulphuric anhydride	1.10
Lime	16.24	Carbonic dioxide	23.90
Magnesia	3.29	Silica	1.27
Potash	43.71	Chlorine	0.14
Soda	2.73		

The author has examined the green husks of 14 Sicilian varieties and has obtained the following extremes: -- Green husks % of almonds 25-55; water % of green husks 14.49-25.85; ash %, of dry green husks 7.35-12.80; potash % of ash 43.76-56.75; soda % of ash 2.04-8.27. The ash of the green husks is extraordinarily rich in potash, richer than any other vegetable ash. Their content in potassic carbonate can be estimated without fear of error at more than 70 % So that if the proportion of green husks of almonds is fixed at 40 % on average, for a production of 1 564 000 quintals of almonds per year, there are 625 600 quintals of green husks; taking the ash from the green husks in an undried condition, an average of 8.6 % of ashes may be calculated, which gives 53 801 quintals of ash with 37 660 quintals carbonate of potash.

There can therefore be no doubt of the much greater economic advantage of incinerating the green husks, than of using them as food for sheep; their use as a fertiliser is irrational, as the author has ascertained that the green husk decomposes with difficulty and very slowly; incineration on the other hand is an operation which, without expenditure on installation and fuel gives large quantities of potash, which the plant draws from the sub-soil with a minimum reduction in the reserves of the land cultivated.

The author has also analysed the shells of two varieties of Sicilian almonds: — Water % of shells 13.13-13.68; ash % of dry shells 0.45 0.58; potash% of ash 30.79-39.15; soda % of ash 2.25-5.34. The potash content of the ash of the shells is also high, and can be estimated at more than 50 % of potassium carbonate; the shells, however, are much less rich in ash; the residue which they leave compared with the moist substance, is only 0.45 %; so that calculating 1 251 200 quintal of shells out of 1 564 000 quintals of almonds there are 5630 quintals of ash with only 2815 quintals of carbonate of potash; it is therefore preferable to continue to use the almond shells as domestic fuel.

Regarding the destination of the ash of green husks of almonds, the idea of using them as a fertiliser should be abandoned because of their high alkalinity, their industrial use for the preparation of concentrated lyes, or for the extraction of carbonate of potash is best.

803 - **Halophytes as Potassic Manure** — See No. 809 of this *Review*.

804 - **On the Fertilising Action of Sulphur.** -- CHAUZIT, J. in the *Comptes rendus des Séances de l'Académie d'Agriculture de France*. Vol. VII, No. 21, pp. 492-493. Paris, June 1, 1921.

After many years of experiment, the author thinks it possible to draw a certain number of conclusions with regard to the use of sulphur as a fertilising agent.

1) Sulphur distributed in cultivated soil has a very distinct action, shown by an increase of the crop, varying according to the greater or less quantity of organic matter existing in the soil, extent of surface in contact and the greater or less time of contact

2) The action is proportional to the quantity of sulphur used, a quantity which apparently should be fixed, economically and practically, between 400 and 600 kg. per hectare.

3) The sulphur should be applied as long as possible before the period during which the plants have an intense need of nutritive elements. In other words the sulphur should be applied in the autumn or the beginning of winter and with it should be dug in farmyard, or other organic, manures whereas, in the case of application early in the autumn (with farmyard manure) 200 kg. of sulphur per ha. gives good results, the quantity should be raised to 400 kg. when manuring is done in winter.

4) The effects noticed (increase of crop, more healthy plants, greater resistance to drought, decrease or disappearance of certain diseases), are due to the fact that sulphur sets free and renders assimilable the nutritive elements in the organic matter and certain mineral matters (potash) of the soil.

805 - **Botanical Identification of Exotic Spects of Phaseolus.** — THANH GIUNG, in the *Comptes rendus de l'Academie des Sciences*, Vol 172, No 13, pp 1436-1438. Paris, June 6, 1921

Those very small kidney beans, generally green, which botanists ordinarily group under the single general name of *Phaseolus Mungo*, are cultivated and eaten in various tropical countries. LINNAEUS, however, distinguished two species: — *Phaseolus Mungo* and *Phaseolus radiatus* Later ROXBURGH added a third species. *Phaseolus aureus*. But the very great resemblance in form and size shown by all these seeds have caused the three names to be considered as synonyms. Only more recently, in 1914, PIPER of the Department of Agriculture revising the genus *Phaseolus*, has re-established, besides the species *Ph. Mungo*, the species *Ph. aureus* Roxb., and he regards *Phaseolus radiatus* L. as the ancestor of *Ph. aureus*

It is nevertheless difficult to distinguish three kinds of seeds so close to each other when, especially in collections, they are not accompanied, as is generally the case, by other parts of the plant. Now in the course of a general investigation of the seed tegument of Leguminosae, the author noticed that the structure of these teguments differs considerably in various species, which enables the different species to be distinguished.

First of all, the seed teguments of *Phaseolus Mungo* and *Ph. aureus* are clearly distinguished from the teguments of *Phaseolus vulgaris* and *Ph. multiflorus* by the number of layers which form them and is 3 instead of 5. On the other hand, the teguments of certain other members of the genus *Phaseolus*, such as *Ph. calcaratus*, have also 3 layers, but the sub-epidermal layer is quite different. In the tegument of the seed of *Phaseolus Mungo* are found from the outside inwards :—

1) An epidermal layer formed of cells of which the cellular cavity, which contains a green substance, is club-shaped; the cavity, very narrow above, becomes very wide at the point of contact with the sub epidermal layer;

2) A sub-epidermal layer in which the cells, which also contain a green substance, are dumb-bell shaped with equal extremities, the cells having all hexagonal passages regularly between them;

3) A parenchyma with thin walled cells, elongated tangentially, those in the last layers being much flattened.

In *Phaseolus aureus*, the number of layers is also 3, but the cells of the sub-epidermal layer, whilst also constricted in the middle, are not so clearly dumb-bell-shaped, for the lateral walls of the cells are more regulary concave instead of being almost straight in the constricted part. Consequently the passages, on a transverse section, are roughly oval and have not, as in *Ph. Mungo*, the form of a radially elongated hexagon. Lastly the presence of these passages is not so constant as in *Ph. Mungo ;* the passages may be wanting here and there.

Generally, the seeds of *Ph. Mungo* have a blackish green tegument more or less spotted with orange yellow, with the hilum slightly projecting, while in those of *Ph. aureus* the tegument is more uniformly green with a hilum not at all or scarcely prominent The " dau xanh " or green kidney bean of Indo-China distinctly belongs, by the character of its seed tegument, to *Ph. aureus*, as had previously been recognised morphologically by MERILL and CHEVALIER.

806 – **Detection of Hydrocyanic Acid in Natural Cyaniferous Glucosides by two Microcristalline Reactions** (1). — DENIGES, G., in the *Comptes rendus des Séances de la Société de Biologie*, Vol. LXXXIV, No. 6, pp. 309-310. Paris, Feb 12, 1921.

The reaction suggested by the author for the detection of prussic acid is: — 1) The production of oxaluramide by the action of NH_3 on alloxan in the presence of HCN (which acts as a catalyst) ; 2) the production of murexide by the action of pyridine on alloxan in the presence of HCN.

The alloxan reagent is prepared in a few minutes by heating slightly in a strong test tube until quite clear, a mixture of 1 gm. of pure uric acid, 1 cc. of nitric acid (1.39-1.40) and 1 cc. of water. To the clear liquid is added 50 cc. distilled water. To use this reagent for the detection of HCN in plants containing cyaniferous glucoside, a few grammes of the plant product are grated or ground, and pounded in about the same weight of water, then placed in a very short test tube, a kind of glass cup with wide spread edges not more than 3-5 cm. long and 15—18 mm. in diameter, filling it to within a few millimetres of the mouth, and left alone for a few hours. At the end of that time the cup is covered with a sheet of glass at the centre of which is placed a small drop (2—3 mm in diameter) of the alloxan reagent rendered alkaline at the moment of use by a very small quantity, of commercial ammonia diluted to $^1/_5$ dropped into it by means of a pointed glass rod. The glass is then turned over when placing it on the cup so that the reagent is on the under surface of the glass and in the centre of the mouth of the cup.

---

(1) See *R.*, Dec. 1914, No. 1101 ; *R.*, Nov. 1918, No. 1227. (*Ed.*)

After a time varying according to the conditions (degree of division temperature, glucoside content, etc.) in which the test is made (generally 4 to 10 minutes) a thickening appears caused by crystals of oxaluramide in star shaped groups.

By replacing the ammonia diluted to $^1/_5$ by an (approximately) equal volume of pyridine, the reaction which is indicated by the appearance of fasciculate crystals, is still more delicate. Often the mixture becomes rose tinted owing to the action, on an excess of alloxan, of dialuric acid which is formed at the same time as oxaluramide and gives murexide.

807 – **Analyses of Saltbush Varieties *(Atriplex spp)*. and Fodder Values Determined in New South Wales** (1).— GUTHRIE, F B., in *The Agricultural Gazette of New South Wales*, Vol XXXII, Pt 3, pp 207-210. Sydney, March 1921

The following 3 varieties of saltbush were identified and analysed at the Botanic Gardens, Sideny, in order to discover the potash value in each : — Creeping saltbush (*Atriplex leptocarpa* F. Muell.) ; red berried saltbush (*Chenopodium triangulare* R. B.,) and old-man saltbush (*Atriplex nummularia* The composition of both crude ash and of pure ash exclusive of carbon dioxidè, sand and charcoal are given in tabular form. *A. leptocarpa* was found to be the most satisfactory of the 3 varieties and showed in the first case (crude) potash content of 34 96 % compared with 29.96 % C. *triangulare* and only 13.88 % *A. nummularia ;* and in the second case (pure) a potash content, of 41.88 % 39.29 % and 15.69 % respectively

TABLE I. — *analyses of ash of saltbush.*

(1) See *R*, July, 1921. No Fos (*Ed.*)

Some years ago the author made some analyses to determine the fodder value of several varieties of salt bush from Bourke and Hay in New South Wales. The figures are calculated to dry substance, owing to the variation in moisture content on arrival at the laboratory. When quite fresh the leaves contain normally about 75 % water. The specimens examined were: *A. nummularia*; *Rhagodia parabolica*, *R. Billiardieri*, *A. halimoides*, *A. Angulata*, and one unidentified specimen.

In addition to this in order to compare the fodder value of salt bush with that of other common green fodders, the following table has been compiled, in which the analytical figures are presented in the usual form and recalculated to a moisture content of 75 %.

TABLE II. — *Comparison of saltbush with other green fodders.*

	Average 3 samples from Bourke	Average of 3 sample from Hay	Maize	Sorghum	Lucerne	Timothy
Water	75.00 %	75.00 %	79.3 %	79.4 %	71.8 %	61.6 %
Oil	0.47	0.61	0.5	6.5	1.0	1.2
Albuminoids	2.37	2.52	1.8	1.3	4.8	3.1
Carbohydrates	10.55	7.78	12.2	11.6	12.3	20.2
Woody fibre	3.52	3.98	5.0	6.1	7.4	11.8
Ash	8.09	10.11	1.2	1.1	2.7	2.1
Percentage of common ash	53.06 %	51.03 %	—	—	—	—

A comparison of the above, shows that saltbushes take a high place among green fodders, the amounts of carbohydrates and albuminoids being high, and the woody fibre relatively low. The high content of mineral matter, especially of common salt, is of course characteristic. In discussing their merits as fodder, it should be remembered that saltbushes possess natural advantages over the ordinary cultivated crops or pasture grasses. They flourish on land which will not support other fodder crops; they resist drought to an exceptional degree; are indigenous, and require no cultivation; are relished by stock, and are exceedingly prolific and easily propagated.

It appears, however, that in spite of the universal recognition of these facts by stock owners, there is some danger of these plants becoming less abundant than formerly, through overstocking and other causes. In California, a number of species have been imported from Australia for the purpose of cultivation on the alkaline soils of the State. The author considers it practicable and profitable to encourage the spread of these plants in the drought stricken districts of New South Wales, and to propagate by seed, cuttings and root. In good seasons there seems to be no reason why saltbush should not be cropped like lucerne and conserved as dry fodder for times of drought

[806]

808 - **Commencement of Work at the New Plant Breeding Station at Aberystwyth (Wales).** — STAPLEDON, R G, in *The Journal of the Ministry of Agriculture*, No 7, pp 630- 639, 5 figs. No 8, pp 739-742, figs 2 London, Oct and Nov 1920

The climatic and soil conditions of Wales are very distinct from those of the neighbouring English counties and require the selection of types with special characters suitable to the local physical environment. An endowment made by Sir. PHILLIPS has recently enabled a Plant Breeding Station for Wales to be created, which began its work in May 1919, in close connection and association with the Agricultural College of Aberystwyth

The Station comprises:

I. — A large laboratory for the practical work of students. It can accomodate 30 persons

II. — Three special laboratories for the staff, intended for the investigation, selection and control of samples, microscopic observation, chemical analyses, etc

III. — A special laboratory for Agricultural Botany and another for Plant Pathology.

The Station is also provided with rooms for collections, storerooms, drying rooms, etc, and has at its disposal 100 acres of land for selection tests and cultivation.

Owing to the character of agriculture in Wales, a grassland country, the work of the Station from the commencement has been devoted to the improvement of grasses and leguminous forage plants

To facilitate the study of individual plants sowing is made in movable boxes and the plants transplanted later. To prevent contamination from seed which may be in the soil, the soil used for the boxes is heated to kill such seeds, germination is started in incubators and the germinated seeds planted in the boxes; in this way a germination test is also provided. The ordinary arrangements to protect the plants from outside pollination have also been provided.

Besides indigenous grasses and leguminous forage plants, several exotic species which may possibly be useful for hybridisation have been introduced, such as: —

Trifolium subterraneum, which gives a good crop late in autumn.

Phalaris nodosa, from South Africa, resistant to drought and frost.

Danthonia pilosa, from New Zealand.

Eragrostis abyssinica, not suited to the moist, cold climate of Wales.

Trifolium alexandrinum, *Hedysarum coronarium*, *Cicer arietinum*, *Chloris Gayana*, and *Andropogon halebensis* also give completely negative results.

Regarding the improvement of local varieties they should comply with the following requirements: —

1) Lateness in flowering to prolong as much as possible the grazing season.

2) Growth of leaves as compared with growth of stem.

3) Good yield of hay (leaves).

Most of the experiments made relate to *Dactylis glomerata*; investigations have beeen made both on indigenous varieties and on numerous Danish, American, and French types.

The indigenous varieties proved superior to the exotic varieties in earliness and leaf production. They have all the character of population with distinct forms with which it should be possible to obtain, by selection, notable improvement in the direction desired. This work of selection has already been started.

Among grain crops, oats is no doubt the most important. Two distinct types are required; one for low elevations and flat country, the other for high elevations near the extreme limit for oat cultivation.

At the higher altitudes *Avena strigosa* and the native black oats are cultivated; at lower altitudes, besides the local black oats, some new varieties such as " Abundance " are grown. In any case earliness and resistance to lodging are essential, combined with good production both in quality and quantity.

The preliminary work is developing in three directions:—

1) Critical botanical study of the native oats to ascertain their agricultural character and to classify them.

2) Systematic study of oats in general.

3) Comparative cropping experiments.

It has been found from a preliminary examination that the local black (Ceirch du Bach) are polymorphous. The author thinks that 5 distinct forms can be isolated, among which one is grey.

At present at least 154 varieties are being tried, among which will be chosen those which are most suitable for further selection and hybridisation.

809 - On a Probable Case of Complete Repulsion of Two Factors in a Di-hybrid. — TJEBBES, H., and KOOIMAN, H. N., in *Genetica III*, Part. 1, pp. 28-34. The Hague, Jan. 1921.

By crossing the striped dwarf Prague kidney bean (seed with wine red stripes on a buff ground) with the light brown Dutch dwarf kidney bean the authors obtained in the F_2 plants in which the two parent types and the intermediate type were found in the ratio 1 : 1 : 2. The F_3 generation confirmed this result; the brown specimens gave descendants exclusively of the brown type; the Prague specimens gave descendants of the Prague type, whilet the descendants of the intermediate specimens were divided into 1 brown, 1 Prague and 2 intermediate (as in F_2).

At first the authors thought that it was a case of Mendelian segregation of characters, in accordance with the typical diagram of a monohybris, and admitting that the Prague type possesses in addition a genetic factor *S* which would determine the stripe by exerting an inhibitory action on the development of the colour. In a heterozygous condition, this factor would not completely suppress the formation of the brown colour, and brown mottling on a buff ground, characteristic of the F_1 generation, would result.

Subsequent research and records have shown that it was quite a different matter and that it was a most interesting phenomenon, namely a probable case of complete repulsion of two factors in a di-hybrid. Genetic literature speaks of two types of mottling in seeds : — constant mottled races, and inconstant mottled races. The latter are submitted to the action of a chromogenic factor present in the heterozygous condition, and, which KOOIMAN designates by the letter B.

In the present case the brown kidney bean possesses the chromogenic factor B ; the hybrid with striped seed would be heterozygous relatively to B ; the Prague kidney bean ought therefore to have the formula bb and possess the factor S which determines the stripe.

On the other hand, the brown kidney bean crossed with a number of other varieties which neither possess B nor S has never produced striped forms ; the presence of S in the cryptomeric condition (hidden by B) can therefore be scarcely admitted. Only one possible explanation remains : — The brown kidney beans have the formula BB ss, the Prague kidney beans the formula bb SS and they differ by two factors, but the two factors B and S exclude each other reciprocally in an absolute manner. According to this hypothesis, the formation of gametes BS and SB is suppressed and there are only the gametes Bs and bS. The following combinations are obtained from them in the F_2 : — Bs × Bs = BB ss = brown kidney beans.

Bs × Bs	=	BB ss	=	brown kidney beans.	)	1
Bs × bS	=	Bb Ss	=	intermediate type of F_1	(	2
bS × Bs	=	Bb Ss	=	» » »	(	
bB × bS	=	bb SS	=	striped Prague type .	)	1

On admitting the complete repulsion, which seens to explain these phenomena quite well, it is easy to picture the existence of a di-hybrid which carries out a diagram of division of character corresponding to that of a monohybrid.

810. – Mass and Pure-line Selection to obtain Types of Noè Wheat Resistant to Brown Smut in Italy. — MORETTINI, A., in *Le Stazioni sperimentali Agrarie*, Vol LIII, Part 10-11, pp. 399-413. Modena, 1920.

Results of a series of selection operations made with the object of obtaining types of Noé wheat less susceptible to brown smut (*Tilletia Tritici* Wint. and *Tilletia laevis* Kuhn). Both selection in bulk and selection by pure lines were used.

SELECTION IN BULK. — During the year 1912-1913, 500 gm. of sound seeds from healthy plants, 500 gm. of sound seeds from affected plants, and the same quantity of seeds of Common Noé crops were taken. These seeds were infected with spores of brown smut from *Tilletia Tritici* (Bjerk) Wint., collected the same year and sown in 3 separate plots. At harvest time the plants in each plot were pulled up separately and the healthy plants, affected plants, healthy ears, smutted and partially-smutted ears, of Noè were counted. The percentages of healthy ears and smutted, ears in the year of selection and control were approximately the same as those of 1911.

	Ears	
	sound	rusted
a) Control not infected	100	—
b) Seed selected from rusted or recently infected ears . .	61	39

	Sound ears	Smutted ears
a) Control not infected	100	—
b) Seed selected from rusted or recently infected ears	61	39
c) Seed selected from sound ears on smutted tufts recently infected	54	46
d) Control infected.	34	66

These are distinctly positive results. On the other hand, selection in bulk enables selection to be made on a large number of plants, and consequently makes it possible to test a large number of types in the variety, thus making future line selection more sure by the elimination of the types more susceptible to attack.

SELECTION BY PURE LINES. — In the crops of the 4th year of selection, 10 heads of line, of which 3 were quite sound, 4 with sound and smutted ears, 2 with sound, smutted and partially smutted ears, were taken. For sowing the author took the seeds from the sound and partially smutted ears as indicated in the following table :—

	sound	smutted	sound and smutted	sound	sound and smutted
I	1	2	3	1	[illegible]
II	1	12	1	1	1
III	1	6	3	1	3
IV	1	12	3	1	3
V	2	5	—	2	—
VI	1	9	—	1	—
VII	4	2	—	3	—
VIII	7	—	—	3	—
IX	8	—	—	4	—
X	3	—	—	4	—

The sound seeds were collected from each ear, separately; they were infected the day before sowing with the spores of *Tilletia Tritici* and then sown separately.

Following on the elimination of the less resistant families and the multiplication of those which responded best to selection, in 1917, of the 10 plants heads of line under examination, only 4 remained, that is to say, the descendants of plants heads of line I, III, VII and VIII. The recapitulatory Table indicates the percentages of sound smutted and partially smutted ears of the selected plants and the control plants during the three years 1915, 1916 and 1917.

Comparison of the percentages of sound smutted, and partially smutted ears in the selected crops and in the control crops.

Years		Sound ears	Smutted ears	Partially smutted ears
		Per cent.	Per cent.	Per cent.
1915. . . .	Selected plants . . .	71.13 %	27.21 %	1.66 %
»	Contiol plants	50.55	49.45	0.00
»	*Difference* . .	**20.58**	**22.04**	**1.66**
1916. . .	Selected plants	50.68	37.10	12.78
»	Control plants	22.72	76.84	1.44
»	*Difference* . . .	**27.96**	**39.74**	**11.34**
1917	Selected plants.	33.61	40.73	23.66
»	Control plants	9.90	86.46	3 64
»	*Difference* . . .	**23.71**	**43.73**	**20.02**

This Table shows a perceptible and constant difference in favour of the selected plants and that difference is still more marked if the partially sound ears, very numerous in the selected families (in 1917 they constituted 23.66 % of the crops and 3.64 % of the control crop) are taken into account. In varieties of wheat, even very susceptible (as Noè really is), resistance to brown smut can therefore be increased by selection to a by no means negligible extent.

811 - **Transmission of the Abnormal Character "Zig-Zag" Culm in Maize.** — EYSTER W. H., in *The Journal of Heredity*, Vol. IX, No. 8, pp. 349-357, figs. 9. Washington, Nov.-Dec. 1920.

Some of these abnormal plants, self-fertilised, gave descendants with zig-zag culms and, on the other hand, by crossing with the normal type, normal plants were obtained in F_1.

The anomaly appears only at the time when the male inflorescence comes out and it concerns the region where the ears are inserted. The decrease in the height of the culm is naturally greater when the number of internodes affected is greater and the phenomenon is more accentuated; it produces also a shortening and thickening of the internodes. The leaves appear normal, but the sheaths, instead of surrounding the internode, are separated out just because of the zig-zags of the culm.

From the commencement this character has shown itself recessive: plants, of the F_1 cross of normal × abnormal are normal. In F_2, the author obtained 343 normal and 23 plants with zig-zag culms, according to a ratio which is nearly the theoretical ratio of 15 : 1, existing when two factors or determinants are concerned. It follows from these data that the character "zig-zag culm" is based on at least two recessive factors.

812 - Genetic Analysis of the Descendants of a Cross between the Prague Climbing Kidney Bean and the Dwarf Kidney Bean. — Tjebbes, K., and Kooiman, H. N., in *Genetica*, III, Part 1, pp. 34-49. The Hague, Jan. 1921.

From a cross between the Prague mottled climbing kidney bean fertilised with pollen of the Hague white dwarf kidney bean the following results were obtained in F_1: —

	Father	Mother	Hybrids of F_1
Habit. . . .	dwarf	climbing	climbing
Flowers	white	lilac	violet
Pods	light streaked azure	bright red stripes	dark blue stripes
Seeds.	white	white stripes colour of wine dregs	grey stripes

In the F_2 generation there was a very complicated disjunction of characters. For each of the characters taken by itself there were: —

Habit: — 12 dwarf, 21 climbing.

Flowers: — 10 dark violet: 12 light violet: 10 lilac; 11 white.

Pods: — (stripes) 22 dark blue; 8 light blue; 10 bright red; 3 pale red

Seeds: — 11 white; 32 coloured (with stripes).

The 32 coloured seeds were subdivided as follows. — 11 white; 5 black; 13 grey-blue; 1 dark violet; 3 light violet; 5 brown-black; 4 reddish grey; and 1 wine dregs colour.

A close study of the F_2 and of a crop in F_3 enabled the key to be found which served to explain these forms of disjunction of characters. There is, doubless, linkage between the colours of the flowers, pods and seed, linkage and relationship which the authors have interpreted by admitting the presence of two factors for the colour of the pods, flowers, and also, in part, of the seed, and one factor (or perhaps a group of factors) which influences exclusively the colour of the seed.

The two parents have in common striped pods, and the palest of these stripes (pale red) is only found in the hybrids of the F_2 and F_3 generations.

The Prague kidney bean has a factor S which has the following properties: —

1) It changes the pale colour of the stripes in the pods into a fine bright red.
2) It produces the lilac colour in the flowers.
3) It produces a wine dregs colour on the surface of the spermoderm. That colour can only be shown by the stripes.

If the factor S in lacking: —

1) The pods have pale stripes.
2) The flowers are white.
3) The seeds are white.

The Hague kidney bean has a factor BL which:—

1) Changes the colour of the stripes on the pods into blue.
2) Changes the lilac colour of the flowers into violet.
3) Changes all the colours of the seed by accentuating all the bluish shades.

In the absence of S, the factor BL only shows its action on the pods.

Regarding the seeds, the black, bluish grey, dark violet and light violet groups have BL, while the brown black, reddish grey and wine dregs groups lack it.

Further, the Hague kidney beans have one (or two?) factor Z, which acts on the shade of the seeds by deepening the tint: — dark violet become black; light violet, bluish grey; red wine dregs, dark brown; pale red, reddish grey.

In the pods and in the flowers the factor S is manifested in the same way in both homozygotes and heterozygotes. But in the seed a quantitative difference in noted between the SS and the Ss: — the black, dark violet, brown and the red wine dregs are homozygotes (they never produce plants with white seeds), while the grey blue, light violet, reddish grey and pale red are heterozygotes for S and produce in F_3 plants with white seeds.

The factor BL influences the pods and seeds of the homozygotes, in the same way as those of the heterozygotes; on the other hand a difference appears in the flowers, and the homozygotes have a much deeper violet colour than the heterozygotes.

Finally, the difference in aspect (climbing or dwarf) between the two kinds is governed by a single factor, since a segregation corresponding entirely to the diagram of a monohybrid is produced in the second generation.

813 - **Contribution to the Selection of Flax by Pure Lines' in Hungary.** — FLEISCHMANN, R., in the *Zeitschrift für Pflanzenzuchtung*, Vol. VIII, Part. 1, pp. 26-43. Berlin, March, 1921.

The "Saatzucht-und Saatgutverwertungs A. G." (Seed Selection and Trading Co.) has a plant breeding Station on its estate at Debrö (Heves, Hungary). From the commencement of its operations and on the initiative of the General Manager ELEMÉR SZÉKÁCS, the Station has paid particular attention to the selection of flax. Although the period of its researches has been short (since 1919), the results already obtained nevertheless deserve special attention. The material for the first operations of selection was in the form of "populations", or a mixture of distinct forms all belonging to *Linum usitatissimum* L., of the closed-capsule type. The first selection bore on the length of stalk: there is a form of flax in which the plants have mostly short stalks (45 cm.), mixed with a small proportion (2-3 % as a maximum) of long stalked plants.

The short stalked plants are also distinguished by more abundant foliage, wider light green or grey green leaves, abundant branching, larger and more numerous capsules and also larger seeds.

There are many intermediate types between the two extreme forms.

The operations were at first upset by several adverse circumstances and could not be started regularly until June 30, 1919.

Sowing was carried out in 1 m. lines; 50 seeds per line; spaces between the lines 15 cm. When mature the plants were measured for two standards of length: — 1) From the bottom of the stalk up to the first branch; 2) from the first branch to the top. As a general average for 49 series of selection the lengths were: —

First length 60.5 cm. *minimum* 40.4 ± 1.87; *maximum* 73.1 ± 0.65 cm.

Second length 22.88cm. (18.3 — 30.1).

In the control plots (same plants without selection) the average for the first length 51.36 cm. *minimum* 33.42 ± 0.323; *maximum* 59.74 ± 0,452.

There was therefore already a gain of about 10 cm. in the first year.

A series of coefficients for measuring the correlation between the parents and the descendants has also been calculated and in each case very high values have been obtained.

(1) Total length of the parent plants and average length of the descendants: — $r = +\ 0{,}647 \pm 0{,}059$.

(2) Length of the unbranched portion of the stalk of the parents and average total length of the plant in the descendants: — $r = +\ 0.7165 \pm 0.0496$.

(3) Length of the unbranched portion of the stalk of the parents and of the descendants -- $r = 0.7300 \pm 0.048$. The results obtained were also confirmed by subsequent work.

Besides length of stalk, other characters such as number of seed per capsule, shape, dimensions and colour of the seeds can form so many distinctive characters by pure lines. And it is in this sense that the author proposes to amplify and continue his researches.

814 - "*830* C Katharine'" a New Type of Whortleberry obtained by Hybridisation in the United States. — COVILLE, V., in *The Journal of Genetics*, Vol. XI, No. 8, p. 338, 1 fig. Washington, Nov-Dec. 1920.

By crossing two wild plants of *Vaccinium corymbosum*, known by the names of "Brooks" (Greenfield, N. H.) and "Sooy" (Browns Mills, N. J.) many hybrids were obtained, the best of which, "830 C Katharine" is the subject of the present article.

This is a new type that is really valuable on account of its colour, perfume, the compactness of its berries, and also because the seeds are so small that they are scarcely noticed when the fruit is eaten.

Scarcely 3 % of the berries are less than 12 mm. in diameter; while the largest berries attain a diameter of 18 mm. The material required for propagation has already been entrusted to several horticulturists.

A specimen of this variety has been deposited at the Economic Herbarium of the U. S. Ministry of Agriculture.

815 - **Rice Irrigation Measurements and Experiments in Sacramento Valley California, 1914-1919** — ADAMS, F., in *College of Agriculture, Agricultural Experiment Station, Berkeley, California, Bulletin* No. 325, pp. 47-69, tables 10, figs. 4. Berkeley Ca., Sept 1920,.

The author refers to a previous Bulletin describing Californian rice irrigation practice, and methods of preparing land for irrigation, employed a the Biggs Rice Field Station, giving results of measurements of the amounts of water used and the subsequent yields for 1914-1916 (1). Further measurements have since been made there and also on a different type of soil on the west side of Sacramento Valley, on the Spalding Ranch, near Norman, and the author here summarises and discusses both the earlier and later measurement and experiments; also gross measurements of use of water on rice fields, taken from operation reports of canal companies and from measurements of diversions from Sacramento River in 1919 by the State Department of Engineering in part cooperation with this Station, are reported in the appendix.

In 43 full season measurements of the amount of water used in rice irrigation from 1914 to 1918, the total depth of water applied ranged from 3.91 to 18.70 ft., and the net depth, after deducting measured or estimated waste ranged from 3.91 to 13.43 ft. The average net depth of water applied to 22 404 acres under investigation was 4.89 ft. Of this area 21 419 acres was clay or clay adobe of the willows Sacramento, Stockton or Capay series.

An annual depth of 5 feet of irrigation water for rice is sufficient for the principal soils of Sacramento Valley, i. e. for the above mentioned districts: pervious loam soils, however, required an excessive amount of irrigation water, and from the water-standpoint are not suitable for rice growing. The use on individual fields of 1 cub. ft. per second of irrigation water to 30 to 40 acres during the first flooding after sowing is not excessive. Owing to the fact that all growers are not ready for the first flooding at the same time, canal diversions at this rate are not necessary, although it appears that probably as much as 1 cub. ft. per second to about each 50 acres served, is desirable during the period of initial flooding. The seasonal use averages about 65 acres per cub. ft. per second.

The following table shows the results of experiments on the effects of yield of slowly changing water, stagnant water, no submergence, and fluctuation of depth during submergence; submergence begun 30 days after emergence.

The maximum rice yields were obtained from submerging rice fields 6 inches deep (30 days after emergence), except on alkali land from which the best yields were obtained from submergence starting 15 days after emergence.

Constant movement of irrigation water through the rice checks during the period of submergence is necessary only where the soil contains alkalis

in sufficient quantities to affect the plants. The author lays special emphasis on the fact that the continued growing of rice on loam soils not underlaid by an impervious stratum that prevents deep percolation of water will result in very serious damage. It is imperative that ground water and rise of alkali be controlled in Californian rice fields both by confining rice growing to the heavier impervious clays and clay adobes, and by thorough and adequate drainage facilities embracing the entire areas affected or likely to be affected. A prime factor in control of water-grass in rice fields is to keep the banks of canals and irrigation ditches, principally the main and field laterals, entirely clean either by pulling or cutting the grass or by pasturing sheep on the ditch banks *before the seed has formed.* Keeping drains and sloughs free of both water grass and tules is also absolutely necessary if the danger is to be minimised.

The effect of irrigation methods and treatment on yields and of varying the date of submergence of rice fields with the 6 inch submergence at the Biggs Station was shown for the years 1914, 1915 in the preceding bulletin and is here supplemented with the data to hand for years 1917-19.

The author gives also summaries of measurements of duty of water, grouped by soil types and arranged in order of depth of water applied, and also of areas of land served per cub. ft. of water per second ; the variation in water temperatures compared with different depths of submergence and the evaporation records. With reference to the last mentioned, about one third of the water applied to rice fields is said to be lost by evaporation from the surface of the standing water during submergence. This cannot be controlled, but is in a way a measurable factor.

The figures illustrate the relative growth under different depths os submergence.

816 - ***Panicum minutiflorum* and *Andropogon rufus*, Good Brazilian Forage Plants** (1). — GABBATO, C, (Viamão Experimental Station, Brazil), in *L'Agricoltura coloniale*, Vol. XV, No. 1 pp. 18-19, figs. 2, Florence, Jan. 1921.

Two forage plants which promise to give good results on most soils in Brazil are *Panicum minutiflorum* (= *Melinis minutiflora*), and *Andropogon rufus*.

Experimental crops grown for some years in Rio Grande do Sul, have given results which warrant the recommendation of these plants in countries of similar mesological conditions (such as Southern Italy and its islands) both for hay, pastures, or permanent meadows.

Panicum minutiflorum or " capim gordura " (fat forage) is a grass with broad leaves, coated with a gummy aromatic substance, with a panicle made up of small rose coloured ears, with very small seeds. The plant forms tufts in which culms are on an average 50 cm. high.The culm is tender and remains so until the autumn frosts, when it dies; the roots remain alive and sprout vigorously in spring. The hay is very easily saved and, either as hay or in a green state, the forage is much liked by animals.

The percentage composition of the hay in digestible matter is as follows: — Total dry matter 78.90 %; proteins 8.42 %; nitrogen free extract 60-51 %; fat 1.75 %. Its nutritive ratio is therefore 1 : 7.7.

Andropogon rufus Jaq. is another grass of extraordinary growth. It forms large tufts of stiff culms, with rather solid rose coloured leaves. The stalks reach a height of 2 m.; they are woody and not much liked by animals: the grass should therefore be mown before it flowers or fed as pasture at that period so as to make the most of it for feeding animals. The hay is easily made. The percentage composition of hay of this *Andropogon* in digestible matter is as follows: — Dry matter 81.05 %; in proteins 5.78 %; nitrogen free extract 64.74 %; fat 1.01 %. Nutritive ratio 1 : 11.6. In Brazil this grass is called "capim jaraguà". The two above mentioned grasses are propagated by seed which retains its germinating power for a long period. The seed is sown at the beginning of spring. The grass can be cut 3 or 4 times a year and average yields of 1000 to 1500 quintals per ha. are obtained. Of the two plants *Andropogon* is preferable for moist fertile soils and *Panicum* for less fertile soils in the hills and plains. Owing to the difference of composition in digestible matter of the two grasses and the greater amount of nitrogenous matter in *Panicum* forage, the latter is more suitable for growing animals, while *Andropogon* forage is better suited to full grown animals.

817 - **The "Caulet de Flandre" Cabbage.** — MANVILLI, C., in the *Giornale di Agricoltura della Domenica*, Year XXXI, No. 24, pp. 186, figs. 2, Piacenza, June, 12, 1921.

The author reports the good results which he has obtained by the cultivation of the "Caulet de Flandre" forage cabbage at the "Istituto agricolo Bonafous". This cabbage, also called "rouge de Flandre" or "rouge de l'Artois", may be considered as a sub-variety of "chou Cavalier" or "grand chou à vaches", from which it differs by its smaller height and by the green red or violet red of its stalk, petiole and the nerves of the leaves. The stalk easily attains a height of 1 m. or more; the leaves are large, the flowers yellow. It is a hoed crop which should normally be placed at the beginning of a rotation; but its special method of cultivation and the time during which it occupies the ground often causes the combination crops to be modified. Thus it is often grown after forage crops harvested early, after rye and vetch, red clover, rape, etc. ; and as it is not cut until the following spring. it can be followed by spring cereals : — oats maize, sugar beet, etc. so that it can then be considered as a regular catch crop. According to the author's observations, sowing, which should be made in nursery beds, should be rather open so as to give vigorous plants: 150 to 175 grammes of seed per are suffice. One are to 1.5 ares of nursery is sufficient for planting out 1 hectare. Sowing may be done in March-April or July-August, and final transplanting in April-May or August-September, respectively, in lines spaced 80 cm. and the plants 50 to 60 cm. apart or else, as the author has seem in Belgium, in the Campine, spaced 70 cm. in both directions.

The crop is harvested from September to the following spring; harvesting is only stopped during severe winter frosts and consists in plucking the leaves, commencing with the bottom leaves which at that season begin to turn yellow; the plucking of the leaves requires much labour daily but at a season when field work is reduced to a minimum. The leaves are detached from the petiole so as not to damage the stalk and they are collected into bundles. The final cutting is made when the cabbages commence to flower; then the whole plant is given to cattle, which only eat portions of it. A total forage production of 450 to 600 quintals per hectare can be relied on.

The nutritive value of forage cabbage is greater than that of magolds; at least that is the author's impression, shared also by many breeders. The milk produced by cows fed on these cabbages yields a deep yellow butter without, however, impairing its quality. With daily rations of 35 kg. per head no ill consequence was noticed except when the cows were allowed to eat too great a quantity of cabbage in full flower.

818 – ***Atriplex leptocarpa, A. nummularia* and *Chenopodium triangolare* as Forage Plants in New South Wales.** — See No. 897 of this *Review*.

819 – **Sunflower Silage** (1) **in Western Canada and in Australia.** — I. HUTTON, G. H., Sunflower Silage for the West in *The Agricultural Gazette of Canada*, Vol. VIII, No. 2, pp 211-212. — Ottawa, March-April, 1921. — II SPAFFORD, W. J., Sunflowers in *Journal of Department of Agriculture of South Australia*, Vol. XXIV, No. 8, pp. 687-688. Adelaide, March 1921.

I. — Many comparisons made between maize silage of the best quality and sunflower silage have shown the balance of economy of gain in beef cattle and yield of milk in dairy cattle in favour of the sunflower. Similar results were obtained as regards peas and oats silage. The yield from sunflower silage was almost 35 tons per acre, or 5 times as great as that of the two latter crops. The following table indicates the yield in green weight per acre of the 3 above mentioned crops; the moisture content at the time the crops were put in the silos and the yield in dry matter per acre.

	I	II	
	lb.	%	lb.
Sunflowers.	79.200	82.41	12.034
Maize.	27.980	78.72	5·745
Peas and oats	14.000	62·64	5·230

If the seed is of good quality, 5 lb. per acre will be found sufficient so that the plants will be from 3 to 4 inches apart in the row and about 36 in. between the rows. The crop is ready for the silo when about 40 % are in flower, or when the first plants to flower have reached the dough stage

Sunflowers have proved an advantageous crop for growing under irrigation and also as a dry land crop, being distinctly drought resistant. The Experimental Station at Scott, Saskatchewan reports a yield of about 6 tons per acre with a precipitation or less than 2 in., during the growing season. Another important feature is its ability to withstand frost (it has been stated that it will withstand as much as 6 degrees of frost without injury). The author considers that this will become one of the main forage crops in Western Canada.

II. — Sunflower is coming into a considerable prominence as a summer-growing fodder crop in South Australia, and the following points relative to cultivation should prove of interest to prospective growers.

---

(1) See *R.*, April 1919, No. 493. (*Ed.*)

A well developed crop grown without irrigation should give a return of from 14 tons to 20 tons of greenstuff per acre. In Australia a fair crop will carry 72 sheep per acre for one month and a heavy crop even more. It has been found that the maximum results are secured in harvesting when about ⅓ of the apex flowers have just opened, but the yield will be higher if the crop is harvested just as the first buds appear, and the land is cultivated between the rows, and the plants left to grow a second crop.

820 - **Possibility of Growing *Eucommia ulmoides* in Italy.** — VERNUCCIO, R., in *L'Agricoltura coloniale*, Year XV, No. 3, pp. 129-140; No. 4. pp. 229-240. Bibliography of 35 works. Florence, March and April, 1921.

Two very fine specimens of *Eucommia ulmoides* Oliv. (a rubber-producing magnolia, native of China) which are growing in the garden of the Botanic Institute of the University of Rome, were used by the author for the study of the internal and external morphology of the tree and, especially the vessels containing caoutchouc, and for experimental extraction of rubber from the tree.

The method of extraction adopted by the author and called by him the " medicinical-chemical method " was as follows : — Drying the leaves or the bark in the sun , trituration ; sifting ; washing in running water; fresh trituration; fresh sifting with water; after these operations the caoutchouc is almost completely purified. To agglomerate the filaments, they were dissolved in carbon bisulphide which on evaporation left the rubber in sheet form.

The author concludes that. *Eucommia ulmoides* is a rubber plant wich gives a considerable yield and which should be cultivated experimentally in Italy. It is rich in caoutchouc both in the bark of the trunk and roots and in the leaves ; it is possible, by the above mentioned mechanical-chemical method to obtain a fairly considerable yield of rubber ; there may be two crops of leaves a year. The tree can be propagated by cuttings.

821 - **Relation between the Height of Tapping, the Width of the Sectors Worked, the Frequency of Operations and the Rate of Renewal of the Bark in *Hevea brasiliensis*.** — VERNOT, G., in the *Bulletin de l'Institut Scientifique de Saigon*, Year III, No. 6. Saigon, June, 1921.

As a good tapper cuts away an average of 1 mm. of bark per day during the tapping period, the average height of bark cut away annually by continuous tapping on a single cut is about 40 cm. If the first incision is made at a height of 1.20 metres, it would take 3 years to reach the bottom of the tree ; the working of a fresh sector would then be started.

According to experienced planters and experimentalists, the proportional width of the sectors is very variable ; tappings over ½, ⅓, ¼, or $^1/_5$ of the circumference have each their supporters and opponents. How is it that after nearly 20 years of discussion and experiment on this subject agreement has not yet been reached ? The author says it is because of the fact that three variable factors : 1) Rate of renewal of the bark ; 2) width ; 3) height of the sectors tapped, are among the data of the problem to be solved and have not been taken into account.

Now, the rate or renewal of the bark is a problem which should be solved separately. The width of the sectors tapped should be decided experimentally and, as will be seen, the height of the sector should be a function of their width and of the time required for the suitable renewal of the bark.

Allowing that the experiments are made by commencing tapping invariably at a height of 1.20 metres, on sectors of varying proportional width of which each should last three years, it would require, before having to tap the renewed bark, that is to say to go round the whole circumference of the tree: —

6 years for tapping over $^1/_2$ of the circumference on a single cut.
9 » » › » $^1/_3$ » › » › › »
12 » » » » $^1/_4$ » › › › › »
19 » » » › $^1/_5$ » › › › › ›

It is at present admitted that it takes 6 years for the bark to be suitably renewed and fit for fresh tapping without ill consequences. It is evident therefore that, in these conditions, tapping over ½ of the circumference is the only method which agrees with this experimental datum. On the other hand, for the smaller working sectors, the yields are trifling while tapping is done in the upper part of the different sectors; they do not become suitable until the bottom of the trees is reached. To make a comparative examination in these circumstances is a great mistake. But the mistake is still greater when, while continuing the same experimental method, a fourth variable is introduced into the problem viz., the period of rest given to the trees between each period of tapping (tapping alternately every other month, one month in three etc.). For tapping on a single cut, commencing at a height of 1.20 metres the number of years indicated above would have to be doubled for tapping in alternate months and trebled for tapping one month in three. Very long periods are reached, which are not worth considering as regards the renewal of the bark. Any comparative yield experiment which neglects these simple data is very incomplete, since it does not take practical possibilities into account.

Contrary to the rough methods of former experiments, the preceding Table makes it possible to foresee an extremely sensible modulation as regards the investigation of tapping and also enables observations which may be made during tapping to be taken into account.

Supposing that it was recognised at any time that 6 years do not suffice for proper renewal of the bark; the whole of the trunk above the tapping being untouched, it will be optional, at each change of sector, to raise the height proportionally to the width of the sector and proportionally to the supplementary period of rest which has been recognised as indispensable. In spite of this change, provided it is simultaneous, the results of the experiment will be none the less perfectly comparative. But is the rate of renewal of the bark the same in all cases, whatever the system of tapping may be? On the contrary it appears to be clearly proved that tapping decreases the rate at which the wounds heal over; to what extent, in each method of tapping, may this fact be prejudicial to the continuity of the yields and to the vitality of the trees? Only long-period experiments can enable this to be determined

Regarding the recognition of the moment when the bark should be considered as regenerated, contrary to the general practice, the external appearance of the trunk of the tree alone should not be trusted. It is not uncommon, in practice, to hear it affirmed that the bark is completely renewed because it has reached the same level as the bark alongside. On the contrary, it suffices to examine, by means of small notches, the real thickness of the bark which appears to be reconstituted, compared with that of the virgin bark to find out that, nearly always, the former is thinner. The reason of this physiological phenomenon is well known; tapping, breaking through the band of bark which encloses the tree diminishes the resistance which the generative layer has to overcome to form fresh cells; consequently the hydrostatic balance at that level is upset and the cell production of the cambium takes place simultaneously both on the side of the wood and on the side of the bark.

Another point must be taken into consideration in examining the degree of renewal of the bark. The bark consists of two principal parts: — The true bark, which so to say contains no latex canals, and the liber, which on the contrary is largely supplied with them. It is therefore the liber which is especially of interest to the planter and investigations should principally bear on it.

And what is to be said when the experimenter, wishing to compare equal sectors tapped daily and tapped alternately, makes the former at 50 cm. and the latter at 80 cm.?

All depends however on this simple arithmetical problem. — If with daily tapping on a single cut 40 cm. of bark per annum is used up, and if 6 years are required for adequate renewal of the bark, the total height of the tapping sectors will be 40 × 6 = 2.40 metres, and that is so whaterer may be the width recommended for the sectors. That being granted, according as tapping on ½, ⅓, ¼ or $^1/_5$ of the circumference on one cut is adopted, it suffices to divide this figure of 2.40 metres by 2, 3, 4, 5, or 6 to get, by simple calculation, the suitable height for commencing tapping in each case.

Regarding alternate tappings every other month or one month in three the last-named figures will be divided, according to the case, by 2 or by 3 to obtain the required information.

The annexed Table gives the following results for tapping on one cut daily or alternately the height at which the incisions should commence according to the widths of the tapping sectors.

It should, be mentioned, however, that each time tapping is recommenced on bark left untouched for a certain time, the first renewed incision uses up a little more bark than the daily average That is to say that the figures given for the alternate tappings ought to be slightly increased. In practice it will suffice if the figures given are simply rounded off.

Concordance of the heights of tapping			
Tapping on one cut	Height of the tapping sector		
	Daily tapping	Tapping alternate months	Tapping one month in three
	Metres	Metres	Metres
on $^1/_2$ circumference	1.20	0.60	0 40
» $^1/_3$ »	0.80	0.40	0.27
» $^1/_4$ »	0.60	0.30	0.20
» $^1/_5$ »	0.48	0.24	0.16
» $^1/_6$ »	0.40	0.20	0.14

822 – "Windrowing" Method adopted for Preserving Sugar Cane from Rapid Deterioration in the North West Frontier Province, India. — I. ROBERTSON BROWN W, The Effect on the Economical and Agricultural Situation: II. The Efffect on the Composition of Sugar Cane. — HARRISON W. H., and SANYAL P. B (Imperial Agricultural Chemist), in *Memoirs of the Department of Agriculture in India, Chemical Series*, Vol. V, No. 10, pp. 237-248. Charts 2. Calcutta and London, December, 1920

I. — A study of the American practice of windrowing (the term adopted by the sugar planters of Louisiana to describe their method of preserving sugar cane from rapid deterioration after the leaves and buds have been killed by frost), was undertaken at the Peshawar Agricultural Station, and the cane was first windrowed there in 1916.

The author describes in detail the 4 recognised seasons in the Peshawar valley and quotes the normals of temperature derived from data of 33 years for each successive month. The normal mean temperature from February to April (spring season) varies from 54.1 to 72.9° F; from May to July (summer) 54.0 to 90.9° F; from August to October (autumn), 88.6 to 73.1° F; from November to January (winter) 61.7 to 51.3° F.

As the average annual rainfall is only about 14 in. the sugar cane is irrigated from 20 to 25 times during its period of growth which extends from April to the end of October. By mid December the cane tops have been killed by frost. As the buds also are liable to be killed off in the same way, growers have long been accustomed to " clamp " a certain amount of their crop to preserve it for seed. If a grower has clamped more cane then is required to plant his field, the surplus cane is crushed, and, usually, the *gur* made therefrom is not inferior to that produced from the cane treated directly from the field: — that no deterioration occurs in cane thus treated from mid November till the end of March, has been proved by a series of analyses.

From a manufacturing point of view, clamping is however expensive (1 anna per maund to pit the cane and take it out again); it was therefore thought that the practice of windrowing might be of considerable advantage to a sugar factory; as this is a far les expensive operation. It consists of cutting the cane, laying it down, unstripped, where it was grown, the leaves forming a thatch which preserves the solid cane from the weather, and frost. On adopting this method late in November 1916, the cane after lying exposed for 3 months, was found to yield first class *gur*. This was a surprising result, as it is a well known fact that as a rule cane deteriorates more or less quickly, directly it is cut in all tropical parts of the so-called sugar cane belt.

II. — As a result, a scheme of investigations on a liberal scale was planned for 1917-18-19 and a report is here given of the changes found to occur in the windrowed canes from the point of view of the conservation of their sugar content.

In December 1917, a large average sample was drawn from a stand of the local *Pounda* cane and a careful analysis of the juice was made. The whole of the cane was windrowed on December 19 and allowed to remain there until April 5, 1918, when another average sample was drawn and analysed. The composition and equivalent weight of cane etc. before and after windrowing may be shown as follows: —

	Average weight of cane	Juice	Sucrose	Glucose	Brix (corrected)	Coefficient of purity	Crystallisable sugar
	lb.	%	%	%			lb.
Before windrowing on Dec. 5 . . .	2.39	75.84	9.57	2.38	13.34	71.70	8.06
After windrowing on April. 5	2.12	71.70	13.25	2.74	18.05	73.41	11.33

Crystallisable sugar has been calculated from the formula $C = S\ (1.4 - \frac{40)}{P}$ when C = % crystallisable sugar; S = % sucrose; and P = purity of juice.

It is evident from this analysis that the *quality* of the juice has improved and consequently, the yield of sugar from equal weights of juice would be greater after the period of windrowing.

A comparison of the estimates of the sugars present in a given quantity of cane before and after windrowing, shows that in addition to the superior quality of juice, the weight of sucrose and crystallisable sugar in the crop was materially increased after windrowing. This conclusion receives support from the analysis of a number of canes which had been allowed to remain in the ground throughout the cold season, and were analysed early in March.

If the values obtained when the cane is left standing throughout the season are taken as representing the maximum attainable under Peshawar conditions, then windrowing in December may be said to have led to a loss of 9.8 lb. of sucrose and 8.1 lb. crystallisable sugar for every 1000 lb. of cane standing in December 1917. Although it appears from this wisest to leave the cane in the ground as long as possible this is hardly practicable owing to the danger of considerable damage occurring through a " splitting frost ".

The analyses determined in 1918-19 indicated that although under Peshawar conditions, windrowing tends to reduce the purity of the juice, yet, owing to the latter becoming more concentrated, the percentage of crystallisable sugar remains fairly constant, and therefore, the practice of windrowing will not lead to any appreciable decrease in the amount of sugar obtained from equal weights of juice evaporation. The period during which canes can be stored varies with different seasons, but it is possible that the occurrence of heavy rainfall is the chief factor which determines the incidence of deterioration.

The appended charts show the variations in the amounts of glucose, sucrose and crystallisable sugar present in windrowed canes; also the rainfall and variation of the mean weekly temperature in the Peshawar valley.

823 - **Trees with Light-Weight Wood Central America.** — ROWLEE, W. W., in *Journal of the New York Botanic Garden*, Vol. XXII, No 256, p 75-78 Lancaster, Pa., April 1921.

During the last 3 years the author has had very favorable opportunities to study light weight woods in the forests and jungles of Central America. Three genera have been selected to illustrate types of light wood, viz. *Ochroma, Cavanillesia* (N. O. Bombaceae) and *Jacaratia* (N. O. Caricaceae).

Ochroma. — " Balsa." In the Tropical Forest Region this attains its largest size and greatest abundance and the trees flower at the age of two or three years. The average growth in diameter under favorable conditions is rapid, nearly 5 inches per year during the juvenile state. The wood ranges in weight from 4 to 12 lb. per cub. ft. The heartwood is homogeneous, silvery white to pink, and the sapwood always white

Cavanillesia. — " Quipo " (Panama) and " Macondo " (N. W. Colombia) and " Barraguda " (Brazil) and Bottle Tree (English). The Panama tree is *C. platanifolia* and attains immense size; the branches and leaves at the very top of the tree and the trunks resemble great columns; the strength of the tree is principally in the thick fibrous bark. The wood is homogeneous, but a large percentage is parenchyma, and is exceedingly fragile in texture.

Jacaratia. — Hitherto considered as confined to South America east of the Andes but in 1920 specimens were found in Panama and Costa Rica. The tree greatly resembles a *Ceiba;* the fruit is characteristic of the Papayas; the wood is soft and spongy. After a portion of the bark is cut away a machete could be pushed in to the centre of the tree with comparative ease. The wood is laminated and the parenchyma bands are very thick and constitute at least nine-tenths of the mass of wood. When fresh it can be cut into blocks, but when dried shrinks to a mere fraction of its original bulk. It is said that the wood of the S. American trees is poisonous when eaten.

The following concomitant features are associated with light wood trees: —

a) Geographically they are confined principally to the Tropical rainy forest region and to the belt of equatorial calms; *b*) the plants possess a very extensive leaf surface; *c*) thick, fibrous bark characterises most of them; *d*) the wood is white or at least very light in colour

824 - **Researches on the Origin of the Oak.** — HAUCH, L. A., in *Det Forstlige Forsøgsvæsen in Danmark*, Vol. V, Part 3, pp. 195-220, figs. 6. Copenhagen, 1920.

The author reports new observations and data resulting from experiments made by the Danish Committee for forest research and experiment on the influence of the origin of acorns on the oaks which grow from them. As has already been reported (1), these researches are carried out on the experimental estate of Sorø (Seeland) with oaks grown from acorns of Danish, Dutch, Russian, Galician, North Hungarian, Slavonian, Moravian, and Istrian (Montona) origin. The importance of this study lies in the fact that the growth of oaks on a large scale is considered to be the most efficient means of afforestation in Denmark, especially after the fellings made on requisition in the last few years, as well as in another fact, viz., the lack of acorns of such quality that the plants grown from them can thrive in the Danish climate. The great majority of the experimental plots bear plantations 8-12 years old, very close grown, which show clearly the influence of their origin. Experience shows in the first place that it is better not to sow any foreign acorns, since oaks grown from indigenous acorns are stronger and more vigorous than those of exotic origin. Ordinarily the former bear matured shoots with large turgid buds and they only produce a few small shoots in summer, for which reason they are less subject to oïdium. Generally, the exotic oaks are straighter than the Danish; they produce, during the summer, a greater number of long thin shoots with small buds much attacked by oidium and often do not mature.

Another difference between oaks of various origins is the time at which they come into leaf; for example plants produced by acorns imported from Russia, from Selmechànya (Hungary) and from Montona come into leaf earlier than the others. Oaks grown from acorns imported from Holland, Galicia, and Slavonia shoot later than the others. The oaks grown from Danish acorns belong neither to the group which comes into leaf early nor to that which comes into leaf late.

In observing the date when the leaves turn, in autumn, it has always been noticed that the oaks grown from Danish (Hald) acorns turn yellow first whereas those of Dutch origin turn latest. However, regarding this character, in some years (for example in 1918 and 1919), the difference between trees of different origins, is very slight or even *nil*; in other years (as in 1917 for example), it is, on the contrary, very marked. As this phenomenon varies from one year to another it seems to be due to the autumn temperature and to the first frosts being more or less early. A mild autumn, without early frosts, accentuates the difference in tints of the turned leaves between the oaks of Danish origin and the oaks of exotic origin; whereas when the trees have been affected by an early frost the leaves of the oaks of various origins all have a similar colour. The Danish oaks turn in about the same degree whether the autumn is mild or whether there are early frosts. When there are early frosts, the exotic oaks turn like the Danish oaks, but a frostless autumn is favourable to keeping their leaves green. This may influence, in turn, the development of shoots in the following spring and to such an extent that, in the case of exotic oaks which always have in spring many shoots that are not yet mature, several of these shoots may become mature if the autumn is mild.

---

(1) See *R.*, 1915, No. 394. (*Ed.*)

Besides these effects of the difference of origin, another fact may be noticed in the experimental plots, namely the influence which the greater or less development of the mother trees may have on the young plants. Thus, among the Danish oaks, the plants in one plot are very vigorous and some of them are higher than all the other Danish plants; the acorns sown in that plot came from well developed old oaks of Bregentved, Boholte. In another plot the growth is fairly vigorous, but the plants are not very high; the acorns from which they grew came from the forest of Heald in Jutland, where the oaks are small but robust. Yet another peculiarity may be noticed in a third plot where the plants are often defective, open and drooping; the acorns from which they grew were gathered at Bregentved from trees with large leaves, much branched and irregular in form. Regarding exotic oaks, a specially luxuriant growth is noticed in those grown from acorns imported from Galicia and Slavonia, where some of the finest oakwoods of Europe are found.

These researches show the important effect of the origin of the seed on the growth of the trees; they also show that oaks grown from exotic acorns are much more sensitive to frost and much more subject to oïdium than those grown from Danish acorns; that, when it is possible to procure Danish acorns and still better acorns from the district where sowing is to be made, it is better to use them only. The author remarks that the available supply of Danish acorns is insufficient to extend the growth of the oaks as much as is desirable so that Denmark is obliged not only to use all the available indigenous acorns but also to import acorns fromabroad.

These researches prove the great importance of knowing the origin of the seed; it would be better to give up planting oak than to use acorns of unknown origin. It is evident that none of the exotic acorns can be used with complete certainly, at least in the colder parts of Denmark; even if, as is the case for certain agricultural plants such as clover and sugar beet, exotic specimens are successful in the warmer parts of the country, in the colder parts thin delicate shoots, which continue to grow until late in the autumn, render the exotic oaks more sensitive to adverse conditions to which oaks grown from Danish acorns do not succumb and under which those grown from local acorns do still better. A difference is, however, noticed between oaks of various exotic origins although it is not advisable to sow acorns from Russia (Poltava), Hungary and Montona (Istria) because they come into leaf early and because they have thin, immature summer shoots in autumn. The sowing of acornsimported from Galicia and Slavonia, which give plants which come into leaf late and whose summer shoots, while abundant are slightly more vigorous and bear mature buds more frequently than the oaks grown from Russian, Hungarian or Istrian acorns, may be tried with less risk.

[824]

825 - **The Possibility of Reproducing Species of Eucalyptus in the Open.** — LEONE, G. (Istituto sperimentale agrario, Tripoli), in *L'Agricoltura coloniale*, Vol. XV, No. 2, pp. 74-78. Florence, Feb. 1921.

From experiments made at the Experimental Agricultural Institute of Tripoli since 1914, it appears that the growth of *Eucalyptus* spp. might render great service in Tripolitania, for these trees do very well under the conditions of soil and climate of that country; even on very poor soils, they can form a powerful wind screen in 3 years and in 10 years they can furnish wood, which is entirely wanting in the country, for many and varied uses.

The species which up to date have proved more particularly suitable and which grow more rapidly are *Eucalyptus resinifera, E. rostrata* and, apparently, also *E. saligna* and *E. rudis*. The two first-named owing to their abundant, close foliage, are excellent for wind screens.

An obstacle to the propagation of this tree on a very large scale lies in the system of reproduction. As a matter of fact, as yet the young plants have only been raised in pots, as it is generally very difficult to get them to take root unless they are transplanted with earth round the roots. The author attempted to raise the plants in the ground in a nursery, sowing being carried out toward the end of winter and transplanting into the open field or on the sand hills at the end of the following winter. The plants were watered when transplanting was done. A few days later the plants lost their leaves almost entirely and appeared to be dead; but after a few months the leaves began to appear again and soon a fine foliage was re-established.

These experiments made with *E. resinifera*, will be continued with similar species, but already some observations indicate that these species will behave similarly.

LIVESTOCK AND BREEDING

826 - **Penetration of the Trypanosome of Dourine** (1) **through Mucosa and Teguments.** — NATTAN-LARRIER, L., in the *Comptes rendus des séances de la Société de Biologie*, Vol. XXXIV, No. 16, p. 824-826. Paris, May 7, 1921.

For the better comparison of the power of penetration of the two trypanosomes *Tr. equiperdum* and *Schizotrypanum cruzi*, the author initiated investigations on mice by means of a fixed virus that is very pathogenic for that animal. He ascertained that, for mice, the conjunctiva, the rectal mucosa, the depilated skin, are penetrated by *Tr. equiperdum*, while they prevent *Schizotrypanum cruzi* from passing. Penetration by *Tr. equiperdum* is not, however, always effected in a constant manner (once in 5 cases for the conjunctiva, once in 3 cases for the rectal mucosa, twice in 2 cases for the depilated skin). The mucosa of the upper digestive

(1) See *R.*, May, 1921, No. 519. (*Ed.*)

organs, which, according to ROUGET is never penetrated by *Tr. equiperdum*, was only penetrated in one of the three mice. *Sch. cruzi* appears to penetrate it more easily.

827 - **Bovine Piroplasmosis in Morocco and its Relationship with the Piroplasmoses of the Mediterranean Basin** (1). — VELU, H. (Vétérinaire Major, Laboratoire de recherches du Service de l'élevage), in the *Bulletin de la Société de Pathologie Exotique* Vol. XIV, No. 2, pp. 116-124. Paris, Feb. 1921.

The author has collected the observations recorded in Morocco during the last ten years and he compared them with other publications relating to piroplasmoses of the Mediterranean basin. From a detailed examination of the observations made up to date in the different countries regarding the symptoms, pathological anatomy, pathogenic agent, diagnosis, experimental inoculation, agent of transmission, the author concludes, in the light of the facts, that circum-Mediterranean piroplasmoses are rarely unmixed diseases and appear generally, to be due to parasitic combinations (*Piroplasma bigeminum-Theileria mutans, Piroplasma bigeminum-Anaplasma marginale, Theileria annulata-Theileria parva*), which conduce to give very diverse clinic types rendering accurate diagnosis a matter of extreme difficulty, even impossible in certain cases. This fact is not peculiar to the Mediterranean basin. The first combination *P. bigeminum-Theileria mutans* is found in a great many countries, but owing to the feeble pathogenicity of *Theileria mutans*, the principal course of the disease is little modified. The type *Theileria parva-Theileria mutans* appears to be the special type in the Mediterranean basin. It is more general but it is not the only type. Thus, on the White Nile BALFOUR has observed *Theileria mutans* associated with *Anaplasma marginale*. In 1916, STEFKO observed in the region of Trebizond, in cattle imported from Russia, mixed infections with *Piroplasma bigeminum, Th. annulata,* and *Anaplasma marginale*. CARDAMITIS found *Theileria mutans* and *P. bigeminum* associated in cattle in Greece. Piriform infections are reported generally in Asia, at Madras, in Japan, Annam, China, at Tsing Tav, and in the Philippines, on the Ivory Coast, at Stanley Pool, at Dahomey, in Queensland, and recently in Morocco, and, at any rate in Morocco, it is possible to differentiate typical piriform piroplasm.

Theileria mutans may cause unmixed infections. It was recognised, in 1911, by MARTOGLIO, STELLA and CARPANO in Erythrea living habitually in Erythrean cattle. PRICOLO, in 1914, observed in cattle from Tunis a piroplasma which was probably *Th. mutans*.

Bovine piroplasmosis in Morocco appears to be an unmixed disease and consequently accurate investigation should be possible on the parasites and intermediate agents, to facilitate the identification of the agent causing the disease and to simplify the complex and important problem of preventive immunisation.

(1) See *R.*, Jan. 1921, No. 72. (*Ed.*)

828 - Special Facts Relating to Anthrax in Morocco and its Specific Prophylaxis (1). — VELU, H. (Chef du Laboratoire de recherches du Service de l'Elevage. Note read at the meeting of the Central Society of Veterinary Medicine on April 7, 1921), in the *Receuil de Médecine Vétérinaire*, Vol. XCVII, Nos. 8 and 10, pp. 176-180. Paris, April 10, May 30, 1921.

Vaccination against anthrax by the direct use of the second Pasteurian vaccine, which has shown itself very efficacious for pigs, remains quite powerless in infected herds of cattle and flocks of sheep and goats in which it has constantly proved ineffective in keeping down mortality. Without fully explaining all the peculiarities, several causes very certainly contribute to give anthrax, in Morocco, an aspect slightly different from that which is commonly seen in Europe. Such causes are overwork, privation, the length of the dangerous season and the extreme dissemination of contagion. Now, two other points require special attention:— 1) *The inefficacy of hte serum in cattle, sheep and goats ;* 2) *the peculiar virulence* of *the bacteridia.*

Regarding the inefficacy of the serum the author remarks that subcutaneous injections in prescribed doses in non-feverish animals (10 cc. for cattle and 5 cc. for sheep and pigs) are perhaps insufficient for cattle, sheep and goats on account of the peculiar circumstance that anthrax, in these species, is always a general infection which develops very rapidly (1) while in pigs anthrax is primarily a local affection (glossanthrax, garothilla).

Quoting the work of BORDET as support, the author considers that it should perhaps be possible to remedy this by using, on all the infected animals, even the feverish ones, intra-venous injection repeated on several successive days of high doses (20,40 and 50 cc.) recommended for the feverish animals by the Pasteur Institute.

The peculiar virulence of the bacteridia should also be regarded as one of the possible reasons for failure. LHÉRITIER, FLEURY, and TRIBOUT have previously (2) shown that in North Africa there is a race of bacteridia adapted to the organism of North African sheep and more dangerous for them than the French bacteria.

The new campaign should show whether the use of the third vaccine furnished by the Pasteur Institute will give greater or longer immunity. Besides there is the question whether the inefficacy of the serum can be remedied by the constant use of larger doses and by intravenous injection and, if these methods prove insufficient, by using as bases in the preparation of various serums, different types of microbes isolated from animals which have died of anthrax in Morocco.

829 - Haemo-prevention and Haemo-vaccination against Foot and Mouth Disease (3) — VALLÉE, H., and CARRÉ, in the *Comptes rendus de l'Académie des Sciences*, Vol. 172, No. 23, pp. 1449-1452. Paris, June 6, 1921.

The specific properties of the blood of cattle cured of foot and mouth disease were brought to notice many years ago by LÖFFLER and FROSCH,

Perroncito, Roux, Nocard, Carré and Vallée. Owing to the impossibility of obtaining serums that are efficacious against foot and mouth disease in sufficient quantity many authors were quite naturally led to utilise, as a remedy against this dreadful disease, the blood or the serum of animals which had been cured (Perroncito, Kuypers, Beijers, Broersma, Aukema, Lebailly, Desliens, etc.).

The results obtained by the various writers being far from agreeing, the present authors have renewed the study of the question and now express a decided opinion on the value of the method and the conditions of its use. It is briefly summed up as follows: —

I. — Just like experimental producers of various therapeutic serums, cattle cured of foot and mouth disease do not all furnish, in equal conditions of infection, equally active serums.

It is therefore necessary, with the object of regularising the results of haemotherapy, to use as much as possible a homogeneous mixture of citrated blood taken from a whole groups of animals from the 12th to the 15th day after the appearance of the vescicular eruption. In no case would blood drawn from a single convalescent be used, no matter how severe its attack had been. It is also necessary, when estimating the severity of the progress of the disease in a sick animal, not to confuse the effects of the disease itself and the effect of various complications attending the injuries caused by the issue of the virus.

II. — By the addition of an antiseptic, citrated blood can be kept in a refrigeration at +1° C. for at least 3 months without losing any of its useful qualities

III. — In any case the dose used, no matter what species of animal is treated, should not be less than 1 cc. of serum per kg. of live weight of the animal to be immunised (1).

IV. — The conditions specified above being complied with, injections of citrated serum from cured animals prove to be very regularly provided with all preventive qualities, which enable animals treated with them to resist both natural infection and subcutaneous inoculation of large doses of foot and mouth disease virus (virulent lymph, $^1/_{20}$ cc.; virulent blood, 5 cc. and 10 cc.).

V. — The duration of the immunity conferred does not exceed 15 days in most cases. It can be prolonged for similar periods by means of a 2nd or 3rd injection under the same conditions as the first.

VI. — Only animals free from the disease at the time of the preventive injection are immunised. Made during incubation of the disease, injection of the serum of cured animals in no way hinders the course of the disease, which, however, takes a milder form. However profitable the practical use of haemoprevention may be, especially for the infallible preservation of young animals, it remains of limited interest regarding the benefit which may be expected from a method capable of conferring a longer duration of resistance on the animals to be protected.

---

(1) The authors previously noted, in 1903, that the effective dose of serum taken from cured animals varied between 500 and 1000 cc. (*Revue générale de Médecine vétérinaire*, Vol. 1, 1903, p. 372). (*Authors' note*)

[829]

The attempts made with this object by LÖFFLER, NOCARD, ROUX and by the authors are well known. Most of them tend to experiments of sero-vaccination

The authors have continued their researches in this sense by using blood from cured animals in various combinations with aphthous virus, either in the form of aphthous lymphs or powdered epithelium filtered through a porcelain filter, or preferably, by defibrinated virulent blood.

Under the protection of an injection of blood of cured animals made under the conditions detailed above, cattle and sheep may safely be inoculated with doses of from 1 to 10 cc. of virulent blood either at the time of inoculation with preventive serum or 5 days later. Animals so treated resist infection and go through the whole of an epidemic without contracting the disease

Experiments in progress will determine:— The duration of immunity thus conferred; its value with regard to aphthous virus of various breeds or action; whether preference should be given to the simultaneous inoculation with the serum of cured animals and of virus or to successive inoculations of one or the other.

830 - **New Method of Ascertaining Gestation by Galvanometric Registration of the Heart Beats of the Foetus. Experiments in Germany.** — NORR, J (Physiologisches Institut und Poliklinik fur grosse Haustiere der Tierarztlichen Hochschule Berlin), in the *Berliner Tierarztliche Wochenschrift*, Year XXXVII, No 1, pp 1-6, and No 2, pp 17-20 Berlin, Jan 1921

Experiments made with cows, goats and mares. The first-named being fidgety and restless, trustworthy results could only be obtained with the mares. Some very useful curves were successfully registered. The places of derivation chosen were the oblique portion of the *ilio-pelvic colon* and the *Regio umbilicalis* or the *Regio iliaca dextra et sinistra.*

Hollow silver electrodes were used for rectal derivation and for epidermal derivation, plates of zinc amalgam which were pressed on the hair well moistened with zinc sulphate. The reception and registration of the heart beats of the foetus were made with the "Siemens und Halske Elektrocardiograph". The advantages of the method are as follows:— 1) Graphic registration eliminating all possibility of errors; 2) derivation from the *Regio umbilicalis* or from the *Regio iliaca dextra et sinistra* is simple and convenient, rendering possible the ascertaining of gestation without injury to the vagina; 3) the result of galvanometric auscultation is legible in a few minutes on the ground glass of the apparatus; 4) the graphs registered can be used as documents in trade.

831 - **On Sanson's Avenine.** — BROCQ-ROUSSEAU, and THOMAS, P. T, in the *Recueil de Medecine Vétérinaire*, Vol XCVII, Nos 8 and 10, pp. 212-218. Paris, April 30-May 30, 1921.

After a critical examination of SANSON's various papers on the supposed alkaloid body in oats called avenine, the authors relate their unsuccessful attempts to prepare this alkaloid by following SANSON's directions. Using a different method by treating 1 kg. of oat pericarps with alcohol at 80° C. in the presence of tartaric acid and subsequent treatment of the viscous extract until a light yellow residue which does not crystallise was extracted, the authors have shown that there was no alkaloid. This residue, redissolved in water has the following characters :— With alkaloid reagents, iodine in potassium iodide solution, iodo-mercurate of potassium, etc., there was no precipitate. The substance obtained is therefore not an alkaloid. Other reagents (Millon's reagent, ferric chloride, Fehling's reagent, ammoniated silver nitrate, vanilline, and hydrochloric acid) seem to indicate the characters of a polyphenol or of a tannin of the phloroglucic group.

The authors conclude that in any case there can be no question of an alkaloid, especially of a substance having the properties described by SANSON. SANSON's avenine therefore does not exist, or at least that writer must have designated under that name a non-alkaloidal substance or a mixture of non-alkaloidal substances, on the physiological properties of which it is necessary to make distinct reservations.

832 - **Dutch Researches on the Colour and Markings of the Coats of Cattle.** — KUIPER, K, jr., in *Genetica*, Vol. II, Part 2, pp. 137-161. 'S-Gravenhage, March, 1920

The author, after an account of the work of other investigators on crossing cattle (1), gives the results of his own experiments. Experiments of this kind, owing to their heavy cost, are always defective, especially considering that the information furnished by owners has always to be more or less depended on, and this the author also has made use of so far as it was authentic It was a case of the cross between cattle of the " Lakenvelder " breed (Dutch Belted Cattle) with Dutch black piebald cattle (sometimes black and sometimes white predominating).

The " Lakenvelder " breed is distinguished from the very variable black piebald breed by the regular distribution of black and white, that is to say the front third and the hind third of the body are black while the intermediate third is white, so that the cattle look as if they were covered with a white blanket. A " Lakenvelder " bull, whose pedigree was known from the Herd Book was used to serve a considerable number of black piebald and red piebald cows, in which the black and the red were very irregularly distributed and most of which had completely black or red backs and white bellies and extremities. The calves resulting from this cross were divided up as follows :— 27 " Lakenvelder," 24-25 black and 3-4 black piebald.

All the animals with a white band round the body were considered as " Lakenvelder " while the animals which had only insignificant white markings were counted as pure black

---

(1) WILSON, James, Mendelian Characters among Shorthorn Cattle. *Sci Proc. R. Dubl. Soc*, Vol. XI, N. S, No 28, 1918. — See also *R.*, Jan. 1920, No 81 (*Ed.*)

Cows of a pure "Lakenvelder" line served by the same bull (*A*), gave birth to 1 black bull calf, 2 "Lakenvelder" bull calves (perfect marking) and 2 heifer calves with slightly irregular coats. Another "Lakenvelder" bull (*B*) bred with the same cows 2 "Lakenvelder" reds with white extremities and 1 "Lakenvelder black (very irregular markings). It follows that plain coloured as well as very different calves may be produced. Red did not appear in the crossings with the bull (*A*) which is homozygous for black. It may also be remarked that, in the calves, produced by cows with white foreheads (" blaarkap "), the character "white forehead" was dominant to the character " black head " (" zwartkop ") of the bull, as is shown by the genealogical Table below :—

Bl = white forehead, **bl** = black head

F_1 white forehead (**Bl bl**) × Jaap (Lakv. ♂) **bl** × Hanna (**bl**).

F_1 Lakenv. white forehead (**Bl bl**) × Kees ♂ (**blbl**) = Else v. Dam (**blbl**)

F_2. . . . . .Lakenv (**blbl**) = Adrian Leer (**blbl**).

F_3. . . . . .black calf (**blbl**)

According to other researches the plain colour (red-brown or black) of calves in a line of "Lakenvelder" thorough breds is fairly common, So that that breed must possess a factor " plain colour ,, that is hypostatic with regard to the factor "Lakenvalder." The latter factor, moreover, is independent of colour, of the factor " spots " (vlekfactor ") and of the factor " white forehead." In the cross between piebald cattle × " Lakenvelder," the same types appeared as in the above-mentioned cross, namely :— " Lakenvelder " black and piebald, but in another numerical proportion which is caused by the more pronounced genotypic difference of the " Lakenvelder " cows. The proportion was 2 black, 1 piebald and 18 " Laken velder of which 12 were with much too wide blankets. The pattern of the spots is hypostatic in relation to the pattern of the blanket. The bull (*A*) is no doubt heterozygous for the pattern of the blanket. In the latter cross the " Lakenvelder " type seems to be more strongly influenced by the factor " piebald." The appearance of three types "Lakenvelder," piebald, and plain colours (black or red brown) may be explained as follows :— When L represents the factor for the pattern of the blanket, l its absence, E the factor for plain colour, e its absence shown by the appearance of spots, the formula for " Lakenvelder " cattle is $L\,l\,E\,e$, while the animals with a defective pattern would have the formula $L\,L\,e\,e$ or $L\,l\,e\,e$. L is epistatic on E. The ratio black : piebald in the blanket, 24 or 25 : 4 or 3 closely agrees with the ratio noticed in the repulsion of factors according to the series of reduplication :— 1 : 7 : 7 : 1 We have therefore 1 $L\,l\,E\,e$: 7 $L\,l\,e\,e$: 7 $l\,l\,E\,e$: 1 $l\,l\,e\,e$.

Calculated on 55 descendents the result would be :— $^{55}/_{16} \times 8 = 27\frac{1}{2}$ " Lakenvelder," $^{55}/_{16} \times 7 = 24\,^{1}/_{16}$ plain colour, $^{55}/_{16} \times 1 = {}^{55}/_{16}$ piebald. All these data may be explained as follows :— There is close correlation between white extremities and too wide blankets.

833 - **Note on a Herd of Albino Cattle in Minnesota, U. S. A.** — DETLEFSEN, Y. A (College of Agriculture, University of Illinois, Urbana), in the *Journal of Heredity*, Vol XI, No 8, p 378-379 Washington, Nov.-Dec. 1920.

The "albino" character appeared in two calves (one male and one female) of a cross between pure Holstein × half bred unrelated grade Holstein. The young bull of the F_1 generation crossed with ordinary Holstein cows behaved as a dominant homozygote. Thus, mated with half-bred unrelated grade Holstein cows, only albinos to the number of about 20 were bred. Four albino cows served by a registered Holstein bull gave birth to 3 albino calves and 1 ordinary calf.

The animals had pronounced albino characters. With one exception, pigmentation of the coat, eyes, horns and hoofs was entirely lacking.

No correlation between the character "albino" and good milk-producing qualities was noticed.

834 - **Purely Somatic Change of the Character "Blue Plumage" with the Character "White Plumage" in an Andalusian Hen, Observed in the United States.** — LIPPINCOT, W A., in *The Journal of Heredity*, Vol IX, No 8, pp 312-317 Washington, Nov - Dec. 1920

A Blue Andalusian hen aged 2 years in the spring of 1917, belonging to a pure pedigree line, produced during the moulting season in October of the same year, white neck feathers and a little later primary wing feathers which were also white, while normal blue feathers appeared on other portions of the body. In the following July, when the hen was moulting, all the old blue and white feathers were replaced by white feathers. Six week later the hen had pure white plumage.

The author has searched the literature but has not come across a similar case. Previously in 1918 (1), he had shown that generally the genetic constitution of Blue Andalusians was the following: — **PP (Re) (rE)**.

P represents the factor for the formation of black pigment, while its allelomorph produces a dominant white. **R** is a dominant factor which hinders the diffusion of the pigment black, thus producing a characteristic slate-blue colour. The factor **E** causes the plain colour of individuals having the factor **P**. The combined action of the factors **R** and **E** on the black pigment produces the character plain blue. According to previous researches it seems reasonable to admit that each of the factors **R** and **E** is closely, perhaps even completely, linked to the allelomorph of the other

The author further quotes the work of BATESON and PUNNETT (2), who have shown that in-breeding produces blacks, blues and speckled in the ratio 1 : 2 · 1. During the years 1917-1920 inclusive, the author continued his experiments with the hen in question, mating her successively with: — 1) A Blue Andalusian cock; 2) a white Wyandotte cock

---

(1) LIPPINCOT, W. A, 1918, The case of the Blue Andalusian. *Amer. Nat*, 52, 95-115 (*Author's Note*).

(2) BATESON W, and PUNNETT R. C., 1906. Reports to the Evolution Committee of the Royal Society, III, pp 11-23 (*Author's Note*).

(genetic constitution ***pp* (*rE*) (*rE*)**; 3) a White Plymouth Rock cock; 4) another white Wyandotte cock (heterozygous for **I P** [inhibitory of pigment], factor for white dominant).

The composition of the young with regard to the character " plumage " was as follows:—

1) — 5 chicks, of which 1 blue spotted with white and 4 blue
2) — 28 » » 13 blue and 15 black
3) — 25 » » 7 blue and 18 black
4) — 9 » » 5 blue and 4 black.

The results clearly show that the new character " white plumage " was not hereditary and that the hen transmitted to her descendants the character " blue plumage " like any normal hen of the Blue Andalusian breed.

835 - **On the Belgian Draught-horse.** — RASQUIN, M., in the *Journal de la Société Nationale des Agriculteurs de Belgique*, Year III, No. 26, pp. 201-203. Brussels, June, 1921.

The XXXIInd national show of stud horses, organised by the Royal Society " Le Cheval de Trait Belge," has proved that marked progress has been made regarding the relationship between the size of the horses and their skeleton.

While in 1880 a horse with a canon bone measuring 25 cm. was a phenomenon, at the present day it is common for stallions to measure 27 to 28 cm.; some even measure more and mares measure 25 to 26 cm. In future, the maximum being reached, the further consolidation of the skeleton should be sought after to maintain the ideal type obtained. Further, this last show has proved that the homogeneity of the breed continues in good conditions and, moreover, that the Belgian horse has a well defined origin, of which " Jupiter " was the pre-eminent founder. Thus the blood of that thoroughbred is in more than 80 % of the horses shown. The champion stallion as well as the champion mare trace descent from " Jupiter."

A considerable evolution in coat may be noted. At the show in 1880, out of a total of 625 horses shown, 44.1 % were bays, 13.4 % chestnut, 6.5 % blacks, 17 % greys, 13.1 % roans and 5.4 % flea-bitten greys.

In 1904, the percentages were as follows: — 43.65 bays, 35.4 chestnuts, 3.38 blacks, 5 greys, 8.8 roans and 3.7 % flea-bitten greys. At the 1921 show the percentage of chestnut horses had still further increased; 41 % of bays, 48 % of chestnuts, 8 % of flea-bitten greys and roans, 3 % of blacks and greys were recorded. The following are the percentages of prizes awarded to the different coats:— Bays, 35 % chestnuts, 54 % flea-bitten greys and roans, 9 %, blacks, 2 %. Blacks and flea-bitten greys and roans are therefore giving place to chestnuts and bays, which are the dominant coats of the Belgian heavy draught-horse.

836 - **The Verification of Herd Books by means of Statistics of Variations.** — FEIGE, E., in the *Deutsche Landwirtschaftliche Tierzucht*, Year XXV, No. 16, pp. 161-163. Hanover, April 1921.

Herd Books, indisputable indicators of the real conditions of breeding, furnish specially accurate bases for the scientific and practical evaluation of breeds, subject to the condition that the measurements recorded in the Herd Books are accurate. The author has studied the data in one of the best known German Herd Books, from the standpoint of the statistics of variations, and has brought to notice some results contrary to all mathematical rules. He investigated the information given in the Herd Book in question concerning the length of body, width of the pelvis, depth of the chest, and the height at the withers, and he proves by the method explained below (1) that no body measurement had been registered less than the initial measurements recorded in the text, that is to say, that when measurements smaller than the initial measurements were made, the figures

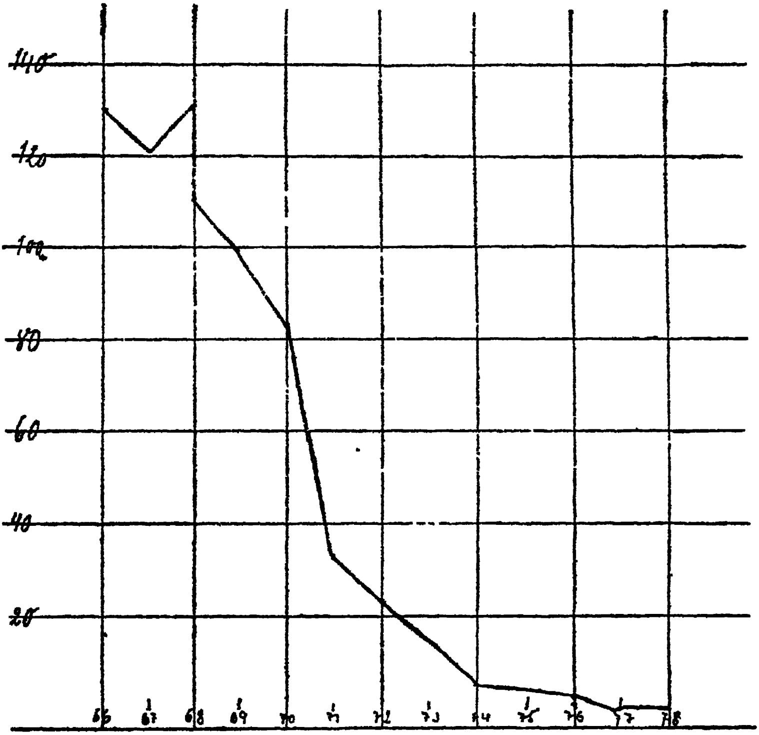

Diagram showing the method of correction.

---

(1) ZORN, W., Die Anwendung des Ausgleichsrechnung und Variationsstatistik auf Rindermessungen usw. *Mitteilungen der Landw. Institute der Universität Breslau*, Vol. VI, Part. 4.

were increased. The method used for proving correction is the following :— All the individual measurements are entered in a table in order of magnitude, and then shown graphically by a curve of variations.

A curve of ideal variations would result when any measurement, length of body for example, is grouped very regularly round an average value (M) in such a way that the nearest measurements to that average value were most frequently represented; hence cumulation of variants round the average value and gradual decrease in two opposite directions from the average corresponding to the binomial formula $(a + b)^n$. Now, in practice, an ideal arrangement will very rarely result, owing to variations due to the kind of life and heredity of the animals; on the contrary several average values may be noticed round which the variations are grouped and when this is not the case in a series of observations some alterations must be admitted.

The limits of variability are found by means of the typical deviation (σ). Practically the average value + or — of the typical triple deviation represents the limit of variations; beyond $M \pm 3\,\sigma$ no measurements are found except in very large series of observations.

Thus the figures for the depth of chest gave, for 644 cows, the following distribution :— (The upper series of figures indicates the class of magnitudes and the lower series the number of cows).

65.5 — 66.5 — 67.5 — 68.5 — 69.5 — 70.5 — 71.5 — 72.5 — 73.5 — 74.5 — 75.5 — 76.5 — 77.5 — 78.5
130 121 131 99 83 33 23 15 5 — 2 1 1

For depth of chest the average value 68.5 cm. and a typical deviation of + 4.181 cm. result, so that the range of variation is $M \pm 3\,\sigma = 81.043$ to 55.96 cm. Some cows should therefore be found corresponding approximately to these limits. In fact above the average (68 cm.) the range is almost reached, whereas, below the average there is a very remarkable lack of continuity, as the limit of negative variations is 55.96 cm. and the series stops at the 66 cm. classes of magnitude (130 cows). Nevertheless the series corresponds with the binomial arrangement because the cows, of classes lower than 66 cm. have not been omitted although the value of the numbers has simply been corrected. The author remarks that the figures having been taken without selection from the mass of data the results can scarcely be contingent.

The diagram given above also shows very dearly the method of correction. The arrangement is almost ideal, but the curve is defective as its left side is completely suppressed. Small measurements are entirely wanting. The peak of the curve is at 68 cm. (average value); after passing the 67 cm. class of magnitude the curve rises steeply to reach a culminating point at 66 cm.; below this limit no animal is found belonging to a lower class. In the classes above 68 cm. (131 cows) are found 99 + 83 + 33 + 23 + 15 + 5 + 2 + 1 + 1, a total of 262 cows while belows the central class 121 + 130 = 251 cows are found. The figures for positive and negative variations are therefore in good agreement. It follows that all negative variations have been recorded, but with altered measurements which appear in the 66 cm. class of magnitude.

837 – Herd Books of French Breeds of Cattle. — MESLAY (Report of the Bureau of cattle improvement), in the *Bulletin de la Société des Agriculteurs de France, Comptes rendus de l'Assemblée Générale de* 1921, meeting of March 9 (fifty second session), Part 2, pp. 44-46. Paris, 1921.

MESLAY emphasises the great services rendered by Pedigree Books (1) and Herd Books in showing the way to improve French breeds of cattle (much sought after by foreign breeders and notes that there are still too few of these Books in France. For the 30 or 35 breeds of cattle there are scarcely 15 Herd Books, of which only 8 or 10 are fully successful; the others are embryonic or in course of formation. Nevertheless the inquiry made by the Bureau of Cattle Improvement shows that a certain amount of progress is being made generally; besides some very good Herd Books some of which have already been 35 years or more in existence, others of more recent date are not less successful.

The different Herd Books regarding which the Bureau has obtained information are the following :– 1) The Herd Book of the *Montbéliarde breed.* 2) The Herd Book of the *Limousine breed.* 3) The Herd Book of the *Charolaise breed* of the Nièvre, Saône-et-Loire and affiliated Departments, fusion of two Pedigree Books of the Nièvre and Saône-et-Loire comprising a total of about 11000 entries of cows and heifers and about 5000 bulls. 4) The Herd Book of the *Normandy breed of cattle* (2), a most successful collection comprising 18 000 to 20 000 entries of bulls, cows, and heifers. 5) The Herd Book of the continental *Jersey breed.* 6) The Herd Book of the *Parthenaise breed* with a family or sub-breed, called Maraichine, very good milkers and very hardy, for which a Herd Book has not yet been compiled. 7) The Herd Book of the *Garonnaise breed.* 8) The Herd Book of the *Bazadaise breed.* 9) The Herd Book of the *Maine-Anjac breed* comprising 1500 members and which has entries of about 8 000 animals. 10) The Herd Book of the *Black Piebald Breton breed of Finistère and Morbihan.* 11) The Herd Book of the *Armoricaine breed*, across between the Black Piebald: and Durham breeds, with entries of 713 animals. 12) The Herd Book of the *Red Piebald Breton breed*, very clearly distinguished from the two last. 13) The Herd Book of the *Pyrenean breed* of the South-West with pink *mucosae.* 14) The Herd Book of the *Tarentaise breed*, in process of compilation. Besides these different Herd-Books, there are a great number of breeding syndicates created before the war and other small Communal Societies with bull owners. It would be desirable that these breeding Syndicates should first endeavour to maintain pure breeds in the districts where these exist, and then to compile for each of the breeds a Pedigree Book or a Herd Book.

838 – Note on Rearing " Minor Breeds " and " Local Breeds " of Cattle in Great Britain. — *Live Stock Journal*, Vol. XCIII, No. 2458, p. 455. London, May 13, 1921.

Since the end of the war, the rearing of " minor breeds " and " local breeds " of cattle has become popular in Great Britain. In particular the rearing of the three most important of the local breeds, Sussex, Red Poll and South Devon has extended considerably, but the keeping of Blue Albinos and Old Gloucester, in Derbyshire and Gloucestershire respectively, has also been revived. Small local breeds, valued specially on account of their adaptability, are preferred in their native districts to any other breed, and it is chiefly for that quality that these breeds are beginning to be imported into other districts of Great Britain where the conditions are similar to those of their native district.

---

(1) See *R.*, Sept. 1920, N. 888 (*Ed.*) — (2) See *R.*, Sept. 1920, N. 838 (*Ed.*)

Sussex cattle, besides their quality as plough cattle, are specially valued as good beef producers with very early maturity. The half-breed produce of the North Devon (also pure red) × Sussex cross is an ideal butcher's beast, profitable to rear, in which the Sussex gives early maturity and the North Devon high quality of meat.

The South Devon had a certain resemblance, a few years ago, to the Sussex, both being red in colour and both being of large size ; on the other hand the South Devons were lacking in symmetry and were very uneven in flesh.

At the present time the improved South Devons may be considered as one of the most important dual-purpose breeds (milking and fattening properties). The bullocks grow to a great size and have good feeding propensities. Further, this breed is perfectly suitable for crossing with small breeds in order to get increased size and weight. There is no doubt that when the qualities of the South Devon become better known the rearing of this breed with still further increase; the cows not only give large quantities of milk but also the milk is rich in quality.

The Red Poll breed of East Anglia, also a dual-purpose breed, is one of the best dairy breeds. Moreover, there is no doubt that Red Polls can thrive under conditions under which a good many other English breeds would not be able to live. Classed a few years ago among the minor breeds, the Red Poll ought now be placed among the major breeds, but as one of the local breeds.

Similar remarks as those regarding cattle might be made regarding pigs. The Gloucester Spots, the Wessex Saddlebacks and the Essex especially have increased considerably but without in any way diminishing the influence of the major breeds such as the Large Blacks, Berkshires, Large and Middle Whites, etc.

839 - **Experiments in Great Britain on the Effect of Feeding Concentrates either as Warm Mashes or Dry, and of the Percentage of Succulent Foods in the Ration, on the Production of Milk.** — BERRY, R. A (Professor of Agricultural Chemistry, West of Scotland College of Agriculture, Glasgow), in *The Journal of Agricultural Science*, Vol. XI, Part 1, pp. 78-98, graphs 6, tab. 4. London, Jan. 1921.

Experiments carried out at the College Experimental Station at Kilmarnock, Scotland, with Ayrshire cows. Conditions which might influence milk production, such as the health and appetite of the cows and the weather were recorded daily. For each ration figures indicating the content in nutritive material are given.

INFLUENCE OF CONCENTRATES FED EITHER DRY OR AS WARM MASHES ON THE MILK PRODUCTION. — During the three weeks preceding the experiments one half of the meals was fed dry in the morning and the remainder as mashes in the evening. For the mashes the concentrates were mixed, scalded with boiling water (½ gallon to 9 lb. of the mixed meals) and 1 oz. of rocksalt was added.

The mixture was fed in a sloppy condition at the body temperature. As short-period experiments (5 weeks) evidenced the beneficial effect of the concentrates fed as mashes on the milk production, experiments lasting 17 weeks were proceeded with, using 10 cows divided into two groups, and taking into account their period of lactation, milk production, etc. During the first period of the experiment, lasting 5 weeks, the cows in group I were given the concentrates dry and during the subsequent periods, lasting respectively 10 and 2 weeks, the concentrates were fed alternately wet and dry. The cows in group II commenced with the concentrates fed as mashes during the first period and during the subsequent periods the concentrates were fed alternately dry and wet.

The daily ration per cow was composed of:— Turnips 30 lb., hay 7 lb., oat straw 10 lb., bean meal 3 ½ lb., crushed oats 3 ½ lb., decorticated cotton cake 2 lb. The cows were watered once a day for 30 minutes at a trough in the yard and drank an average of 5.7 gallons and 4.6 gallons respectively per head for groups I and II.

The quantity of milk produced by feeding the concentrates as mashes was greater by about 1 lb. per head per day than the quantity produced by feeding the concentrates dry. The increase diminished with the advance in lactation. The warm mashes produced a distinct laxative effect and were more readily eaten than the dry meals. It was noticed that the cows fed on rations containing the concentrates in a dry state lost the good condition of their coats. With a change back to rations containing the concentrates in a wet state or when water was readily obtainable in the byre, the animals recovered the normal condition of their coats. An increased water supply did not appear to have any effect on milk production.

In another experiment carried out in similar conditions to the former, except that the ration was modified, the periods reduced and that the cows were given water *ad lib.*, it was ascertained that for the production of 1 lb. of milk an average of 3.5 lb. of water (drinking water + water contained in the food) was consumed when the cows were fed with a normal winter ration containing 30 lb. of turnips and part of the concentrates given as wet mashes. The ratio of water consumed varied with individual cows, with the preparation of the food (concentrates wet or dry), the proportion of fodder in the ration, the period of lactation of the cows, and the temperature. For 1 lb. of dry matter in the food 3.6 lb. of water was consumed. The total quantity of water consumed per day (drinking water + water contained in the food) amounted to about 10 gallons, of which 50 to 60 % was drinking water; from 25 to 30 % of the total water consumed was contained in the milk.

[839]

INFLUENCE OF THE QUANTITY OF SUCCULENT FOOD (ROOTS) CONTAINED IN THE RATION ON THE YIELD AND FAT CONTENT OF THE MILK. — Experiments in which the quantity of water necessary for the animals was furnished respectively by feeding with succulent food (swedes) and by feeding with rations in which part of the water was taken as drinking water (1).

The experiments were made with 7 cows which during the first period of the experiment were given 112 lb. of roots in their ration. During the subsequent periods 56 lb. and 22 lb. respectively, of roots were replaced by concentrates and fodder so as to maintain the same weight of proteins, fats and carbohydrates in the ration. The daily ration per cow was the following:— Turnips 112 lb., hay 5 lb., oat straw 12 lb., mixed concentrates 7 lb. (bean meal, earthnut cake, crushed outs, bran and fish meal). One half of the concentrated was fed dry and the remainder in a sloppy condition.

Experimental data collected for the various periods.

	January	February				March				
	28	4	11	18	25	3	1		24	31
Average daily milk yield lb.	30.3	29.1	28.7	27.2	26.3	25.2	25	25 0	24.8	24.0
Total solids . . . . . . %	12.69	12.91	12.72	12. 8	13.21	13 4	13 53	13.62	13 31	13.45
Fat weight . . . . . . lb.	1.03	1.06	1.00	0.99	1.02	1.04	1.12	1.13	1.01	1.08
Solids not fat . . . . . lb.	2.83	2.70	2.65	2.49	2.45	2.34	2.32	2.29	2.24	2.16
Total solids . . . . . . lb	3.86	3 76	3.65	3.58	3.47	3.38	3.44	3.42	3.34	3.24
Roots . . . . lb		112					56		90	

A heavy root ration (112 lb.) had a strong purgative effect which adversely affected the health and general condition of the animals. The milk yield, which had shown a tendency to increase at first, definitely decreased later. Although there was an increased percentage of fat, the weight of fat produced diminished. The fall in milk yield was partly, but not immediately, arrested by a change to a moderate root ration. As a consequence there was a decided increase in the percentage and total yield of fat. The consumption of water (drinking water + water contained in the food) per 1 lb. of dry matter amounted to 3.9 lb. with a ration containing 112 lb. of roots and to 3.3 lb. with the moderate root ration. Some of the cows fed with the heavy root ration took on an average between 5 and 6 % of the total intake of water in the form of drinking water. The data relating to the influence of the temperature on the milk yield are given in 6 graphs in the text.

---

(1) It is the practice in some of the milk-selling farms in the west of Scotland to feed heavy root rations amounting to 1 cwt. of roots per day W. R. DUNSTAN states that over 100 lb. of roots are fed per head per day on some of the farms in Kent. LAUDER and FAGAN found that cows receiving 112 lb. of roots with wet mashes refused drinking water.

See A. LAUDER, and T. M. FAGAN, " The effect of heavy root feeding on the composition and yield of milk " *Bull 26, Edinburgh and East of Scotland Agricultural College*, 1912. (*Author's note*).

[839]

840 - **The Effect Produced Upon Sheep's Wool by Adding " Ovagsolan " (1), a Digestible Preparation of Decomposed Horn, to Rations Poor in Protein. Experiments in Germany.** — LEHMANN (Institute of Animal Physiology of the Berlin Agricultural College , Abstract from a Report made to the Minister of Food and Agriculture, in the *Deutsche Landwirtschaftliche Tierzucht*, Year XXV, No. 15, pp. 157-158. Hanover, April, 1921.

Careful experiments made at the Institute of Animal Physiology of the Berlin Agricultural College. These results were at variance with those previously obtained when this preparation was given with much success to two-year old sheep (" Zeitschafe "), and the author could not detect any effect that could be attributed with certainty to " Ovagsolan." Usually, however, micrometric investigations revealed a considerable thickening of the wool, when this preparation was added to restricted rations containing little protein.

In experiments carried out on the patients of some of the Berlin hospitals, a similar thickening of the hair was observed, though in many cases no effect was produced by the use of " Ovagsolan."

LEHMANN discusses the experiments of HELLDORF (2) made upon 100 sheep of two years of age, and throws some doubt upon the accuracy of this work, comparing the results with the data previously obtained by HENNEBERG. In the experiments of the latter, 50 gm. of protein added to scanty rations produced 3.3 gm. of pure wool, and 0.8 gm. when added to fattening rations. HELLDORF, by giving 50 gm. of " Ovagsolan," obtained an increase of as much as 1.5 gm. per day per head. LEHMANN deduces from this fact that the same effect could be produced by giving the sheep pure digestible protein, instead of " Ovagsolan."

The author, basing his opinion on the experimental data, allows that it is possible, that " Ovagsolan," like protein, may have a stimulating effect upon the formation of wool and hair, but believes that it has no nutritive value, that is to say, it does not supply substances like cystine which are lacking in the ration, but stimulates the follicle, and under the most favourable conditions, may induce greater activity in the latter without increasing the ration. On the other hand the efficacy of this stimulus depends chiefly upon the excitability of the hair or wool follicles, as well as upon the protein content of the rations

---

(1) The experiments made by ZUNTZ, who added horn decomposed by chemical action to rations poor in protein, having given satisfactory results, a special preparation containing all the substances necessary for wool formation has been made and sold under the name of " Ovagsolan," See *R.*, June, 1921, N. 656. (*Ed.*)

(2) As control animals, 20 two-year-old sheep were taken having the same quality of wool, and of the same size and weight as the sheep subjected to the experiment. The latter were given for 100 days, in addition to their ordinary ration, 50 gm. of " Ovagsolan " per day and per head, and during this time produced 400 gm. more wool per head. (*Ed.*)

Nevertheless, the author states that on account of the limited number of experiments so far carried out, it is impossible to give a conclusive opinion upon the value of " Ovagsolan " as a sheep food, though he thinks that in the case of a temporary dearth of concentrated feeds, and when there is any fear of the fibre of the wool being too fine, a dose of " Ovagsolan " varying from 25-50 gm. might prove efficacious.

841 - **Fattening Lambs With and Without Shelter (Shelter Versus Open Lot).** — WITHYCOMBE R., and POTTER E. L., in *Oregon Station Bulletin*, No. 175, pp. 1-11. Corvallis, Oregon, September, 1920.

The results of two experiments carried out from 1914 to 1919 with two lots of lambs which were fed for the market. Lot 1 was kept through the winter in an open feed yard, while Lot 2 occupied a similar yard, with the exception that it was provided with a low shelter-shed closed on two sides. The lambs were given lucerne hay *ad libitum*, and a limited grain ration consisting of oats and barley. The animals under shelter made slightly higher gains (0.30 lb. per head per day) than those kept in the open yard, which gained 0.29 lb. The shelter lot required per 100 lb. gain 914.10 lb. of hay and 279.29 lb. grain, whereas the lot in the open pen, ate 944.72 lb. hay and 290.49 lb. grain.

The Bulletin is provided with an appendix giving information on the management of fattening lambs, and a discussion of the feeding costs.

842 - **A Study of the Present Condition of Pig-Breeding in Italy.** — I. Una grande mostra di suini a Bologna. *Il Giornale agrario*, Year III, Nos. 20 and 21. Bologna, May 28, and June 4, 1921. — II. CAMFORI, G. C , *Ibid* , No. 22, June 11, 1921, and No. 24, June 25, 1921. — III. Relazione dell'Esposizione provinciale ed interprovinciale dei Suini, tenuta nel Mercato bestiame di Bologna, il 25-29-30 maggio, 1921. — *L'Agricoltura bolognese*, Vol. VI (New Series), No. 6, pp 52-61, figs. 8. Bologna, June 15, 1921. — IV. PERGOLA, V., Lo stato attuale della suinicoltura italiana, in the *Bassa Corte*, Vol. II, Parts 33-34, pp 770-773, figs. 3. Molassana (Genoa), May 1921 (1).

I — II — II. — Pig breeders from the different regions of north and central Italy were exhibitors at the pig-show held at Bologna from May 28-30, 1921, which made it possible to obtain a very accurate idea of the principal tendencies governing pig-breeding throughout a large part of Italy Thus, it was noticeable that there was a strong inclination to use the black breeds, especially the " Large Black " for improving the breeds, instead of the " Large White " and Middle White Yorkshires that had previously been the favourites. This change was fully justified by the greater hardiness of the " Large Black," its superior resistance to the Italian climate, its marked suitability for mixed farms, and especially by its excellent returns in meat and fat.

---

(1) See *R*, July-August, 1920, No. 779; *R*., June, 1921, No. 658. (*Ed.*)

The white breed, when acclimatised in Italy, has however developed a tendency to hardiness, and the pigs, though they are less fat, are stronger, better-proportioned, and move with greater ease

Other breeds less known in Italy, on account of their more recent introduction into the country, were also to be seen at the show such as "Gloucester Old Spots" and "Poland China." The latter is raven-black, and was imported from the United States. It resists fatigue and long journeys very well, and is particularly suited for large farms and grazing-grounds Finally, some very promising specimens of a cross between the "Large White" and "Large Black" breeds were also on view.

When the show was about to be closed, Prof. CUGNINI gave a lecture in which he sketched the lines that should be followed by pig-breeders in Italy, basing his remarks upon the results of the show, the experiments he had made during many years at the Reggio Emilia Royal Depôt for Stock Improvement, and the facts he had observed on his visits to the best pig breeders of the region. Prof. CUGNINI is a staunch partisan of the Yorkshire breed for the purpose of improving the type, for the present pigs are larger, hardier, less flat-nosed, better adapted to grazing than their predecessors, and they always transmit to their progeny the characters of size and early maturity. According to the lecturer, "Large Blacks" and their crosses never attain the size, or the early maturity, of the "Large Whites" and their crosses, although the animals of both breeds, and their hybrids, are excellent in their several ways The Yorkshire pig is particularly valuable in turning to account the waste products of cheese-factories. These products, however, should not be fed to breeding animals, for they depress the nervous system; and fatten the pigs. The best feed for sows is lucerne but this should bot be given exclusively; in order to keep the intestines active, bran and ground lucerne hay should be fed, and an aperient administered every fortnight. It is advisable to include mangolds in the sows' ration during the winter, as these roots encourage milk-secretion (1).

---

(1) At a model pig Service-Station, that of GEMINIANI Bros, on the Galanta estate near Imola, of which the products (especially the Gloucester pigs and the crosses between "Large White" and the Romagnole breed) were much noticed at the Bologna Show, the following rations are fed to *sows in farrow*: 30 % beans, 15 % maize, 6 % barley, 4 % oats, 45 % dry fodder; *sucking-pigs* until weaning, that is to say, until they are 70 days old, receive 35 % maize, 15 % barley, 10 % oats, 40 % beans, while *pigs to be fattened* are given 40 % beans, 20 % barley, 20 % oats, 20 % maize If oats are scarce, they are replaced by dry fodder. The rations are fed *ad lib.* to all the animals, which are also alloved to graze at will in the lucerne and clover fields. During the winter, their drinking-water is warmed The piggeries are very well ventilated, and are made of a wooden frame covered with reeds. Out of 15 sows from 100 to 150 young are obtained on an average annually; of these 75 % can be used for improving stock. — A. NEGRI. *Giornale agrario*, Vol. III, No. 16. Bologna, April 30, 1921. (*Ed*)

Of recent years, the number of pigs reared in Italy has greatly increased. Two types of pig-breeding are practised in this country, viz., extensive breeding in wooded pastures (this is very suited to local races of the Iberian type, which, however, thus become very mixed), and intensive breeding on the farms. The latter is best adapted to early-maturing and very thrifty animals, which need not be good walkers. It is a mistake to cross local breeds with larger and earlier-maturing breeds that are weaker and less thrifty; what is necessary in extensive pig-breeding, is the rearing and selection of pure-bred animals. Crossing, however is very useful in intensive breeding. The type of pig that has hitherto been used for this purpose is the Yorkshire; the purest-bred animals of this race in Italy are to be found in Lombardy, while in Emilia, and especially in the Province of Reggio, the largest number of the finest Yorkshires are reared. The "Large Black" and Poland-China breeds have recently been introduced, and appear very promising. The Large White × Large Black cross made by Marquis STANGA has produced splendid animals in the first generation, which are much finer than their parents; it, however, remains to be seen how the subsequent generations turn out.

Of the Italian hybrids used for extensive breeding the Siennese, or "cinta" pig (Large White × Iberian var. Tuscan) is worthy of mention. The animals are of good size, well shaped, and thrifty, but do not yet show the early maturity, fixity of character, and perfection of type that are to be desired.

843 - **The Sericultural Institute at Portici and its Work.** — MORESCHI, B, in *L'Italia agricola*, Year 58, No. 5, pp. 142-144. Piacenza, May 15, 1921.

The Sericultural Institute of Portici (Naples), which is attached to the Royal Agricultural College of that town, was founded, together with other institutes of the same character, by the Law of 1912 relating to the silk-industry (1). It was opened in May, 1916, and was in full working in 1920. During the five-year period 1915-1920, the Director of the Institute was Prof. ACQUA (now Director of the Experimental Sericultural Station at Ascoli Piceno).

The author mentions the work done by Prof. ACQUA, or carried out under his supervision, during his time of office.

In addition to the articles of which abstracts have been given in this *Review* (2), the author mentions a histological study by Mme (Prof.) A. Foà (at the present date Directress of the Portici Sericultural Institute) on the alterations produced in the intestinal epithelium of the silkworm by the disease known as "flacherie"; a study by Mme (Prof.) P. LOMBARDI on the orientation of the cocoon and its possible influence on the laying of the moths; this study proves that there is no such influence, and that the divergent conclusions arrived at by other writers on this subject are to be attributed to the small amount of material used in their experiments); a study by Mme (Dr.) C. DI MAIO (1), describing the manner in which the moths of *Bombyx mori* bore through the cocoons under abnormal conditions; this study shows that the moths can perforate the cocoon equally well, whether their heads are turned to the usual side, or to the opposite one, and that the hole is made with the assistance of the alkaline liquid with which the moths are amply provided; etc.

(2) See *R.* March, 1916, No. 328; *R.* Nov. 1916, No. 1202; *R.* June, 1917, No. 572; *R.* Jan. 1918, No. 70; *R.* Feb. 1918, Nos. 145-196; *R.* March., 1918, No. 327; *R.* June, 1918, No. 673; *R.* Dec. 1918, No. 1342; *R.* May, 1919, No. 589. (*Ed*)

844 - **" Muscardine" (*Botrytis Bassiana*) a Disease attacking Silk-Worms and Other Insects.** — CAMPBELL, C., in *Il Coltivatore*, Year LXVII, No. 9. pp. 266-269. Casale Monferrato, March 30, 1921

During the sericultural season of 1920, there was a serious outbreak of " muscardine " (*Botrytis Bassiana*), in the low valley of the Liri. As the region is very isolated, without railway-stations, and as it is difficult to suppose that the conidia of the fungus had been sent with the silkworm eggs, it must be concluded that the disease was transmitted to the silkworm by other infected insects.

AUDOUIN, in 1836-1837, found that it was possible to inoculate the caterpillars of several Lepidoptera (amongst others those of *Limantria dispar*), with *B. Bassiana*; and in 1838, he observed that the disappearance of the Galerucella of the elm (*G. luteola*) was due to the development of " muscardine " in the pupae.

TURPIN (1836) succeeded in inoculating various caterpillars (*Malacosoma neustria, Pieris crataegi*, etc.) with the fungus, which causes the death of its hosts in 8 to 10 days. More recently (in 1914), PICARD reported that he had found *B. Bassiana*, which he calls *Beauveria Bassiana*, in both the perfect and larval states, of cochylis and eudemis, as well as of the cockchafer.

The author was preparing to study the above-mentioned outbreak of muscardine with the object of determining whether it had been transmitted to the silkworm through the agency of other insects, when GHIRLANDA (2) announced his intention of employing *B. Bassiana* as a means of controlling the processional Bombyx of the pine (*Thaumetopoea* [*Cnetocampa*] *pityocampa*).

The author states that such a proceeding is not advisable, for he is of opinion (though GHIRLANDA does not share his view) that the artificial dissemination of *B. Bassiana* would be a serious danger in districts devoted to sericulture, for in the first place, the conidia of the fungus retain their power of germination, under favourable conditions, for over a year, and when transported by air currents, can find suitable hosts, even where silkworms are absent, in the form of other insects, which when attacked, might be a source of fresh infection. In the second place, the fact that it would be necessary to sow the conidia of *B. Bassiana* in August, in order to control the processional Bombyx of the pine, constitutes a serious danger to the summer and autumn rearings of silkworms.

845 - **The Chinchilla Rabbit.** — Castle, W. E, in *Science*, Vol. LIII, No. 1373, pp 387-388. Lancaster, Pa., April 1921.

A considerable interest exists in the breeding of the "Chinchilla" rabbit for its fur, which is of a fine pearl grey colour similar to that of the wild grey rabbit except that:— 1) It contains no yellow, yellow being replaced by white; 2) the black portions are replaced by slaty blue

Apparently, these differences come from a single genetic change, that is to say, from a mutation in the "colour" factor that is less extreme than that which has occurred in the white or albino variety, but affecting the same genetic factor.

If a Chinchilla rabbit is crossed with any of the common colour varieties except white, the "Chinchilla" character, like the "albino" character, behaves as a recessive. If the Chinchilla is crossed with the albino, however, a generation composed entirely of Chinchillas is produced, while in later generations both "Chinchilla" and "albino" young will be found.

These facts indicate the existence of an alternative form or allelomorph of albinism, constituting the fourth allelomorph, albinism, recorded in rabbits. These allelomorphs (in order of decreasing pigmentation) are:— 1) Ordinary pigmentation; 2) Chinchilla; 3) Himalayan albinism; 4) ordinary albinism (snow white). A similar, but not identical, series of allelomorphs was described by Sewall Wright for guineapigs (*Carnegie Institution of Washington*, Publication No. 241, 1916). A homologous albinism to Chinchilla albinism was described by Whiting and King for the rat (*Journal of Experimental Zoology*, Vol. XXVI, 1918).

From an industrial standpoint pelts as large as possible, are desirable, whereas the pelt of the Chinchilla rabbit is relatively small However, it is easy to remedy this defect by crossing pure bred Chinchillas with white Flemish Giants. The F_1 generation will all have the Chinchilla fur and will be in addition intermediate or even larger than intermediate, compared with the parents

By further crossing the half bred Chinchillas with white Flemish, still larger progeny may be obtained, until practically the size of the white Flemish is reached The progeny obtained with this method will be composed of 50 % white and 50 % Chinchilla.

846 - **Canada's Fur Farming Industry** (1). -- Brittain, J. I., Consul General, Winnipeg (Manitoba), in *Commerce Reports*, No. 118, Washington, D C, May 21, 1921.

The raising of wild fur-bearing animals in captivity for their pelts has been carried on in Canada for many years, but it is only within the last few years that fur farming has become an established industry, according to a recently published official report on this subject.

---

(1) See *B.* 1911, No. 2851; *R.* 1914, No. 51; 1916, No 94. (*Ed*)

In 1912 and 1913 the Dominion Commissioner of Conservation conducted an exhaustive inquiry into the history and possibilities of fur farming in Canada, and the resulting data published in 1913, stimulated the industry. The fox has proved the most suited to domestication, although success has been attained in a few instances with mink, skunk, raccoons, and Karacule sheep. The earliest record of raising foxes in captivity comes from Prince Edward Island, where they have been raised for the past 40 years.

In 1919 the Dominion Bureau of Statistics began the annual collection of returns of fur farms in Canada. The returns show that 424 fox farms, 3 mink farms, and 2 raccoon farms were in operation in Canada in that year.

The fur-bearing animals on the farms at the end of the year 1919 numbered 8 396, valued at $3 201 388, comprising 7 181 silver foxes, value $3 110 915 ; 852 patch foxes, value $77 058 ; 275 red foxes, value $11 345 ; 1 gray fox, value $150 ; 1 blue fox, value $120 ; 77 mink value $1 685 ; and 9 raccoons, value $115. There were born in captivity, during the year 1919, 5 048 silver, 510 patch, and 174 red foxes, and 40 mink.

The number of silver pelts sold was 2 134, with a total value of $501 973. This gives an average value of $235 per pelt of silver fox. Patchfox pelts sold numbered 319, value $21 526 (average value $67), and red fox 164, value $4 586 (average value $28). One blue fox pelt was sold, value $65 ; 56 mink, value $1 030 ; and 2 raccoons, value $30. The number of pelts sold in 1919 does not correspond with the number of animals killed for pelts, the sales for the year including some pelts carried over from the previous year, while the pelts of some animals, killed in 1919 were not disposed of in that year.

Of the 429 farms reporting in 1919, 244 were operated by individuals 87 by partnerships, and 98 by joint-stock companies.

FARM ENGINEERING

847 - **The Increase in the Price of Agricultural Machinery since 1913 and the Principal Reasons which have caused it.** — SCHWANECKE, H., in *Die Landmaschine*, Year I, Nos. 8 and 9, pp. 141-143 and 157-162, diag. 2 Berlin, March-April, 1921.

Despite the improvements made, agricultural machinery and implements used to be sold, in Germany, before the war at lower prices than other mechanical productions ; the prices used to vary between 0.45 and 0.75 *mark* per kg. for ordinary ploughs and 2.20 to 2.60 *marks* for motor ploughs (Intermediate prices are given in the text). Favourable conditions having ceased during the war, prices increased, at the beginning of 1918, by 15 to 25 %, and still further ot the end of the war, and after the revolution in Germany at the beginning of 1919, to such an extent that in March, 1920, prices were 12 to 20 times what they were before the war. From that date a decrease commenced, but a very small one, and it was arrested in the following autumn.

For this reason and on account of the greatly increased prices of material used for agricultural machinery (lubricating oils 30 fold, leather 40 fold the pre-war prices), as well as on account of the limits imposed on the prices of agricultural produce, farmers avoided more and more the purchase of fresh machinery in spite of their increasing need for it

The cost of producing machinery depends on three factors, viz. cost of raw material wages, general expenses.

The raw materials required for the manufacture of agricultural machinery are metals, wood, leather, and coal. When the revolution broke out in Germany cast iron and hematite had only doubled in price, relatively to the pre-war period; but towards January, 1919, prices increased 4 to 6 fold, in October, 8 to 9 fold, in January 1920, 14 to 20 fold and reached the maximum of 30 fold in May, 1920, to decrease later to 23-24 fold in the following January. Iron bars and sheet iron reached higher prices in spite of control by the Government. Wood leather, and coal also reached maximum prices of 20, 50 and 12-24 times pre-war prices respectively in March 1920. At present there is a decrease and the author, gives details of the variations. The wages of adult local labour varied in 1914 between 2.45 and 3.80 *marks* in the towns and 2.00 to 3.30 *marks* in the country; in 1918, it varied between 2.70 — 5.10 *marks* and 2.00 — 4.15 *marks*, respectively. Since 1919, wages have increased considerably and at the present time have quadrupled in the towns and tripled in the country, compared with 1914, and there is no sign of the increase bring arrested. In addition, the hours of work and the industry of the workmen have decreased, so that in many foundries production has decreased by one half and the labour required to produce 1 kg. of cast iron costs 8 times as much as it used to.

General costs have approximately increased in the same proportion as wages

These are the reasons why the cost of production of agricultural machinery, which is made up of about ⅓ for the cost of raw material, ⅓ for wages and ⅓ or less for general expenses, has reached 8 to 10 times the pre-war cost.

The author summarises in figures and in diagrams the rates of the three factors of the cost of agricultural machinery and the price of such machinery during various periods between 1914 and 1920 and concludes: — 1) That although the price of machinery varies with the three factors of the cost, it does not increase to quite the same extent; 2) that further considerable decreases in the price of agricultural machinery, at short credit, can scarcely be expected (1).

---

(1) These remarks may also be applied to other countries besides Germany. In Italy the rise in minerals and metals reached a maximum in April, if not in March, 1920, according to BACHI, and the general index number for all wholesale goods reached 836.30, relatively to 100 in 1901-1905 (Cf. *La Metallurgia italiana*, Year 13, No. 3, p. 122. Milan, March 31, 1921). Also the English *Labour Gazette*, which gives some statistical information regarding the variation of wages, price of raw materials, etc. for 1920, states that for that year the general index number for wholesale goods reached the maximum in March, 1920, while wages continue to increase (Cf. *The Economist*, Vol. 92, No. 4040, p. 162. London, Jan. 29, 1921)

848 – **Motorcultural Tests in Vineyards at Béziers.** — PAUL, P (Ingénieur Conseil Viticole), in *Le Progrès agricole et viticole*, Year 38, No, 7, pp. 168-171, figs 1. Montpellier, Feb. 13, 1921.

The Béziers trials are the first at which the practical solution of motorculture in southern vineyards has been considered and treated. They were carried out at the château de Lignan, in vineyards planted at a spacing of 1.75 m., partly in straight lines and partly in " gobelets, " on particlarly favourable ground formed of sandy alluvion. Fifteen machines took part in the tests.

In general, almost all the motor cultivators for vineyards which entered had 18-20 HP motors, giving a tractive force of 10-12 HP working an entire space between lines of vines, either with 5 furrows of a plough or with tillage implements ploughing or digging the same area. The tractive force required seemed therefore well determined. The work performed by the plough pattern machines seemed preferable provided that they can be substituted by implements with vibrating teeth for summer work.

The width of all the machines that entered was approximately 1 m., except one which was only 50 cm. and which was balanced by a wheeled spud working in the next space.

If the tillage implements were of the same width they would leave 37 cm. untilled on either side, with a spacing between the vines of about 1.75 metres, say hand work 70 cm. wide, which would be expensive and inadmissible; with a spacing between the vines of 1.50 m., 25 cm. would remain untouched on each side and hand work 50 cm. wide would have to be done.

Actually the borders remaining to be cultivated by hand in the case of the best driven machines were 45 cm. wide, corresponding to a spacing of the working implements of 1.25 to 1.30 m., while in the same vineyards, with horse traction, the borders which had to be tilled by hand were only 15 cm. wide, or one third of the width.

Under these conditions, which may be considered as extreme, driving is ticklish. The slightest deviation caused by the ground, the machine or the driving, entails damage to the vines in lines on wire palisades. In old vineyards that are not so well aligned and with vinestocks bearing old branches and spaced 1.50 m between rows, it would be almost impossible to use these implements because the deviation could only be straightened out by moving forward and this would tear the vines.

With a 20 H.P. engine taken as an ordinary basis, the work must be done in two operations, working 2 complete half rows in one, two or three parallel spaces between the vines at each transit. The working implements, suitably guided, could thus be brought nearer to or further from the vines as in ordinary work. The instrument of tillage, instead of having its 5 or 6 plowshares on the same frame, would have them on 2 separate frames.

The 18-20 H.P. tractor would be followed by 2 workmen each driving, for winter work, a triple plough instead of a single plough arranged with ploughs similar to those which experience has shown to be suited for each kind of ground. Implements suitable for summer work would be similarly worked.

In this way 1 tractor and 3 men could take the place of 7 teams, and get through more work as the machines would travel at an even, quick pace, less fatiguing for the men drawn by the tractor.

The driver, helped behind by the 2 men guiding and disengaging the implements, raised or not by the engine, would turn more easily and quickly without damage and could work the headlands. At a pace of 3.500 km. per hour (a maximum which should not be exceeded), 4 ha. could be tilled in one way per day. A tractor in similar conditions would till 40 to 45 ha.

The cost of paraffin or petrol for the tractor (about 35 litres) would be approximately the same as for the keep of 6 horses. Three men would be saved as well as the cost of feeding the horses for the many days on which they would be idle.

The cost of maintenance and repair of the tractor would be approximately equal to the cost of maintenance and replacement, in case of accidents, of the 6 horses.

The original purchase price of the tractor (20 000 fr.) would be less than that of the corresponding number of horses.

The recruitment of workmen reduced by $^2/_3$ would be easier and consequently more economical because they would only be required to guide the implements and not have to trouble with the driving and care of the horses.

With work distributed in this way it would be possible to carry out all winter work when the leaves are dead, digging up and cultivating the vineyards, and attached fields. The tractor used and served in this way should be economical. But that is not sufficient. Cultivation in vineyards becomes particularly active and profitable from the time that the branches begin to grow. The more cultivation is prolonged the better. It would be ideal to continue such work up to August.

The use of machines 1 m. wide entered at Béziers ceases be possible in April. From that date it would be necessary either to purchase horses or to use horses which had been fattening idly during the winter, which is economically impossible.

If therefore motor culture is to extend and become general is vineyards it will be necessary to have tractors of such a shape as will permit them to pass between the vines as long as horses can pass there, or even longer if possible.

To solve the problem all that is required is to fit the tractors so that they will pass over the vines (generally so that they will move in a plane about 1.25 m. above the level of the ground.

The tractor so constructed could straddle a line of vine-stocks and move on 2 suitably high wheels in two parallel spaces between the vines. Each wheel being 15 cm. broad and having separate control could pass at any season along the space between the vines. Steering would be done by a lateral hind wheel.

The tractor would draw suitable cultivators, sprayers and powdering machines, in short would carry out all cultural work, during 11 months of the year. The motor-cultivator would then become economical and profitable and find a large market.

A final effort of ingenuity by manufacturers should enable the same tractors, with a simple special addition, to act as transport, for the vintage.

To sum up, according to the author, although the competition of Béziers has not solved the economic problem of "motor-viticulture," it has decidedly put it in the way of being solved at a very early date.

849 – **Causes of the Greater Resistance met with by the Plough when Drawn Mechanically in Comparison with that met in the Case of Animal Traction.** — CASTELLI, M., in *L'Italia agricola*, Year 58, No 4, pp 97-100. Piacenza, April 15, 1921.

Capt. JULIEN (*La Motoculture*) admits that a plough, owing to the fact that it is drawn by a tractor which compresses the ground in front of it, meets with resistance 30 % greater than it would meet with if drawn by animals; he admits therefore that 30 % of the tractive power measured at the draw bar should be attributed to the tractor. The increased power rendered necessary by the use of the tractor may amount to as much as 50 %.

To clear up the question as to whether this increase should be attributed solely to the compression of the soil caused by the tractor, the author investigated the causes which might affect the unit effort (per sq. dm. of section ploughed) of the plough, assuming that the comparison is between ploughing done in the same soil, at the same depth. He limits his consideration to the influence of different conditions of ploughing respectively with a tractor and with animals which are: — 1) The weight of the plough; 2) the direction and position of the line of traction; 3) the compression of the soil; 4) the speed; 5) the errors which may be made in measuring the average force and the depth of ploughing have an importance which is not negligible.

Weight of the plough. — Ploughs for mechanical traction are always heavier than those drawn by animals by at least 10 kg. per sq. dm. of section ploughed; in soils with resistance of from 60 to 100 kg. per sq. dm., an increase in the resistance or tractive effort of about 10 % and often more, results.

Direction and position of the line of traction. — The author considers separately the effect of the slope up (angle between the line of traction and the horizontal) and that of the slope down (angle between the line of traction and the vertical plane of the side of the furrow).

In the case of animal traction the coupling point of the line of traction is always high (yoke for oxen or collar for horses), and it is always possible, by lengthening or shortening the draught, or even by raising or lowering the coupling point of the plough to obtain the slope which requires the least tractive effort, or else to obtain the minimum horizontal projection of that effort more easily. On the other hand, in the case of tractors, the line of traction is always very nearly horizontal; in certain cases, the author has noticed that it was even inclined downwards, so that the force was not at a minimum and that generally it is greater than in the case of animal traction.

The effect of the slope downwards of the line of traction is in practice still more important. It is very variable and greater for tractors, of great breadth which move entirely on the fallow with a short central coupling (in the centre of the axle of gripping wheels), for ploughing with a single plough body. The author considers that, when these conditions are simultaneous, they may cause an increased tractive effort which may exceed 30 %. On the other hand this effort may decrease to nil if the conditions are the reverse (tractors which move with one of the fixed wheels in the furrows; long draught; coupling to a bar jutting out sideways; use of multiple ploughs ploughing widths little less than the breadth of the tractor.

Soil packing. — Naturally in all but exceptional cases, the compression of the soil by the passing of the tractor increases its hardness; but up to what depth is the effect of the pressure noticeable by increasing the resistance to the edge of the ploughshare? The effect is more noticeable in the case of shallow ploughing; and perhaps only noticeable in such cases; but until the contrary is proved, the author thinks increases of 30 %, or even of 20 %, in the resistance may be excluded, since, according to him, the compression of the soil may very considerably increase the resistance to the ploughshare, much less that to the coulter, and scarcely at all that to the mould-board; so that to get total increased resistance of 30 % an increase of 50 %, in round figures, in the resistance to the ploughshare would have to be allowed, which is at least doubtful.

Speed of the plough. — It is generally thought that the resistance to the plough increases with the speed. But the author suspects that effort has often been confused with power. Often an increased speed improves the quality of the ploughing by helping disintegration and turning over, with a presumable increase of effort which should not be attributed to the tractor since it is compensated for by better ploughing.

Influence of the methods adopted on the measurement of the tractive effort and of the depth of ploughing. — The tractive effort is generally deduced from the displacement of a spring placed between the motor and the plough; the deviation of the line of traction from the line of movement is therefore not taken into consideration. The additional error made in neglecting the slope is compensated, wholly or in part, by the decreased work required with a moderate slope up; the additional error made in neglecting the slope down has to be added to the increased work due to the slope down itself. The measurement of the depth of ploughing is below the actual in the case of mechanical ploughing, because it is made from the surface of the fallow next to the furrow which has been compressed by the tractor; in the case of animal traction the measurement is above the actual, either owing to the raising up of the soil at the edge of the furrow or to the constant sideways movement of the plough.

Summary: — It is true that the resistance and, consequently the mechanical work, required for ploughing, is considerably greater when the plough is drawn by a tractor than in the case of animal traction, but the greater work (also noticed with windlass traction) should be attributed in a small degree to the compression of the soil and in a greater degree to various causes, such as the heavier weight of the plough, the downwards slope of the line of traction, the greater speed, and to systematic errors in the measurement of the depth of the furrow.

Regarding remedial measures, it is not necessary to trouble about the greater speed, since the greater resistance which results from that cause is compensated for by better ploughing; the greater weight is necessary, up to a certain point, to give greater stability which is indispensable owing to the greater speed; beyond that limit it should be avoided either by good material or by eliminating complicated mechanism for raising, steering, etc.; the effect of deviation of the line of traction, especially of the slope should down have the serious attention of manufacturers and agriculturists. Means eliminating errors of measurement of the depth of the furrow are known (use of pantographs, accurate horizontal planes for reference, etc.) but are laborious and they are not always applicable to tests laid down in competitions.

850 - **The Torelli Spraying Motor pump.** — BARDELLINI, S , in the *Giornale di Agricoltura della Domenica*, Year XXXI, No. 24, p. 190, figs. 2. Piacenza, June 12, 1921.

This machine is made by TORELLI Brothers, of Villa Sesso (Reggio Emilia) and is of two types: — 1) Mounted on its own truck; 2) mounted with the barrel of copper solution.

It is essentially composed of a 3 HP., 1 cylinder, benzol engine and a force pump. The motor runs at 800 revolutions a minute; it has controlled valves with high tension magneto, Zenith carburettor and centrifugal governor. Transmission is by cylindrical gearings; these work on a bent shaft, fixed on adjustable sockets; this shaft transmits the motion to the horizontal piston of the pumps. The latter is in bronze and is double action, that is to say with 4 valves which enable the force of the forward and backward strokes of the piston to be utilised. The pump, with 4 jets, gives a pressure of 7-8 atmospheres and the piston makes about 60 forward and 60 backward strokes a minute. It is provided with an ample compressed-air chamber with a special safety valve, adjustable to all pressures which allows the unused liquid to flow back into the barrel. The engine consumes about 9 litres of benzol in 10 hours', work and the four jets can spray about 10 quintals of copper solution an hour.

The pump works easily even for jets of a distance of 40-50 m.

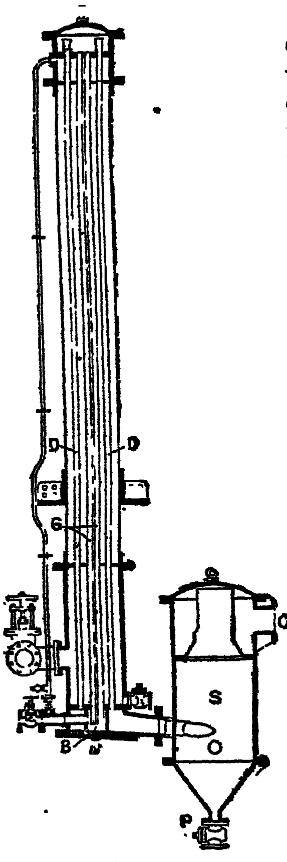
An arrangement enables any excess of copper solution, due either to rupture of the rubber or blocking of a jet, to pass back into the barrel.

To work the pump 4 persons are required for the 4 tubes, one for the motor and a child to move the rubber tubing.

The motor pump gives economy in the use of spraying solution and the spraying is more perfect because the jet, propelled at high pressure, penetrates the foliage better. As the machine moves along the paths there is no treading down of the crops.

851 – **The Kestner Concentrator.** — CAUVERGER E., in the *Revue agricole de l'Afrique du Nord*, Year 19, No. 97, pp. 456-458, figs. 2. Algiers, June 10, 1921.

The essential characteristic of this apparatus, already used in many establishments, is that they concentrate the juice in a single passage; the juice put into the apparatus passes out of it after a few seconds at the desired concentration.



Section of the KESTNER apparatus.

The process of working is as follows: —

The evaporator consists of a tubular bundle *G.D.* 7 m. long enclosed in a jacket which holds the steam for heating. The lower box is chambered and divides the bundle into two parts; one of which is attached to the tubing through which the unevaporated must enters, the other to a separator; this is the so-called " ascending and descending " method.

The unevaporated juice, drawn in by a feed pump, with regulated output is forced into the evaporator situated in the lower part of the ascending tubes first of all passing through a heater.

Under the influence of the heat it begins to boil rapidly, the closed bubbles of steam rise rapidly and carry with them the liquid in a thin layer along the heating walls of the ascending tubes.

When it reaches the upper part of the apparatus the liquid descends in a similar manner by a series of descending tubes in which concentration is completed.

Finally, the liquid being concentrated, the steam escapes at the bottom of the bundle and passes into the centrifugal separator where the separation of the concentrated liquid is effected and the concentrated liquid runs off by gravitation or is drawn off by an exhaust pump while the steam from the evaporation of the water taken out of the must escapes by the upper part into the air or is taken off by a vacuum pump, according as the apparatus works at atmospheric pressure or *in vacuo*.

The KESTNER concentrator can, in fact, work *inv acuo* if a vacuum pump and a water condenser are attached to it. In that case the evaporation temperature does not exceed 50°C. and this low temperature evidently adds to the certainty that the concentrated juice will not be changed in any way.

RESULTS. — Tests carried out by Prof. WARCOLLIER, Director of the Pomological Station at Caen, with apple juice gave the results indicated below in Table I.

But, and this is of capital importance for the concentration of grape musts, the apparatus can concentrate strongly sulphited musts by causing complete desulphitation See Table II, for the results obtained by Prof. WARCOLLIER with apple juice.

Finally complete desulphitation of strongly sulphited musts was obtained with a $^1/_{10}$ evaporation that, is to say with practically no concentration.

TABLE I.

Estimations calculated for 1 litre of juice	Must as it left the press	Same must after concentration at reduced pressure (vacuum = 35 ‰)	Same must concentration at atmospheric pressure
Density	1.045	1.3316	1.2906
Degrees Baume	6°	35.9°	32.4°
Saccharose. . . . . gm	8.4	61.5	52.5
Glucose . . . . gm	17.7	143	119
Levulose . . . . gm	66.9	503	432.05
Total dry extract at 100° C. . gm	115.2	857.2	738.4
Total acidity	2.2 per 1000	12.5 per 1000	10.7 per 1000

TABLE II.

Estimations calculated for 1 litre of juice	Must defecated and sulphited with 40 gm of sulphurous acid per hl.	Same must concentrated under reduced pressurs (vacunm = 35 ‰)	Same must concentrated at atmospheric pressure
Density	1.048	1.3428	1.2492
Degrees Baumé	6.6°	36.7°	32.7°
Saccharose. . . . . gm	8.4	64.2	54.5
Glucose . . . . gm	20.8	158.5	136.5
Levulose . . . . gm	67.9	521	439.5
Total dry extract at 100° C . gm	120.1	905.4	772.6
Total acidity	21 per 1000	12.9 per 1000	10.7 per 1000
Free sulphurous acid. . . . gm	0.025	nil	nil
Sulphur. acid in combination, gm	0.487	0.280	0.270
Total sulphurous acid. . . . gm	0.512	0.280	0.270

The quality of the products obtained leaves nothing to be desired; the rapidity with which the concentration takes place does not allow of any modification of the peculiar properties of the juice.

The working of the apparatus, once regulated, is automatic, requires no learning and can be attended to by any workman. It is quite easily cleaned; all that is required to keep it always clean is to pass a little water made slightly alkaline through it from time to time.

852 - **The Cirio Aeropycnometer for Measuring the Concentrations of Tomato Preserves** (1). — CARRASCO, A (Laboratorio chimico della Società generale delle Conserve alimentari "Cirio"), in *L'Industria alimentare italiana*, Year III, No. 1, pp. 6-8, figs. 2. Rome, Jan. 15 1921.

It is composed of 3 parts, in glass, easily put together: — 1) Central cylindrical container of the most suitable shape for filling with products of a soft consistency; 2) ground-glass stopper and 3) a graduated column connected with the floating bulb.

The graduation of the apparatus is based on a solution of sugar; the zero indicates the level at which the apparatus floats when the pycnometer is filled with distilled water; the 10th degree the level at which it floats when the pycnometer is filled with a 50 % solution of saccharose ($d = 1.223$); the interval is divided into 10 equal parts. As liquid for immersion distilled water is used or common drinking water can be used without affecting the result.

The central container must be filled without air bubbles; with this object a special pipette is used for products; of average concentration; for very concentrated products a kind of bag with a hood is used.

RURAL ECONOMICS

853 - **Researches into the Returns of Swiss Agriculture During the Years 1917-1918 and 1919-1920 Part 1** (Report presented by the Swiss Peasants' Secretariat to the Swiss Department of Public Economy). — LAUR, E. Director of the Secretariat, ZAUGG F. Chief of Division, and NATER, H. Assistant, in the *Landwirtschaftliches Jahrbuch der Schweiz*, Year 35, No. 1, pp. 91-173, Tables 38. Lucerne, 1921

This is the first part of a detailed account of the yields of Swiss agriculture during the agricultural years 1918, 1919 and 1920 (beginning on March 1), drawn up under the auspices of the *Swiss Peasants secretariat*, which has its head-quarters at Brougg (2).

According to an agreement made with the *Federal Department of Public Economy*, this 1st part (containing the results of general researches dealing with matters of which the publication is most urgent), will be followed by a 2nd part containing data referring to researches on the effect of the system of utilising the ground, and to the direction production is taking, as well as an account of a series of special investigations.

This first part of the Report is divided into 2 chapters: —

1) The Progress and Present condition of Swiss Agriculture;
2) The Results of Investigations into the Returns.

---

(1) Made by Dr. BONAZZI and Co, Scientific instrument makers, Milan.

(2) This work is connected with others of the same character relating to preceding years, and of which the *Review* contains special résumes. See: *Investigations into the Returns of Swiss Agriculture During the year* 1913-1914 in *R.* Jan. 1916, Nos. 101 and 104; *Research work of the Swiss Peasants' Secretariat on the Swiss Agricultural yields During the years* 1914-1915, 1915-1916, 1916-1917 and 1917-1918, in *R.*, Sept. 1920, No. 907. — On the utilisation of the profits made by Swiss peasants, and the results of book-keeping by double entry, See *R.* Sept. 1917, No. 546, and *R.* May 1920, No. 571. (*Ed.*)

The progress and condition of Swiss Agriculture. — The authors furnish information and data regarding agriculture in Switzerland during the biennial period under consideration. and draw useful comparisons between this time and previous years as far back as 1901, the date at which the Secretariat commenced work. The information and data deal with the climate, unfavourable conditions for crops, yield, milk production, epizootic diseases, foreign trade, variations in price, rates of interest on mortgages, political economy, political events, the general business, situation, and summary of the agricultural situation.

The following is a summary of the observations of a general nature, or of technical and economic agricultural interest. In 1918, the February frosts produced large bare patches in the winter wheat-fields, the injury being aggravated by the atacks of wireworms (*Agriotes lineatus*). Many fields had to be resown with manitoba wheat or spring barley. The few fields that remained almost immune, were liberally manured with sulphate, of ammonia or cyanamide ot calcium and recovered fairly well. Injury due to straw blight (*Ophiobolus graminis*) was also observed in the fields of cereals, especially in those that had been re-sown. The dry spring of that year protected cereals well from the attacks of rusts (*Puccinia*) but decreased the leguminous and forage crops. Some late frosts did temporary damage; *Phytophthora* and leaf-curl did a little injury to the potatoes; the larvae and butterflies of *Pieris brassicae* were few in number, but nevertheless the Cantonal authorities ordered them to be caught. The vines and fruit trees promised well in March 1918, but they suffered from late frosts, and, subsequently, from the attacks of Geometrids, moths, aphids and *Anthonomus*; to these injuries must also be added the damage caused by the spring drought and the dry summer which made the fruit fall.

In the spring of 1919, a terrible hurricane due to the " föhn, " burst over Switzerland, and overthrew 30 or 40 % of the trees in the orchards and forests (1). This was followed by mild days, but subsequently there were late frosts which caused great injury to arboriculture and set back the spring crops. The oats were especially backward, and their germination was imperfect; in addition, much damage was done by frit fly, and the crops had to be resown in many places. Wheat and spelt suffered much from smut and the crops which were apparently healthy, sustained a loss amounting to from 10 to 30 %; these last years have appeared very favourable to this disease both in Switzerland and elsewhere (2).

(1) For the damage caused by this hurricane, see, GREYEYZ, Ueber die Föhnstarmkatastrophe vom. 4-5. Januar 1919, in Berner Oberland, dans *Schweizerische Zeitschrift für Forstwesen*, year 71, p. 2, Berne, Jan. 1921. (*Ed.*)

(2) According to MUNERATI's experiments, the late sowing of winter wheat and the early sowing of spring wheat promote the growth of smut, Cf. PEGLION, *Lemalattie crittogamiche delle piante coltivate.* Ottavi, Casale (Italy), 1912, p. 145 The same facts were noticed by JOVINO at Foggia, in 1918 and 1919; he considers that this recrudescence of smut during and after the War as due to defective cultural operations (of natural occurence at such an exceptional time), especially to the untimely preparation of seed-beds, and to sowing out of season Cf. *L'Agricoltura Materana*, Year 8, No. 2, Matera, Sept. 1920. (*Ed.*)

The summer pastures were poor, and were injured, by cockchafer larvae, the hoed crops were fairly good, but the potatoes, though sound when lifted, were attacked later, in store, by dry rot. Field-mice also contributed their quota to the damage. Fruit was scarce, but vegetables, with the exception of kidney-beans, were good.

The report contains data referring to the crops of 1917, 1918, and 1919 expressed in percentages of the average for the preceding decade. It also contains tables giving the milk production during the same period — all information which has been obtained by the *Central Office of the Swiss Peasants' League for Communicating Prices*; the monthly consignments of milk to the cheese factories and milk-collecting centres are also given.

The number of Associations for supplying milk vary annually from 1384 to 1598; a total of 477 238 kg. in 1917, 471 222 kg. in 1918, and 402 868 kg. in 1919. On account of the enormous drop in production in 1919 (to 62.3 % of that in 1914), milk ration cards were introduced.

The statistics referring to epizootic diseases from 1886 to 1919 are of special interest, and show great variations in the prevalence of foot-and-mouth disease. This disease was worst in 1913, when there were 45 966 cases among the cattle and 22 125 among smaller stock. During the last 5 months of 1919, it was exceptionally severe both in Switzerland and Italy, 50 % of the cases being in some instances fatal, which meant sheer ruin to the Swiss.

The imports and exports are given from 1885 to 1919. As regards the variations in price, the *Central Office* was able to verify these every month by means of its agents all over Switzerland, who sent information on the subject once or twice every month.

Of the many data referring to different agricultural products for the years 1870 to 1919, the basis adopted (100) was the average price from 1900 to 1909, it is enough to mention that the highest prices were in 1918; in round figures, 431 for tobacco, 449 for wine, 445 for vegetables, 497 for pork products, and 431 for eggs, with a general average of 310.07. In 1919, there was a considerable fall in prices, the average being 291.50 except in the case of milk which rose, and from 17.05 centimes per litre in 1914 gradually reached 25 65 centimes in 1917, 30.75 in 1918, and 34.40 in 1919.

The interest on mortgages rose on an average in the 28 Institutes of Credit from 4.143 % in 1900-1905, to 4.908 % in 1917, 4.915 in 1918, and 5.055 % in 1919.

In 1918, the Office of Food and other similar war institutions found themselves confronted by serious difficulties, and agriculturists had to submit for a second time to the compulsory planting of crops. Cattle were exported by way of compensation, but trade was increasingly difficult, owing to the depreciation of the foreign exchanges. Switzerland could not escape the effect of the economic depression that followed the defeat of the Central Powers.

An improvement took place in the second half of 1919, the year, when, owing to the removal of trade restrictions, Switzerland was able to throw large reserves of goods upon the markets where production was held up by strikes and sabotage, but the high foreign exchange was a serious obstacle. As a matter of fact, Switzerland itself was not free from strikes, but the local agriculturists restored the order disturbed by the strikes of Zurich and Bâle.

The elections of Oct. 1919 (which were proportional for the first time in Switzerland) gave unexpecteed power to social democrats and to the agrarian party.

During the last two years, artisans have, as a rule not suffered from want of employment in the country, although this was not often the case in the towns.

Results of researches on returns. — Book-keeping by simple entry is employed by the Secretariat (1). From 1918 to 1920, the number of farms whose books were submitted for examination increased in a very satisfactory manner. In 1919, the Secretariat received, at the right date, 405 book-keeping returns for the financial year 1918-1919, and 392 of these could be used as a basis for statistics; in 1920, the Secretariat received 426 returns for the year 1919-1920, and 421 supplied balance sheets that could be utilised.

1) *Production costs.* — Table I, which has been reproduced as it stands from the publication in question, gives the production cost per hectare of cultivated area for each of the 5 classes of farms, arranged in decreasing order of size, viz., *a*) *small farms* (3 to 5 hectares ;) *b*) *small peasant farms* (5 to 10 hectares); *c*) *peasant farms* (10 - 15 hectares); *d*) *large peasant farms* (15-30 hectares); *e*) *very large* farms (over 30 hectares). The monetary unit is the franc at par, and simple interest is calculated.

Table I is followed by notes on each sub-group of accounts, giving the method of enquiry, any possible unusual influences, and deductions of an economic and social character.

Under the head of *depreciation*, the annual wear and tear of objects in daily use is taken into account. In order to estimate, in a somewhat conventional manner, the difference between the purchase price (initial value) of an object, and its value when it can no longer be used (final value) is divided by the number of years it has been used; in this way, the annual depreciation is obtained. In the case of plantations, lots are taken. As regards cattle, the register of the number of head is customary in Switzerland. The depreciation of cattle is calculated on the basis of information obtained by means of a special book-keeping formula giving the depreciation, or plus-value of each animal. The high depreciation figures of late years are due to the fact that, the accountants were obliged to conform to the high war prices. The authors, however, are of opinion that these figures were actually too low, because the high war prices, at which cattle forming the stock capital were purchased, must soon, perhaps in 4 years, fall to their normal level.

---

(1) Cf. E. Laur., *Grundlagen und Methoden der Bewertung, Buchzltung und Kalkulation in der Landwirtschaft*, Parey, Berlin, 1911, p. 129; also " *Les Offices de comptabilite agricole dans les divers pays*, Inst. Intit. of Agric., Rome, 1920, p. 184. (*Ed.*)

The accountants raised the rate of depreciation of the cattle each time that the prices showed great variation, no matter whether they fell (1914) or rose (1919).

For 100 francs of the capital under consideration, the accounts show the variations in annual depreciation given in Table II as the average for the different classes of farms for the period 1909-1919.

TABLE II. — *Variations in annual depreciation* (in %).

	Buildings	Improvements	Implements and machines	Horses
Minimum . .	1.08 (1908-1910)	2.14 (1916)	5.06 (1908-1910)	3.66 (1908-1910)
Average (1908-19). .	1.44	2.57	5.29	6.34
Maximum . .	1.76 (1916)	2.87 (1919)	5.95 (1915)	10.54 (1919)

The average depreciation of the horse capital was 7.9 % in 1918, and 10.5 % in 1919; 10 % being the estimate according to rule.

On the other hand, the average annual depreciation of the cattle between 1913 and 1919, was 3.96 % with variations ranging from 1.95 % (1916) to 6.85 (1914) for time and between 3.68 (small farms) and 4.67 (very large farms) for area. The average for cows considered separately was 5.9 % with variations from 2.81 (1916) to 9.5 (1914) and from 5.3 (small farms) to 6.2 (very large farms).

If the repairs and depreciation of machinery and implements are added the purchase cost of small objects of inventory, together with interest at 5 % and 0.2 % allowed for taxes and insurance, we obtain the sum of the annual allocation, which for the years 1908-1919, can be estimated on an average at 16.66 % of the capital employed, and for 1918-1919 at 19 %.

As regards the crop account, the authors leave out of consideration the actual outlay, as it a question of book-keeping by single entry, and merely consider the extraordinary cultural operations of which the effects will only be shown in future years and they register a decrease in the cost of production, and an increase in the annual gross production. The small amount of the crop account estimated in this way is perhaps due less to the low rate of depreciation than to the amount of capital placed in crops, as this has greatly decreased during the war.

By stock in hand is to be understood all the raw material produced on the farm and of which the greater part is consumed on it. The increase in value at the end of the year is credited to the total gross produce account, and the decrease to the cost of production. The small difference due to the stock in hand is explained by the fact that the agricultural year begins with March 1. Of recent years the stock in hand also increased with the prices.

The *working expenses* («Betriebskoste») include, in the first place, the *cost of running the farm* («Betriebsausgaben») exclusive of payment of interest, wages, the purchase of live stock, and all the out goings that increase the estate capital or the dead stock; into this account also come any expenses incurred under the three heads of houschold, dependant branches, and family, and finally all changes in the inventory due to purchased raw materials. The working expenses have risen considerably of recent years owing to the increased cost of goods, and to the more intense system of, agriculture adopted.

Table III. gives the quinquennial averages of the working expenses per hectare cultivated as calculated from the authors' Table.

TABLE III — *Quinquennial averages of working expenses* (in francs).

Years	Area of the farms					Average
	3–5 hectares	5–10 hectares]	10–15 hectares	15–30 hectares	Above 39 hectares	
1908–1913 . . .	219	171	156	154	143	**169**
1914–1919 . . .	293	220	212	200	192	**220**

In 1919, the working expenses per hectare attained their maximum, being 100 % above the average for 1908-1913, and 1 % above that for 1914-1915. It must be noted that the increase of these expenses was in inverse proportion to the size of the farm, a fact which is not without effect upon the returns.

The charge of the current banking account on the production expense was very small, for as a rule in Swiss agriculture, this account is rarely used for obtaining credit; it is more often employed for making payments.

The rate of interest on the various capital accounts are calculated as follows: —

Estate capital	Land.	3.5
	Improvements	4.0
	Buildings	4.0
	Plantations	4.5
Farm capital		by difference (1)
Working capital (total)		4.0

The interest on the capital is on the increase, especially in 1919. That on the farm capital is steadily and considerably increasing; in this respect the figures for 1919 show a rise of 56 % as compared with the average for 1913-15. The interest on the land capital in 1919 is 10 % higher than the average for 1913-17, owing to the purchase of land at high prices. This fact has however, but little effect upon the total production expenses; in fact the increase observed in 1919 only amounted to 0.9 % of the production expenses for the period 1913-17. The interest of the money invested in buildings has altered in a similar manner.

---

(1) It is a question here of the difference between the total interest on the working capital and that on the estate capital.

Cost of labour (*"Arbeitsaufwand"*) includes: — *a*) All the expenses connected with all workers other than members of the family; these expenses usually consist of wages, board and payment in kind; *b*) the customary remuneration paid to members of the family in cash for manual work and management, these being calculated at the rate fixed for salaried hands (1).

The authors give in detail the increase in, and the apportioning of, these payments for the years 1901-1919. It suffices to give a summary here of the maximum, minimum and average for farms of different sizes. It is to be understood, that by working day is meant the entire work that can be performed by an adult man of full strength in one day.

TABLE IV. — *Increase and apportioning of the cost of labour from* 1901-1019.

		Minimum	Average (1901-1919)	Maximum
		fr.	fr.	fr.
Cost per hectare of work	farmer's family	185.50 (1901)	231.49	445.20 (1919)
	salaried hands	71.85 (1901)	118.70	245.99 (1919)
Days of work per hectare	farmer's family	47 (1910)	53	60 (1904)
	salaried hands	26 (1902)	33	35 (an. div.)
Cost of work per day. .	farmer's family	2.70 (1905)	3.76	8.04 (1919)
	salaried hands	2.17 (1901)	3.15	5.83 (1919)

In the average for 1901-1919, the ratio of the days of work performed by the family and salaried hands per hectare is 123 :19 for very small farms, 84:28 for small farms, 58:29 for average sized, 36:39 for large farms, and 20:35 for very large farms.

The sum of the preceding figures gives the *total cost of production for the farm*, and this, minus the interest on the working capital, gives the *working-expenses* (" betriebsaufwand "). The Secretariat gives the cost of production since 1908, and the working expenses since 1901. to find the cost of production for each article of produce, special calculations are required.

In the general average of the farms, the increase in the cost of production, as compared with the preceding average for 1908-1917, may be apportioned in round numbers as follows: — To cost of labour 66 % in 1918, 54 % in 1919; to current working expenses 18 % in 1918, 26 % in 1919; to interest on capital 9 %. Of the latter 6 % is on the farm capital, and 3 % on the estate capital, of which only 1.3 % is represented by the land capital.

2) *Gross Return*. These are exactly reproduced in Table V (pp. 1026) extracted for the Report.

---

(2) See LAUR, l. c, p. 113 (*E. d.*).

It should be noted that the gross-returns account is divided under 3 sub-headings i. e., sales account, gross-returns account proper, and complementary accounts.

From 1915 to 1919, the prices fetched, per quintal by fodders and cereals in Switzerland and registered by the Central Bureau, are given in Table VI.

TABLE VI. — *Prices of fodders and cereals in Switzerland from* 1915 *to* 1919 (*francs per quintal*).

	1915	1916	1917	1918	1919
Wheat	38.34	44.65	60.15	64	64
Spelt	27.39	35.48	51.25	52	50
Oats	33.98	41.16	54.53	62	61.50
Rye	32.96	41.77	58.80	64	63.37
Potatoes	13.44	18.71	20.11	20.80	20.99
Hay	9.03	12.05	13.77	17.00	30.06

The variations in the sales account given in the text show that until the end of 1917, the sales and consignments of potatoes and cereals per hectare were the same; that until the war, all the sales decreased (8 % of the total gross returns from 1908 to 1917) in proportion to the reduction in the fields cultivated, then rise considerably until 1918 (15.7 %), and again fell in 1919 (13.8 %), at the time when compulsory cultivation and requisitions were no longer in force.

The authors give the crops from various trees with the unit prices, or indices; the data show that the gross yield of the trees greatly increased during the last three-year period.

The gross returns from the cattle are derived from: — Increase in number, milk and its products, service of bulls, carting, etc. Usually, milk production rises, and the increase in the number of the stock declines when the farm becomes larger. The large increase in the stock that began in 1915 and attained its maximum in 1918, can be explained by the reduced milk production, and the high price of cattle. During the last 5 years, the number of young cattle in the spring per farm was as follows: — 2 3 (1920) to 3.4 (1916) on an average inv *ery small farms*; 3.6 (1915) to 4.5 (1917) for *small farms*; 5.4 (1915 and 1919) to 6 (1918) in *average sized farms*; 7. 5. (1915 and 1919) to 9.7 on *large farms*; and 12 (1915) to 16.7 (1917) on *very large farms.* The prices per quintal of live weight show that the prices in 1919, were in round numbers three times what they were in 1913.

The data of the gross dairy returns are most interesting. The price curve shows a first maximum (20 centimes per kg. of milk) in 1912, followed by a minimum in 1914 (17.05), then another rise continuing until 1919 (34.40), the year when the reduced production was compensated for by the high price.

[853]

Pig-breeding is practised most on small holdings, and has proved very remunerative of late years, owing to the high unit prices. The same holds good as regards other stock.

3) *Net returns.* — These are the returns on all the working capital belonging to the farmer, or borrowed by him, and can be calculated in different ways.

a) Total gross returns — Working expenses = Net returns.

b) Agricultural returns + interest on reserve capital — Remuneration of farmer and his family = Net Returns.,

The authors show the variation of the net returns from 1901 to 1919, on the one hand, as a percentage of the working capital and, on the other, per hectare of area under cultivation, including forests. These data are summarised in Table VII.

Further, between 1901 and 1919, in the average of all the farms the total gross returns were divided into 67.7 % for working expenses, and 32.3 % for the net returns (30.9 in 1919), respectively, the working expenses ranging from 49.1 (1918) to 84.1 (1913) and the net returns from 15.9 (1913) and 50.9 (1918). Under the same conditions, 100 fr. of working expenses correspond to 44.63 fr. of net returns varying at the time between 18.84 (1913) and 103.54 (1918) (44.65 for 1919) and, in proportion to the increasing size of the farm, in round numbers as 28 : 44 : 49 : 54 : 57.

All the net return accounts show that the relative net return, that is to say the return per hectare, is less high in small farms. Hence, the large farm has the advantage over the small one from the point of view of the returns it furnishes to the farmer himself, but the small property proves itself equal, or superior, to the large from the standpoint of national economy and the possibility it offers to the farmer to engage in accessory occupations.

4) *The return on the net capital* obtained by the method of ponderable averages constitutes the remuneration of the net capital engaged in the farm (not including the goods belonging to the honsehold and dependent branches). It can be calculated in two ways:

a) Agricultural income — Remuneration of the labour of the farmer and his family = Returns on the net capital.

b) Net returns — Interest on reserve capital = Returns on net capital: —

Further: —

Returns on net capital — Interest on net capital = Gain or loss of the farmer.

Of recent years, the returns on the net capital have generally been higher than the net returns. This is because the interest on the borrowed capital has always been less than the increased nèt return that it is has been possible to obtain ; the interest on the net capital has increased by this difference.

(5) *The remuneration of the labour of the farmer and his family* is calculated as follows:

TABLE VII. — *Variations in net returns from* 1901-1919.

Agricultural Income — Interest on the net capital = Remuneration of the labour of the farmer and his family.

This remuneration, which is calculated in kind per working day of an adult man, was low before the war* (on an average from 1.19 fr. to 4. 55 fr. for the 5 classes of farms between 1901 and 1914), but afterwards it rose rapidly.

If 5 % is the rate of interest on the capital, the amount remaining for the remuneration of the farmer and his family is that given in Table IX

(6) *Agricultural income.* — By this is understood all that can be used without decreasing the net capital. It is estimated in two ways, of which the simpler is as follows: —

TABLE IX. — *Remuneration of the Work of the Farmer and his Family*

(in francs per day)

Size of Farms		1916	1917	1918	1919
3–5 hectares	3.74	4.90	7.66	11.06	7.44

Average (at 5%) . . .	**5.77**	**8.40**	**12.87**	**20.20**	**13.37**
Average (at 4%) . . .	**6.39**	**9.04**	**13.53**	**20.63**	**14.13**
Difference	*0.62*	*0.64*	*0.66*	*0.43*	*0.76*

Consumption of the farmers family + Variations in income = Total income.

Hence we deduce: —

Total income — (Household income + income from independent branches) = Agricultural income.

TABLE X. — *Agricultural Income + Household Income from* 1901 *to* 1919

The present publication gives the total agricultural income including the household income per farm, per hectare and per day's work of the family. Table X gives the summary

Given the needy condition of the Exchequer, the amount of the agricultural income is of great importance at the present time, both to the agriculturalists themselves, and to the authorities. It should be remarked that as calculated above, it includes not only the income of work properly so-called, but also the interest on the income engaged in agriculture. It is therefore necessary, when taxing work, to differentiate between these two elements, and only tax what is really work. It must further be mentioned that the figures given refer to the whole farm, and not to a single individual; now, an entire farm occupies, on *an average,* from 1.5 to 2.5 adult members of the family. The authors also lay great stress on the fact, that in levying the tax, these figures must be used with the greatest caution.

[853]

If they are employed for this purpose due regard must be paid to the system of cultivation, the class of produce, the debts contracted, and the number of workers in the family.

The agricultural income of the farmer, not counting the household income, is given in Table XI.

Compared with 1918, there were the following falls in 1919.

	Per cent.
Net return	43.7
Net income	57
Remuneration of work	33.8
Agricultural income	23.3

(7) *Conclusions.* — The year 1918 gave results favourable beyond all expectation. The cost of production increased, but its effects were more than counterbalanced by the larger gross returns realised in every branch of agriculture. Prices rose considerably higher than in 1917, but nevertheless, the produce of the soil was more in demand than it had ever been before the war. The agriculturist had every reason to be satisfied; the vintage was more abundant then it had been for many years, and the wine fetched high prices. Good returns were also obtained from bee-keeping. The price of cattle gave great encouragement to the breeder. By a fortunate coincidence, the factors were all favourable to the net returns which rose to 15 % of the agricultural capital. The year 1918 was a record one for Swiss agriculture.

TABLE IX. — *Agricultural income without household income.*

(in francs).

Years	Farms					General average
	very small	small	average	large	very large	
			Per Farm:

1919	4128.45	7779.65	10915.25	13332.00	23060.30	10070.70
1908–1919	2601.05	4420.45	6307.75	8299.75	11581.00	5819.10
			Per Working-day.			
1908–1913	3.56	4.55	5.24	6.91	6.32	5.35
1914–1918	7.90	10.08	12.66	17.20	22.50	12.83
1917	9.06	11.90	13.82	20.42	24.27	14.17
1918	12.38	15.92	21.21	29.52	42.01	21.43
1919	9.84	12.92	17.11	19.86	29.82	16.43
1908–1919	5.63	7.31	8.75	12.05	14.42	9.09

In 1919, the first step was taken on the downward path The field crops were light, there were few grapes, the cattle returns were low, and it was only due to the high prices of milk and pigs that the gross returns were but 7.25 % lower than in the preceding year, though the working expenses rose by 26 %. The cost of labour was increased to a special degree, and the current working expenses, amount of depreciation and subsequently, other costs, followed suit. The retrograde movement of the returns must be attributed to the twofold influence of the fall in gross returns, and the rise in the working expenses, which were responsible respectively for $^2/_3$ and $1/3$ of the decrease in the net returns of 1918, though the former increase, and the latter decrease, with the size of the farm.

The agricultural results obtained in 1919 should, however, be regarded as satisfactory, but it is to be foreseen that the fall in returns will continue, and become still more marked, owing, among other reasons to the spread of foot-and mouth disease.

AGRICULTURAL INDUSTRIES

854 - **Studies on Fruit Wines.** — MULLER-THURGAU and OSTERWALDER, U.: I. — The Influence of the Stage of Ripeness of the Fruit upon the Acceleration of the Fermentation Due to the Various Nitrogenous Compounds. — II. — The Importance of Blending Musts in Order to Preserve Fruit Wines. — III. — Cellar Experiments to obtain Pure Fermentation and to Preserve Fruit Wines. — IV. — Lactic Fermentation appearing in Fruit Wines after the Complete Fermentation of the Sugar. — Reprint from the *Landwirtschaftlichen Jahrbuch der Schweiz*, 1920, p. 62. Lucerne, Keller and Co., 1920.

I. — The juice obtained by pressure from 4 varieties of pear (Theilersbirne, Schweizer Wasserbirne, Marxenbirne, and Sürlerbirne), when green, ripe, and over ripe, with or without the addition of ammonium, chloride or carbonate, was left to ferment in the presence or absence of pure yeasts.

The ammonium salts (in the proportion of 0.4 gm. per litre of juice) were found to accelerate the fermentation, thus confirming the results previously obtained (Untersuchungen über die Einwirkung von Stickstoffzusätzen auf die Gärung von Obstwein, *Jahrbuch der Schweiz*, 1917, pp. 44-98). In the case of the unripe pears, the acceleration was less than in that of the ripe fruit, so that it may be concluded that the juice of the former contains more assimilable nitrogen than that of the latter. In all the cases, the fermentation proceeded slowly, but on the addition of pure yeasts, the juice of the green pears fermented at least as quickly as the juice of the ripe pears, for the high tannin content of the unripe fruit had no perceptible retarding effect. The juice of green pears, especially if nitrogen salts are present, ferment completely in a fortnight when pure yeast is added. This rapid fermentation prevents the deleterious action of other ferments which are naturally present (for instance, *Saccharomyces apiculatus*), and often occur in large numbers in the juice.

III. — Fruit wines, particularly those containing little tannin and of a low degree of acidity, usually require more careful treatment in the cellar than grape wines.

A common disease of fruit wines is characterised by the formation of lactic and acetic acid, and contrary to what occurs in ordinary acetic fermentation, it cannot be stopped by the exclusion of air. The best preventive measures are as follows: 1) Rapid fermentation by means of the addition of pure yeasts and ammonium salts; 2) the avoidance of high temperatures. When the fermentation is finished, it is advisable to treat with sulphur dioxide or metabisulphite, in order to prevent the appearance of disease.

IV. — Another clearly defined disease, accompanied by the formation of mannite and of lactic and acetic acids, is caused by *Bacterium mannitopoeum*. During fermentation, the above-mentioned acids and other volatile acids are produced at the expense of the sugar, but as soon as the fermentation is finished, they can also be formed from the glycerine and other extractive substances.

II. — In order to prevent the occurrence of the disease in juices deficient in acidity, and with too low a tannin content, it is advisable to mix them before fermentation with the juice of pears or apples rich in acids and tannin. The attempts at correction by adding pear-juice with a high tannin content alone did not give wholly satisfactory results. The juice thus corrected should be fermented as soon as possible by means of the above-mentioned processes, and treated with sulphurous acid when the fermentation is terminated.

855 – Sudden Physiological Changes in Lactic Ferments Due to Individual Divergences.

— GORINI, C., in the *Comptes rendus de l'Académie des Sciences*, Vol. 172, No. 22, pp. 1382-1384. Paris, May 30, 1921.

As the author stated in 1892, certain lactic ferments, called by him " acidoproteolytic ", have the power of rendering soluble the casein in an acid medium, hence the part assigned to them in the ripening of cheeses. This property is not always easily detected, and has often been unrecognised.

In a series of articles (1), the author has shown that the double saccharolytic and proteolytic function of these ferments shows variability and irregularity according to their conditions of life (temperature, aerobiosis, the quality of the medium, and especially that of the milk, etc.), caseolysis being chiefly noticeable in cultures at low temperatures (20° and 25° C.) in the presence of air, and in milk that has been moderately sterilised (not in the autoclave, but by the Tyndall process) so that it still retains its white colour.

Recently, the author has discovered that, in addition to transitory variations in their behaviour connected with external factors and with the *modus operandi*, these ferments also show abrupt, spontaneous and transmissible changes in their mode of action.

He has observed that, whereas normally lactico-proteolytic ferments first coagulate milk, and subsequently re-dissolve the curd, sometimes, though very rarely, a certain variety of the ferment always peptonises the milk in an acid reaction, without, however, previously coagulating it; this modified action is transmitted to its descendants.

---

(1) *Atti della Reale Accademia dei Lincei*, Roma, 1910 to 1921, *passim*.

The author has also met with cases of "retromutation" that is to say, a sudden return after several generations, from these deviations to normal behaviour; the change, however, does not take place in the whole culture, but only a portion of it is modified.

For this reason, is order to explain these phenomena of sudden mutation, the author has recourse to the hypothesis of individual divergence brought forward by Charles RICHET to account for the irregularity of the behaviour of a lactic ferment in the presence of toxins. In fact, it is only logical to suppose that, amongst cells endowed with a two-fold saccharolytic property, some must be chiefly saccharolytic, and others chiefly proteolytic, and when it chances to occur that the sowing consists exclusively, or almost exclusively, of spores of the same type, a sudden divergence takes place, which is perpetuated by heredity, until by accident, a set of spores happen to be sown, which give rise to cells possessing both qualities in equal proportions.

The more favourable the cultural conditions, the more numerous the sub-cultures, and the shorter the intervals between them, the greater the number of spores taken from the whole thickness of the parent culture, and sown, the less apparent and less frequent are these modifications. Nevertheless, in spite of every precaution, these mutations inevitably occur, even under the most eugenetic conditions, and are not merely the result of unsuitable environment, as some authors believe.

The theory of individual divergence would also explain certain doubts in the determination of different types of various milk bacteria (*Streptococcus lacticus*, teat coccus, etc)

In fact, it substitutes for the idea of the plurality of species, races, types and varieties, the conception of a single species with variations connected with the normal differences present in individual cells In this manner, the classification of lactic ferments, which tended to become unduly complicated, is at once simplified.

856 - **Does Any Correlation Exist Between the Fineness of Wool Fibres and the Number of Undulations?** — VOITZ, in *Mitteilungen der Deutschen Landwirtschafts Gesellschaft*, Year XXXVI, No 22, pp 339-340, tables 2 Berlin, May, 1921

The author, from a further study of the question, using the data obtained by W. VON NATHUSIUS as basis, as well as his own observations, states that in many cases, especially in Merino combing-wool poor in yolk, there is no correlation between the fineness of the fibre and the diameter of the undulations. NATHUSIUS offered no explanation of the fact that equally fine wools may have very different undulations. According to the author's observations the development of a very fine fibre with coarse undulations is due to the following factors:—

1) The more elongated shape of the spiral sheath of the bulb.

2) In wools with little yolk, the fibre encounters but slight resistance in the strand (*Strahnchen*).

3) One or more coarser straight hairs in the strand draw out the adhering fibres.

4) The reduced elasticity of the wool.

In the following Table, the author gives the qualities of the different wools calculated from the diameter of the fibres, and the undulations. Thus the diameter of the undulations is no index of the fineness of the fibre. For this reason, the author lays much stress upon the necessity of measuring the fineness of isolated fibres as accurately as possible with a micrometer, in order to avoid all errors in determining the quality of a wool, especially if the fibres are very fine, and coarsely undulated.

857 - **The Cold-Storage of Fruit.** — MONVOISIN, A., in the *Revue général du Froid et des Industries frigorifiques*, Year II, Vol. II, No. 3, pp. 80-85. Paris, March, 1921.

The author, who is the Head of the Physical and Chemical Department of the Alfort School, and lectures on the preservation of perishable articles of food before the French Cold-Storage Association, writes a summary of the facts, so far as at present known, as regards the cold storage of fruit.

I. — CHOICE OF FRUIT TO BE PRESERVED. — Since cold storage is relatively expensive, it is in the first place necessary to select fruit that, after the normal period of storage, will have sufficient market value to ensure a reasonable profit, and can for instance be put on the market in winter, when there is a scarcity of fresh fruit. The amount sold should bear such a proportion to that stored, as to prevent the waste unduly increasing the net cost.

In the choice of fruit for cold storage, it is necessary to take into account: — *a*) The nature of the fruit; *b*) its place of origin; *c*) its degree of ripeness; *d*) its individual qualities

a) *Nature of the fruit.* — Only fruits of best quality should be used. Naturally the fruits of late autumn are principally chosen. For this reason, the cold storage of peaches is not profitable, since they have reached the limit of their keeping powers at the time when the market is abundantly supplied with grapes, pears and apples.

Different varieties of the same fruits do not behave alike during cold storage; some pears, for instance, cannot remain over a month in the cold chamber, whereas, in the case of others, only a few are spoiled, even after four months.

b) *Origin of the fruit.* — The soils of the orchards, by affecting the composition and constitution of the fruits, have also considerable influence upon their keeping qualities.

There seems to be little difference between orchard fruit and that of scattered trees growing in fields. The fruit of trees on damp soil does not keep as well as that of trees growing on fairly well-drained soil. Nevertheless, LÖHNIS has found that fruit from sandy soil often keeps badly

According to POWELL, the older the trees, the better the fruit keeps.

The influence of the climatic conditions during the growth, and especially during the ripening, of the fruit is very great, but differs with the variety under consideration.

c) *Degree of ripeness.* — The degree of ripeness of the fruits when gathered depends upon the variety, and also, to some extent, upon the storage period. The nature of the soil and climatic conditions can also determine the date of picking.

As a general rule, the fruit should be gathered a little before it is quite ripe, for otherwise it would be necessary to eat it either at once or after a short journey. Stone-fruit can be picked riper than fruit with seeds.

Firm fruits that are well-coloured keep better in the cold chamber than less ripe fruit, which would be expected to stand preserving better. This is clearly shown, in the case of 6 varieties of apple, by the experiments of RAMSEY MAC-KAY, MARKELL, and BIRD.

TABLE I. — *Results obtained with "Rome Beauty" Apples.*

	Total loss in hundredths			
Length of preservation at 0° C.	On leaving the Cold Storage Dépôt		Ten day after leaving the Cold Storage Dépôt	
	Normal ripeness	Unripe	Normal ripeness	Unripe
3 ½ months	0	1.1	1.9	50.5
4 ½ months	0	20.5	0.2	70.5
6 months	1	49.1	12.0	91.3

Over-ripe fruit should not be placed in cold-storage, for the loss incurred is great, as is shown by Table II, the figures having been obtained by the same authors with " Esopus " apples ; at a temperature of 0° C.

TABLE II. — *Results obtained with the " Esopus " Apples.*

Length of Storage at 0° C.	Total Loss in hundredths Normal ripeness On leaving Cold Storage Depôt	 Normal ripeness Ten days later	 Lot gathered 15 days later On leaving Cold Storage Depôt	 Lot gathered 15 days later Ten days later
[illegible] ½ months	0	1.3	2.3	2.3
4 ½ months .	0	1.3	9.1	25.0
6 months	1.3	2.7	4.0	26.0

d) Individual qualities. — Fruits to be placed in cold storage must be subject to severe individual examination, and only sound and perfect specimens should be used.

II. — TREATMENT OF THE FRUIT BEFORE STORAGE. — This consists of *sorting* and *packing*.

Sorting is absolutely indispensable, not only in order to weed out the fruits which show signs of rapid decay, but for the purpose of grading them according to size, colour, and ripeness In the case of oranges, the operation is sometimes preceded by washing, but the results are unsatisfactory and the cleaning of these fruits, if necessary, must be carried out by brushing them while dry. STUBENRAUCH, RAMSEY, and TENNY found the losses after only a fortnight's storage at 0° C to be as follows. — Unwashed oranges, carefully gathered and packed, 1 %; treated according to the usual commercial methods, 3.6 %; washed oranges, 4.1 and 10.2 % respectively.

The packing-cases should be adapted to the nature of the fruit they are to contain, the length of storage and the amount of handling to which they are to be subjected They must be strong, and at the same time not unduly heavy, and should allow of the air circulating freely inside them. As a rule, these cases are made of osiers or wood, and sometimes of ordinary or corrugated cardboard.

Delicate fruit, such as strawberries and choice grapes, are generally put in to small hampers or baskets (" fleins "), which only contain 3 to 5 kg., and are themselves placed to the number of 4 or 6, in larger receptacles, or " cageots ". As these fruits are too delicate to be allowed to come into direct contact with the packing-cases, these are lined at the bottom with a small elastic cushion formed of strips of paper, or wood-shavings, covered with a sheet of tissue paper ; cotton may also be used.

Choice fruits of a certain size (pears, apples, peaches) are packed separately in boxes with compartments, or with movable divisions made at the time of packing

They are sometimes placed in a small mass of shreds of paper, which is usually coloured, in order better to show off the hues of the fruit. Such fruits are generally packed separately, each one being wrapped in a sheet of thin paper Such a covering is of advantage, especially in the case of varieties with thin skins and delicate flesh. Air-tight packing has its disadvantages when the fruits are delicate, for their flavour and aroma is quickly deteriorated by remaining long in an atmosphere charged with carbon dioxide.

Cork waste, or wood sawdust, are used for packing tomatoes, and grapes. In such cases, the fruit is always put in deal barrels.

Fruit requiring less care, such as winter apples, are as a rule, put without any special care in large barrels

III. — GENERAL REMARKS RELATING TO THE COLD STORAGE OF FRUIT — Sometimes the store-rooms are heated to hasten the ripening of certain fruits, whereas on the other hand, cold is applied to retard ripening, or to prevent any change taking place for some time in fruits that are already mature

Cold is applied in two ways; chilling is the most useful and widely practised method, while freezing is resorted to in the United States

A Chilling. 1) *Method of chilling.* — The best method is by the circulation of brine, provided it is so arranged that the air of the room can be completely changed.

2) *Temperature* — The intensity of the cold depends upon the fruit to be preserved, its degree of ripeness, and the length of storage The temperature ought, as a rule, to be kept at about 0° C., except in the case of bananas (details are given later). The temperature should be maintained as uniform as possible, with daily deviations not exceeding 1°C. To raise the temperature above the given limits has the disadvantage of hastening the ripening of the fruit, and thus shortening the time it can be stored. A fall in temperature may cause freezing and the loss of some of the stock It must be remembered, however that the freezing-point of fruits is lower than that of water, on account of substances dissolved in the cell-sap, such as organic acids and especially sacchariferous matters.

It is in order to prevent freezing that the circulation of the air must be well regulated, and that so-called wet refrigerators cannot be used

On account of the combustion due to their respiration, the temperature of the fruits is always above that of the cold chamber in which they are kept. The average difference is 1°C., though it may vary from 0.5°C to 1.5°C.

Some fruits, especially apples, can resist a slight amount of freezing for a short time, such as a day, if they are thawed slowly and gradually, first to −2°C. and then then to −1°C.

3) *Immediate cold storage* — Fruits of normal ripeness should be put into cold storage as soon as they are picked, and before any alteration has had time to set in. This precaution is all the more necessary if the fruit has been gathered during the heat of the day, and when the temperature out of doors, is very high. The temperature of fruits at the mo-

ment of picking is always higher than that of the atmosphere; the difference may be as much as 8° C. and 9°C. during the hot hours of the day.

Experiments carried out on many kinds of fruit in Canada and the United States show the great importance of immediate cold storage as compared with delaying the treatment until several days after gathering.

TABLE III. — *"Rome Beauty" Apples; Loss after preservation at 0°C. for three months and a half*

	Loss in hundredths	
	On leaving the cold-storage chamber	Ten days after leaving the cold-storage chamber
Placed in cold storage: —		
Immediately after picking	0.3	13.8
A fortnight after picking	0.6	21.1

TABLE IV. — *Oranges preserved at 0°C.*

	Loss in hundredths Time that elapsed between picking and cold-storing		
	1 day	3 days	4 days
Sound oranges, brushed	0.1	2.3	3.4
Sound oranges, washed	0.9	2.3	5.5
Oranges treated commercially	2.3	6.2	9.1

The fruits placed at the depot take a variable time (according to their size and the way they are packed) to reach the temperature of the treatment. The time required is shorter, the lower the temperature of the air, and an attempt has been made in Canada to bring the fruit rapidly to the cold-storage temperature by placing them for a short time, and with careful supervision, in a chamber at from —9°C. to —10°C. Under these conditions, the fruit is chilled in 4 to 7 hours, instead of requiring one or two days. The advantage of this quick chilling, from the point of view of the preservation of the fruit, is, however, not very clear. It is, advisable, however, in the case of small fruits with thin skins, such as strawberries and gooseberries, as has been shown by HAWKINS and SANDO for it prevents the skin from breaking, and also renders the fruit less liable to bruise.

4) *Hygrometric condition.* — This should be as constant as possible, and is generally kept at between 70 and 80 hygrometric degrees according to the variety of fruit.

If the water-content of the air falls below 65, or even much lower than 60 hygrometric degrees, it induces too rapid evaporation, a perceptible loss of weight, and dries up the epicarp, which becomes wrinkled, owing to the shrivelling of the fruit. Even if the flavour remains unimpaired, the appearance of such fruit greatly reduces its market value.

The increased moisture of the air, even if it rises to about 85°, or even 90°, is of much less importance, if the temperature is low (between — 0.5°C. and + 0.5°C.) than if it rises to about + 2°C. or + 3°C.

5) *Reneaal of the air.* — The atmosphere should not contain much carbon dioxide, both for the sake of the workers handling the fruit, as well as for the fruit itself. For this reason, and also in order to ensure uniformity of temperature, the cases of fruit ought to be so arranged, that there is a free circulation of air around and inside them. The passages left to enable the stored fruit to be easily inspected also promote proper ventilation.

In any case, the air of the chambers must be renewed about once a day at the beginning of storage, and oncea week subsequently. The opening of the doors in the course of handling the cases, is often sufficient to ensure aeration. Should it not prove to be so, it would be necessary to have recourse to artificial ventilation; the current must be slow and well regulated, in order to prevent any chance of freezing.

6) *Inspection of the stock.* — The stored fruits must be examined every fortnight, or every month, according to their nature and the condition they were in when put in cold storage. In this way, any fruits that are becoming rotten can at once be removed, which sometimes prevents the loss of a large quantity, and also enables the fruit to be sold gradually as it becomes ripe .

7) *Removal from the cold chambers.* — If the fruit is removed with a view to taking it for a long distance, either for immediate consumtion, or re-storage, it should be place in a separate truck, in order to prevent the temperature rising after loading. Fruit intended for immediate consumption must not at once be subjected to a high temperature. As a rule, it is removed from cold storage during the winter, when the exernal temperature is relatively low. The condensation of water-vapour is little to be feared, and the moisture is absorbed by the packing-material. If the external temperature be high, the fruit must be left for at least. ten or twelve hours in a room at a temperature of about + 6°C.

Fruit keeps better when removed from the cold-storage depôt into the outer air, if it has been preserved at 0°C , than if the temperature has been kept at + 2°C or +4°C.

Table V gives the losses sustained in the case of the removal of Esopus apples from the cold chamber as estimated by RAMSEY, MACKAY, MARKELL and BIRD.

IV. — CHANGES OBSERVED DURING PRESERVATION. — These alterations are due to evaporation, physiological processes, or supervening bacterial action. They are either physical, chemical, or bacterial.

a) *Physical changes.* — These consist in loss of weight, alterations in texture or appearance, or loss of aroma.

TABLE V. — *Losses in Esopus removed from the cold chamber.*

Duration of Storage	Proportion of spoiled apples expressed in hundredths			
	at 0° C.		at +2° C	
	On leaving the depot	Ten days later	On leaving the depot	Ten days later
3 ½ months	0	0.7	0.7	8.4
4 ½ months	0.6	2.9	4.8	11.9
6 months	10.1	12.4	13.9	17.4

1) *Loss of weight.* — Loss of weight is caused by the united effects of water-evaporation and the combustion of certain substances resulting from the respiration of the fruits. This loss is more marked when the fruit is preserved at high temperatures, and the air frequently renewed. Thus, TRUELLE estimated the loss in weight in the case of Grosse Grise pears from the Auge Valley, that had been knocked down from the trees and preserved under usual conditions at the ordinary temperature to be as follows :—

Initial weight.	1 000 kg.	
Weight after 15 days	936 kg., or loss of	6.4 %
» » 30 »	887 » » » »	11.3 %
» 45 »	836 » » » »	16.4 %
» » 60	791 » » » »	20.9 %
» » 75	495 » » » »	50.5 %

At the temperature maintained in the cold-storage depots, under the above conditions, the loss amounted to between 2 and 5 % for the normal duration of storage.

1) *Changes in appearance.* — When there is great loss of weight, the volume of the fruit decreases, and the epicarp, not being able to adjust itself to the variations in volume, becomes wrinkled.

When the alteration in the fruits is due to rotting, or to the fact that they were placed in cold storage at an unsuitable stage of ripeness, certain parts of the epicarp, usually the uncoloured portions, turn black. When the change is more advanced, the fruit on being cut, reveals a dark brownish coloration of the underlying portions. At this level, the tissues of the pulp, which were very firm at first, become soft and are soon transformed into a brown pap.

These changes generally affect a considerable part of the surface of the fruit. Other alterations take the form of small circumscribed areas, sometimes clearly defined, of a brown, or blackish, colour.

The common affection of oranges, due to the invasion of the pericarp by a species of *Penicillium,* is soon revealed by the appearance of the green fructifications of the fungus.

The " sleepiness " of acid fruits, which cannot be detected by inspection and feeling, is shown when they are cut, by the liquefaction of the pulp in the neighourhood of the pips; this pulp, which was previously ligh brown, soon takes on a dark coloration. Like all other changes, "sleepiness" appears more quickly the higher the temperature at which the fruit is preserved. In the case of Grosse Grise pears under ordinary storage conditions, TRUELLE found that "sleepiness" did not manifest itself till about the 45th day.Towards the 60th day, 3/4 of the stored pears are "sleepy," and ¼ rotten.

3) *Loss of aroma.* — This is undeniable after the fruit has been in cold-storage for a certain time, sometimes it occurs even at the end of a month. As a rule, the aroma is not appreciably affected until the fruit, peaches for instance, has been at least two months in cold-storage.

b) *Chemical changes.* These are the alterations occuring during the normal process of ripening, with the sole difference that their rapidity is considerably lessened. This is clearly shown by comparing the results obtained by BIGELOW with the Ben Davis apple, which was preserved for 133 days at 0°C., and also at ordinary temperature.

TABLE VI. — *Results obtained by* BIGELOW *with the Ben Davis apple.*

	At the beginning	Preserved 133 days	
		at ordinary temperature	at 0° C.
Total dry matter	15.40 %	13.02 %	14.21 %
Acidity expressed as malic acid.	0.63	0.33	0 50
Saccharose	3.83	0.90	2.25
Total sugars (in invert sugar)	10.17	8.57	9.46

The loss in weight is more noticeable at ordinary temperature than at 0°C. The combustion of the acids, although perceptible, is less pronounced at 0°C. than at ordinary temperature; the same may be said respecting the combustion of sugars.

The results obtained with other fruits such as peaches, plums, etc., are very similar to those observed in the case of apples.

c) *Bacterial changes.* — These are due to the penetration through the unbroken epicarp, or more frequently through lesions on its surface, of spores deposited on the outside of the fruit during its growth, or in the course of the handling it has undergone.

B. — *Freezing.* — In the United States, certain fruits used in making side-dishes, confectionery, effervescing drinks, and ice-creams are preserved by freezing. The fruits thus treated are strawberries, mulberries, black currants, raspberries, cherries, gooseberries, plums, and whortle-berries.

These are put into ordinary cases, if they are to be preserved for a short time, or into little boxes of waxed cardboard. As soon as possible after picking, the fruit is placed in a cold chamber kept at a temperature varying from —12°C. to —19°C.

The fruits are frozen at the end of 24 or 48 hours and remain, until the time of using, in the same chambers, the time varying from 4 to 10 months. They must be used at once after thawing.

When the fruit has only to be kept for a short time the aroma is better preserved by subjecting it to the action of heat, or by desiccasion.

It has recently been proposed to freeze apples in a salt freezing-mixture.

V. — DETAILS RELATING TO THE COLD STORAGE OF THE PRINCIPAL FRUITS. — *Apples.* — These, as a rule, keep very well in cold-storage. Sound fruit, picked when nearly ripe, should be chosen. The Grey Golden Reinette, Autumn Grey Reinette, and Orleans Reinette cannot stand being kept long in a cold-chamber.

The case in which the fruit is packed varies with the quality of the apples to be treated.

The temperature may vary between — 1°C. and + 2°C., with 85 hygrometic degrees. Apples can even be kept in an atmosphere of 90 hygrometric degrees Under these conditions, the fruit can stay in cold-storage for a year, and even two years.

The loss of weight during 3 to 6 months' cold-storage varies from 2 to 5 %.

Apples have little to fear from freezing; they usually freeze at about — 3°C., ; if they have frozen for a short time at about — 4°C., they take no harm, provided they are thawed slowly at — 2°C, and — 1°C.

Pears. — These also stand cold-storage very well; as in the case of apples, autumn and winter varieties should be selected Choice pears are packed in small cases, or placed in a single, rarely a double, row.

The conditions of temperature and moisture are the same as for a apples.

The Beurré d'Amanlis, and Bonne Louise varieties can be preserved for 3 months, Williams, Duchesse d'Angoulême, and the Curé for 4 months, and Beurré Clairgeau for as long as 6 months.

Peaches. — The cold-storage of peaches might be useful to the export trade. They should be picked when well coloured, but still hard, and packed, one row deep, in small wooden cases. The best temperatures for short transport are from + 6°C to +8°C. They should be placed in cold-storage at from 0°C to 1°C., the moisture content of the air being 85°. Peaches lose their aroma after 6 months cold-storage, an appreciable decrease being noticeable at the end of 2 months.

Strawberries. — These must be picked carefully when they are well-coloured, but hard. They are packed in hampers, which are placed, to the number of 4,or 6, in cases. At a temperature of — 1°C., in an atmosphere of 90 hygrometric degrees, strawberries of a proper ripeness will keep well for four, or even, five weeks.

Bananas. — The fruits of cultivated bananas weighing on an average 70 gm. consist of about 25 gm of skin, and of a farinaceous pulp weighing nearly 45 gm. The sugar content of this starchy pulp increases progressively as the fruit ripens, and when the banana is quite mature, it may contain as much as 15 to 20 % of its own weight of saccharose. The weight of bunches of large bananas ranges from 20 to 35 kg., and the number of fruits they contain varies from 100 to 250.

The bunches of bananas are wrapped up in a cotton leaf then in paper, or in banana leaves, and placed, one or two in number, according to their size, in crates usually octagonal in shape.

Bananas are characterised by their great sensitiveness to low temperatures. At 0°C, + 5°C., and even +6°C., the fibrous pericarps quickly becomes discoloured and black, which detracts greatly from the marketable value of the fruit.

In order to keep them green, and prevent ripening, bananas are kept in cold-storage at a temperature of + 8°C. This is raised to + 12°C to make them ripen gradually, the hygrometer being at about 70 degrees. They finish ripening in the store of the retail dealer, where the temperature should be kept at from 18°C. to + 20°C.

858 - **Observations on the Evaporation and Dehydration of Fruits and Methods Employed in California.** — I CRUESS W. V., Observations on the Evaporation of Pears, Prunes and Figs, *Monthly Bulletin of the Department of Agriculture State of California*, Vol X, No 2, pp 88-93 II. CHRISTIE A. W, Some Observations on the Dehydration of Apricots, Peaches and Grapes, *Ibid*, pp. 94-96 Sacramento Ca, Feb 1921

Report of investigations carried out by the Division of Fruit Products during the 1920 season. Data were accumulated both from commercial scale tests and from the University Farm Evaporator and from visits to most of the dehydrators in operation in the State of California.

I. — *Pears*: — Small scale laboratory tests were made in the Fruit Products Laboratory at Berkely. and 6 ½ tons were dried in the two commercial size evaporators on the University Farm Davis.

Pears were ripened in boxes in the shade, in straw with a layer of straw between each layer of fruit and on 3ft. screen bottom trays stacked in the shade about 30 trays high. The fruit in the screen trays did not ripen quite so evenly or rapidly as that in the straw.

As regards the preparation of fruit for drying, the best results were obtained by first peeling the fruit, before cutting in half and before it is too ripe, (it has been found that pears may be satisfactorily lye peeled in the spray type of lye peach-peeling machines) The author also recommends the removal of the core, and the sprinkling of the trays with a dilute salt solution and then a 3 hours sulphuring before proceeding with evaporation. He does not consider steaming an essential part of the process. Slat-bottom trays were far more satisfactory than screen trays which became badly corroded in the sulphur fumes and imparted a strong metallic flavour to the fruit.

With reference to sun-drying versus evaporation, the yield by the former was slightly greater than in the evaporator, but the latter contained less water. Although pears will withstand temperatures up to 145°F, the best results were obtained by drying the fruit until about $^2/_3$ dry at 140°F, followed by 110°F. It is also much easier to maintain a high relative humidity at 140°F. (30° is satisfactory) In the laboratory test, pears required over 40 hours to dry in air of low humidity, while only 27 hours were required with air of high humidity. The fuel consumption at the University farm was 42½ gallons of store oil per green ton of fruit and the drying ratio 4.5 : 1.

Prunes. — Somewhat surprising results were obtained in the drying of undipped prunes in comparison with dipped fruits. In the evaporator in which natural draught is relied upon for air circulation or in which the air flow is very slow, the fruit which was not dipped dried just as rapidly as the dipped fruit. In evaporators in which a strong blast of air was used the latter dried much the more rapidly of the two. No explanation is offered at present for these observations.

The author found that a temperature of 160°F at the start of drying and a finishing temperature of 145°F gives good results, although quite good dried prunes are produced at 165°F. It is believed that 20 to 22% moisture is approximately the proper range. The fruit should not be steamed until it cracks badly (steamed fruit was lighter in colour than dipped fruit). There was no noticeable difference in the yield of dried product from sun drying and evaporation.

Figs. — Calimyrna figs from Merced were dried in an evaporator at Davis. Lot I was dried untreated, lot II was fumigated in sulphur for 5 hours, two hours are however sufficient) and lot III was prepared by slitting the fruit on one side and spreading it on trays.

Lots I a II required 9 hours to dry at 155° and 160°F. Lot III required only 5 hours at the same temperature. From the results of the preliminary experiments made up to the present it appears that it will be feasible to evaporate figs grown in those districts of California where there is not sufficient sunshine to permit satisfactory drying and curing in the sun.

II. *Apricots.* — A 1 hour exposure to sulphur fumes was sufficient to preserve the colour of the dehydrated fruit, whereas 4 to 5 hours was required when the fruit was sun-dried. The time required for dehydration was 12 hours, the temperature of the intake air being 165° to 170°. No injury to the apricots resulted from this temperature. Inadequate air-flow, caused by insufficient horse-power lengthened the drying time. The experiments indicated that an excellent quality of dehydrated apricots can be produced if fully ripened fruit, properly sulphured is used.

Peaches. — The usual drying time for unpeeled peaches was 24 hours while the packed fruit dried in 14 hours ; but this can with adequate treatment, be reduced considerably. The temperature used was about 10° less than for apricots, as a higher temperature tends to scorch the fruit. Experiments demonstrated that high quality dehydrated peaches if dried only when thorougly ripe either peeled or unpeeled can readily be produced.

II III. *Grapes* (1). — Drying has proved to be one of the most feasible method of converting the wine grapes of California into a non-perishable saleable product It is contended by many that a greater yield and a better quality of raisins are obtained by artificial drying in an evaporator than in the sun.

---

(1) See *R.*, April 1921, No. 435.

All grapes dehydrated at the University Farm in 1920 were lye-dipped, rinsed, sulphured at least 1 hour and dried at a final temperature of 165°F. The average drying time was 30 hours.

PLANT DISEASES

GENERAL INFORMATION

859 - The Coleopteron *Pissodes notatus* Declared an Insect Injurious to Agriculture in Uruguay (1). — *República Oriental del Uruguay, Ministerio de Industrias, Defensa Agricola, Boletin mensual*, Year II, No. 5, p. 121. Montevideo, May 1921.

In accordance with the recommendation of the Central Commission of of the "Defensa Agri ola" of Uruguay, the " Consejo Nacional de Administración " passed a decree on April 29, 1921, declaring the coleopteron *Pissodes notatus* to be included among agricultural pests.

DISEASES NOT DUE TO PARASITES OR OF UNKNOWN ORIGIN

860 - " Scottatura " or " Allessatura " (Scald) of Citrus Fruits, in Southern Italy. — SAVASTANO, L., in the *R. Stazione sperimentale di Agricoltura et Frutticoltura, Acireale, Bollettino* 40, pp 4-5. Acireale, 1921.

The winter of 1920-1921 was, generally speaking very wet in South Italy, and the temperature was higher than it had been for at least ten years.

Many cases of scald were observed during this period among the oranges and lemons. Fruits that were already ripe first turned a whitish red, as if they had been dipped in boiling water; this took place very quickly within a day. Afterwards the colour changed to brownish-red and finally to black, and at the end of two or three days, the fruits became detached from the peduncle. For the first few hours, the rind alone is attacked, but later the alteration extends to the interior of the fruit. Usually the disease begins at the navel, and passes upwards, although the side alone may sometimes be affected. The fruits growing lowest on the tree suffer most, those in the centre are rarely attacked, and those at the top are almost immune. The scald begins during the night, so that fruits which were perfectly healthy the evening before, are found to be affected the next morning. The alteration is confined to citrus plantations in the valleys, or on the plains, those situated on hilly land remaining immune.

During the winter 1920-1921, there was much fog in the eastern region of Etna, and scald was so wide-spread, that even the fruits on the top of the trees were affected. In certain very bad cases, as much as 20 %. of the fruit was attacked.

---

(1) See *R.*, May, 1921, No. 591. (*Ed.*)

Given the meteorological nature of the affection, it is clear that any remedy is most difficult to find. In the Sorrento plantations the branches near the ground were cut away, but this method was not adopted in Sicily and it is unnecessary in many cases, and even harmful, for if the lower branches are removed, the higher ones develop too much, and thus the fruits are exposed to another danger, of annual occurrence, not incidental like scald, viz., insolation.

DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS.

862 - **Plant Diseases Observed in Morocco.** — MIÈGE, E, in the *Bulletin de la Société de Patologie vegetale de France*, Vol VIII, Part 1, pp 37-46, Paris, 1921.

First contribution to our knowledge of the plant disease recorded in Morocco.

It can be stated that, in general, with the exception of the Uredineae and Ustilagineae, which are very common on a large number of plants, the diseases hitherto observed in Morocco are few and of little importance.

The Uredineae attack many plants, especially cereals, which are the crops most cultivated in Morocco.

Puccinia graminis and *P. glumarum* are frequently found; the hard wheats seem somewhat less susceptible to the attacks of these fungi than the soft varieties, whereas the native barleys (*Hordeum tetrastichum*) behave in a similar manner to the Svalöf varieties (*H. disticon*). *P. Maydis* is found on maize; the different species of *Oxalis*, especially *O. cernua*, which are found plentifully in a wild state are attacked by an uredinea considered by some authors to be the occidial form of *P. Maydis*. *P Malvacearum* is often seen on the numerous Malvaceae infesting the fallow land Other fungi of common occurrence are:— *Uromyces Pisi* on peas and vetches; *U. Fabae* on garden beans; *U. appendiculatus* on kidney-beans; and *U. Anthyllidis* on lupins. Flax is attacked by *Melampsora Lini*, roses by *Phragmidium subcorticium*. The presence of Uredinae has also been reported on castor plants, and Euphorbia. The injury done by these various parasites has, however, been hitherto of little importance.

Cereals, especially along the coast, are much attacked by Ustilaginae: in 1920, *Ustilago Tritici* infested 25 % of certain soft wheats at Rabat. The barleys are attacked by *U nuda* and *U. Hordei*; the latter parasite seems less common than the former. *U. Maydis* occurs more rarely on the female inflorescences, and also in the axils of the leaves of maize; the species of *Sorghum* suffer little from fungi. *U. Cynodontis* lives on *Cynodon Dactylon* which grows abundantly on the sandy soils of the coast region. Species of *Tilletia* are not very widely distributed, nevertheless the hard wheats of several districts are attacked by what is probably *T. Tritici*.

Phytophthora infestans attacks the potato, but this plant suffers perhaps more from a disease characterised by large, brown, very well defined patches, which appear on its terminal leaves, and soon deform them (*Sporidesmium*).

Asterocystis radicis has been found on flax.

Ascochyta Pisi is not rare on a certain number of Leguminosae.

Gleosprorium caulivorum has been seen on wild clover.

Armillaria mellea is chiefly found on land that has been much irrigated, or liberally manured.

Plasmopara viticola, and *Oidium Tuckeri* have been noticed on some vines, but native stocks seem endowed with a considerable degree of immunity, while the European varieties, taken as a whole, are rarely seriously injured by the attacks of these parasites.

Diseases of bacterial origin are not infrequently met with on ligneous plants, specially olives and almond-trees, and in 1920, even carnations were similarly affected.

As regards indeterminate diseases, one which seems chiefly to infect Leguminosae (beans, peas, and chick peas), has been discovered in several localities, where it causes a good deal of mischief. It chiefly invades the root-collar and the base of the stems, but it may descend to the tap-root, or even ascend to the epigeal organs, which become covered with patches of the colour of wine-dregs, or of a brown tint and then dry, and split, after which the plant dies.

Another disease, which has not been identified, has been reported as attacking potatoes growing on experiment plots.

863 - **Seed-Coat Injury and Viability of Seeds of Wheat and Barley as Factors in Susceptibility to Moulds and Fungicides.** — HURD, A. M., in *Journal of Agricultural Research*, Vol. XXI, No. 2, pp 99-122, pl II Washington, D C. April 15, 1921.

The saprophytic fungi that infest both soil and seed are serious enemies to successful wheat and barley culture.

The authors experiments have shown, that an unbroken seed-coat ordinarily offers absolute protection against attacks of living seeds by *Penicillium* sp. or *Rhizopus nigricans* in damp storage, in the soil, or in the blotting-paper germination. Infection of such seeds has, however, been obtained by retarding germination by means of low temperatures.

The location of a break in the seed coat determines the ability of saprophytic fungi to invade seeds in the soil, in storage, or in laboratory (blotting-paper) experiments. If the injury is over the endosperm, 100 per cent fatal infection results when spores of *Penicillium* or *Rhizopus* are present, but if it is over the embryo, the seeds remain practically immune.

The vitality of seeds is a factor in determining the power of *Penicillium* and *Rh. nigricans* to attack them Death, or injury, resulting from seed treatment, or other cause renders previously immune seed immediately susceptible. Even perfect seed coats are no longer a protection.

No visible infection with either *Penicillium* or *Rhizopus* occurred when the temperature remained as low as 10°C., throughout the experiment.

Penicillium sp. requires an atmospheric humidity of at least 80 per cent for its development on stored wheat. *Aspergillus* sp. develops with 70 % atmospheric humidity.

These moulds develop more slowly on stored wheat and barley which has been treated with copper sulphate, or formaldehyde, than on equally moist, untreated wheat.

Although a break in the testa over the endosperm of wheat does not result in any injury to the embryo upon short exposures to copper sulphate, injury becomes apparent after exposures of an hour, showing that the poison is eventually absorbed through the endosperm and scutellum. A similar break over the embryo results in its death after exposures of only 3-5 minutes.

When the seed coat is badly injured, liming does not prevent fatal consequences, because the copper sulphate enters such seeds quickly. When the seeds are only slightly injured, a lime dip is effective in neutralising the solution before any bad effects manifest themselves.

Stunted roots, rather than injured plumules, are characteristic of the toxic effect of copper-sulphate, because machine-thrashing usually breaks the seed coat directly over the radicle.

The damage that will be done to wheat seed by the copper sulphate treatment and by saprophytic fungi can be pradicted by examination of the physical conditions of the seed. All these troubles can be reduced by greater care in thrashing the seed wheat, so that the testa is not so badly broken.

Perfect seed coats are also an absolute protection against short exposures to strong formaldehyde solutions, and are a partial protection against post-treatment injury after disinfection with formaldehyde.

The seed coats of Turkestan barley and of varieties having the same structural type, are broken at the hilum in either machine, or hand thrashing Death results from exposing such seeds to strong copper sulphate solutions for even short periods, or to weaker solutions for a longer time. Barley kernels left attached to pieces of the rachis were not injured by these treatments.

Wheat seeds were always damaged after exposures to saturated solutions of copper-suphate for longer than 7 hours, and sometimes in less time.

The temperature of the solution was found to be a factor in the resistance of wheat to injury from long immersions in saturated copper-sulphate solutions, the germination being poorer as the temperature increased.

864 – **Types of Noé Wheat Resistant to Brown Smut in Italy.** — See No. 810 of this *Review*.

865 – **Flag Smut *(Urocystis Tritici)* a Tilletia Injurious to Wheat, Recently Introduced into the United States.** — TISDALE W. H. and GRIFFITHS M. A., in *United States Department of Agriculture, Farmers' Bulletin* 1213. 6 pp., figs. 2. Washington D. C., May 1921.

Flag smut of wheat (*Urocystis Tritici* Koern), a parasite long known in Australia, where it causes considerable loss every year, and also occurring in Japan, India and South Africa has recently been introduced through some unknown means into the United States.

The first report of the disease in the latter country came from the vicinity of Granite City (Madison Country Ill.) in 1919, in which year a number of fields in the district were found to be infested. During the season of 1920, in the neighbouhrood of Granite City, flag-smut was found in 111 fields comprising 2 500 acres, in an area of about 47 sq. miles.

The disease is characterised by the appearance of black stripes running lengthwise in the leaf blades and sheaths, due to the chlamydospores of the fungus. The upper leaves of the plant are usually the most severely attacked, the stems are also infected to some extent. The diseased plants are generally more or less stunted, and they rarely head out, or produce seed. As a rule, all the stalks of an infected plant are attacked, but occasionally one or two remain immune.

Flag smut is spread in two ways. In thrashing, the spores are knocked out of the diseased leaves and scattered over the grain to which they adhere ; they germinate at the same time as the wheat, when the latter is sown. This is perhaps the chief method by which the pest is propagated, the other way of spreading it, is by means of spores which find their way into the soil from infected straw, stubble and fragments of plants left on the ground when the wheat is cut, and may be carried long distances by wind and running water. Sometimes they are blown out of the separator to land near to the place where grain is being thrashed. In whatever way they reach the field, the chlamydospores germinate there, and if near to seeds, may infect the young wheat seedling in the same way as those clinging to the seeds.

In order to prevent the spread of flag smut beyond the quarantined area in Madison County, and to eradicate it if possible from the infested district, the United States Department of Agriculture and the Illinois Department of Agriculture have taken steps in cooperation, and agreed upon the adoption if the following measures.

1) Thorough treatment of all the grain with formaldehyde as it comes from the separator.

2) Burning all straw in the infected area as soon as possible after thrashing.

3) Sowing no wheat on infected land, and as far as possible sowing no wheat on land which was under wheat the previous year.

4) Obtaining seed from localities known to be free from flag smut.

5) Treatment by the copper-sulphate, or blue-stone method, of all seed to be sown. The coating formed by the blue stone and lime protects the seed from infection by chlamydosphores present in the soil.

6) Growing varieties of wheat that are considered resistant to the disease.

The experiments conducted by the United States Department of Agriculture and the Illinois Agricultural Experiment Station have already shown, that certain varieties of wheat are, more or less, resistant to flag smut.

Fulcaster, Gipsy, Red Wave, Turkey Red, and Early May are wheats with a combination of disease resistance and good yielding ability.* They arethere fore strongly recommended for use in the flag smut area of Madison County.

Certain other varieties (for instance Red Cross, Salzer Prize Taker, Salzer Pride, Dawson Golden Chaff, Illini Chief, and Jones Winter Fife), should not be grown under any consideration in the infested area, because of their susceptibility to the disease.

The United States Department of Agriculture, the Illinois State Department of Agriculture and the Illinois Agricultural Experiment Station are aiding farmers in every possible way to eradicate this destructive wheat pest.

866 - ***Rosellinia* sp., an Ascomycete Injurious to the Roots of the Coffee Plant in Porto Rico.** — MATZ., J., in the *Gobierno de Puerto Rico, Departamento de Agricultura y Trabajo, Estación Experimental Insular, Rio Piedras P. R. Circular No.* 32, 11 pp. 2 figs. San Juan, R. R., 1920.

Root disease, although of limited occurrence at present, is the most serious of the maladies attacking the coffee-plantations in the island of Porto Ricco, as it eventually causes the death of infected plants. The most noticeable symptoms are loss of leaves and the withering of the plant.

The usual cause of this root-disease is an ascomycete (*Rosellinia* sp.), which forms characteristic black incrustations in the cortex and wood of the lower part of the stem.

The fungus lives in the soil covered by a thick layer of decomposing vegetable matter consisting, to a large extent, of fallen leaves from the trees planted for the purpose of providing shade for the coffee-plants. If the fungus comes into contact with a single root, it soon spreads over the whole root-system and the base of its host.

Different causes contribute to the development of the disease. One of the principal is irregularity of the ground, which renders cultural operations more difficult in many plantations. Further, the coffee-trees are not planted at proper intervals, so that it is difficult to clear and work the ground around them, while the shade-trees are allowed to grow irregularly, and large quantities of vegetable matter and weeds accumulate on the ground in the plantation, instead of being dug into the soil. The shade trees are not only useful in providing a protection against the intense light of the sun, but also because the leaves falling from them contribute to form a protecting layer, which prevents the necessary moisture from escaping from the soil. In some places, however, not only is the shade too dense, but leaves form too thick and damp a covering on the ground ; in this case, decomposition takes place very slowly, and the decaying mass is an ideal medium for the growth of micro-organisms injurious to the coffee plants. Many of the coffee plants are old, and should be pruned to induce them to send up fresh shoots, or else they should be dug up.

Individuals to be transplanted ought to be selected from the seedlings of vigorous plants.

The most practical method would be to grow coffee-plants and shade-trees alternately in the same row. Enough space ought to be left betwen the rows to allow of spreading manure and hoeing, and of easy access to the trees when the crop is gathered. This system would make it possible to collect the layer of leaves covering the soil into the centre of the space between the rows during the rainy season. The leaves could be again spread over the ground during the dry months. By working the soil, the roots of the coffee plants would be encouraged to grow continually deeper and in this way, they would be less affected by drought. In addition, they would not be so much exposed to the attacks of micro-organisms, since these usually live very near the surface of the soil.

It is not advisable to apply any substances to the soil, the best remedies being good hygienic methods by which the production of the plants is increased, and the disease controlled.

In plantations suffering from root disease, the soil ought to worked and exposed to the action of the air and the sun. Clear soils can be improved in texture by the addition of lime, which renders them more porous, and allows the air to circulate freely in the lower strata.

867 - ***Bacterium exitiosum* n. sp. Injurious to the Tomato in the United States.**

— GARDNER M. W., and KENDRICK J. B., in *Journal of Agricultural Research* No. 2, pp. 123-156, pl. 5. Washington D. C., April 15, 1921.

During recent years, the tomato crops in many of the north Central States (Tennessee, Illinois, Michigan Iowa, Indiana — where the authors researches were made — Georgia, and Florida), have been affected with a spot disease of the fruit of bacterial origin. Outside the United States, this disease has only been found for certain, up to the present, in Canada, and the Union of South Africa.

It attacks both the leaves and fruit of a large number of varieties of tomato. Sometimes, it occurs not only on adult plants, but also on seedlings. From the experiments made, it appears that the fruits of the capsicum, and the leaves of the potato are also infected with this disease.

On the tomato, the fruit lesions are small, black, scab-like spots usually superficial, sometimes crateriform. Leaf lesions are at first translucent, later black and greasy, with transparent margins, and are not usually limited by the veins.

The spots on the fruit are unsightly, and if numerous and large, render the tomatoes unsaleable, further they afford entrance to rot-producing micro-organisms. Canners object to this disease, because even the rather superficial lesions are not removed with the skin, so affected fruits cannot be used for first-grade canning stock.

Seedlings suffer equally severely from this malady.

The pathogenetic organism is a bacterium of which the authors give a detailed morphological and biological account in their paper under the name of *Bacterium exitiosum* n. sp.

Field observations indicate that fruit infection occurs through the punctures of insects. Inoculation tests prove that no infection of fruits takes place unless the epidermis is mechanically punctured. It is not, however. necessary that the bacterium should enter at the time the puncture is made; once present on the surface of the fruit, it takes advantage of any pre-existing wound. Leaf infection apparently occurs through the stomata, and the lesions are more abundant on the lower surface. Young leaves are the most susceptible to the disease.

The bacterium winters on the surface of the seed and is thus disseminated. Commercial seed from fields known to be diseased has yielded about 1 % of infected seedlings. The disease is also propagated by young plants when transplanted.

868 - ***Pseudomonas Apii* n. sp.' a Bacterium Injurious to Celery in the States of New York and Michigan.**— JAGGER I. C., in *Journal of Agricultural Research*, Vol. XXI. No. 3, pp. 185-188, 2 pl. Washington, D. C., May 2, 1921.

Since 1910, a bacterial leaf spot disease of celery has been under observation. It has been widely distributed each season in western and central New York State on all the varieties of celery commonly grown. Of late years, the disease has also made its appearance in Michigan.

It is characterised by spots of a rusty brown colour, irregularly circular in outline, and rarely exceeding 5 mm. in diameter. They closely resemble the leaf blight spots produced by *Septoria Petroselini* var., *Apii*, and can only be distinguished with certainty by the absence of pyconidia, which show as black dots in the *Septoria* spots. Occasionally, the brown spots produced by *Pseudomonas Apii* are so numerous, as to cause the death of many of the older leaves, but usually the injury is limmited to the disfiguring of the foliage, and a possible reduction in the plants growth. As a rule, the leaf blades alone are affected, spots seldom, if ever, occurring on the petioles.

A bacterium, described by the author as a new species, under the name of *Pseudomonas Apii*, has repeatedly been isolated from the infected plant, and the characteristic spots have been obtained by inoculating celery with pure cultures of the micro-organism. When the latter are sprayed on the uninjured leaves, abundant infection is produced through the summer season under field conditions.

During the years 1915-1917, spraying as a means of controlling the disease was tested at Irondequoit and Williamson (New York), Bordeaux mixture (5-5-50) being used, and also commercial lime-sulphur solution (32° Beaumé) which was diluted 1 parts to 25 parts of water. The results obtained seem to show conclusively, that *Ps. Apii* is very satisfactorily controlled by spraying with Bordeaux mixture, but that lime-sulphur solution is useless for this purpose.

869 - ***Thelephora terrestris T. fimbriata* and *T. caryophylea* Basidiomyceles Injurious to Forest-Tree Seedlings in the United States.**— WEIR, R. A., in *Phytopathology* Vol. XI, No. 3, pp 141-144, 1 pl. Lancaster, Pa., March, 1921.

During the years 1912-1916, numerous specimens of three species of *Thelephora* were collected in the several National Forests in the North-West of the United States. Of these, one *T. terrestris*, Ehrh., was already known in Europe as attacking the seedlings of various forest trees, while the other two *T. fimbriata* Schw. and *T. caryophyllea* (Scheffer) Fr., were reported for the first time as injurious in this respect. The destruction caused by these basidiomycetes is due to the fact that they rapidly invest the organs of the plant (especially the stem, but also the leaves and root) either wholly or partially, so that the seedling is finally strangled.

T. terrestris has been observed to injure forest-tree seedlings in the States of Washington (on *Pseudotsuga taxifolia*, *Pinus monticola*, and *Thuja plicata*); Oregon (on *P. ponderosa*) ; Idaho (on *Abies grandis*, *Ps. taxifolia*, *P. ponderosa* and *Picea Engelmanni*) ; Montana (on *Larix occidentalis* and *P. contorta*); Utah (on *P. ponderosa*); Wyoming (on *P. contorta*) ; South Dakota (on *Acer Negundo*) ; Minnesota (on *P. mariana* ; Michigan (on *P. divaricata*) ; and Indiana (on *Quercus alba*).

The same fungus has also been found in British Columbia (Canada) on *Acer macrophyllum* and *Ps. taxifolia*.

It behaves in the same manner to various plants other than the seedlings of forest trees.

T. terrestris frequently appears in the sandy soil of forest-tree nurseries, and especially where the plants are dense enough to shade the ground. Although the behaviour of the fungus is often apparently parasitic, repeated examination of the young pine-seedlings enveloped by it has not shown any living part to be invaded. The mycelium ramifies in the surface soil, and merely penetrates the dead outer tissues of any plant encountered. If the plant is completely smothered by the fungus, the mycelium may penetrate into the tissues of the leaves through the stomata, and even form a brown layer between the dead bark and the wood of the stem. The fungus is often found hibernating in the thick moist bark at the base of young trees, and in this case, the mycelia may not be connected with the forest soil, but may draw its nourishment entirely from a damp, woody substratum. It has been found that the substratum exercises an influence on the form and colour of the basidiomycete.

During damp weather, the fungus grows very rapidly and may envelop a small seedling in a comparatively short time. It grows most rapidly during the night.

Nursery seedlings that are affected with *Thelephora terrestris* should be pulled up and burnt. It was found that where this was done the fungus did not develop in the beds the following year. The use of forest soil in the seed beds promotes the growth of the basidiomycete.

In 1914, and again in 1915 *T. fimbriata* appeared in considerable quantity at Haugan (Montana). Two-and three-year-old seedlings of *P. ponderosa* were in some cases completely enveloped. The same fungus was found, in 1916, on seedlings of *P. rigida* in Lycoming County (Pensylvania).

T. caryophyllea was observed on one-year-old seedlings of *Larix occidentalis* and *Tsuga heterophylla* in the seed-beds at the Priest River Experiment Station (Idaho).

[869]

Since then it has not reappeared, but is abundant in the surrounding forest, where it is occasionally found enveloping the stem of young lodgepole-pine seedlings.

INJURIOUS INSECTS AND OTHER LOWER AMIMALS

870 – **Lepidoptera in Texas Likely to be Confused with the Pink Bollworm of Cotton. — *(Pectinophora gossypiella)*** (1). HEINRICH, C., in the *Journal of Agricultural Research*, Vol XX, No. 11, pp. 807-836, pl. 18. Washington, D C, March 10, 1921.

The author purposed in this paper to define the characters distinguishing the larva and pupa of the pink bollworm, *Pectinophora* (*Gelechia*) *gossypiella* Saunders from those of other Lepidoptera attacking cotton, or related malvaceous plants, and of those feeding on other quite different hosts, but frequently found in the neighbourhood of cotton fields.

A few of these Lepidoptera, *Dicymolomia iulianalis* Walker, and *Crocidosema plebeiana* Zeller, for example, so closely resemble the pink bollworm in their habits and larval stages, that they can only be distinguished by a careful examination of their structure.

The field work upon which this paper is based was conducted throughout the area in south eastern Texas where the pink bollworm has been found to occur, as well as in Cameron County at the southern extremity of the State. Special attention was devoted to discovering whether *Pect. gossypiella* was attacking plants other than cotton. Thousands of seed pods of okra (*Hibiscus esculentius*) and other Malvaceae were examined. In one case, at Smith's Point (Chambers County), all the seed pods of a plant related to cotton (*Hibiscus lasiocarpus*), growing in the immediate vicinity of a field where a heavy infestation of the pink bolloworm had occurred during a previous year were removed and minutely examined. Similar investigations were made on other wild and cultivated Malvaceae growing in, or about fields where the pink bollworm had been found. In no place was the bollworm discovered on any plant other than cotton.

In this paper, 38 species of Lepidoptera, in addition to *Pect gossypiella* are described. Of these, six are mentioned as new to science and four already described are recorded for the first time from the United States.

In each case, the male genitalia of the type specimen of the new species is figured. The essential larval and pupal characters are dealt with in the text as fully as possible, and purely descriptive matter is reduced to a minimum.

The species are as follows: —

1) Fam. *Gelechiidae: Pectinophora gossypiella* (Saunders); *Gelechia hibiscella* Busck; *G. bosquella* (Chambers); *G. neotrophella* n. sp. *Telphusa mariona* n. sp., *Isophrictis similiella* (Chambers).

2) Fam. *Oecophoridae: Borkhausenia diveni* n. sp.

3) Fam. *Stenomidae: Aedemoses haesitans*. Walsingham.

---

(1) See *R*, Sept. 1917, No. 879. (*Ed*)

4) Fam. *Blastobasidae: Zenodochium citricolella* (Chambers); *Holcockera ochrocephala* Dirtz: *H. confamulella* n. sp.

5) Fam. *Ethmiidae: Ethmia delliella* (Fernald); *Eth. bittenella* (Busck).

6) Fam. *Cosmopterygidae* : *Pyroderces rileyi* (Walsingham).

7) Fam. *Tortricidae: Platynota rostrana* (Walker); *Pl. flaveiana* Clemens; *Amorbia emigratella* Busck.

8) Fam. *Olethreutidae: Crocidosema plebeiana* Zeller; *Eucosma discretivana* n. sp., *Euc. helianthana*, (Riley); *Laspeyresia tristrigana* (Clemes).

9) Fam. *Phaloniidae: Phalonia cephalanthana* n. sp.

10) Fam. *Aegeriidae: Zenodoxus palmii* (Neumoegen).

11) Fam. *Pterophoridae: Oedematophorus venapunctus* Barnes and Lindsey.

12) Fam. *Pyralidae*: *a*) sub-fam. *Thyridinae* : *Meskea dyspteraria* Grote; *b*) sub-fam. *Pyraustinae: Noctuella rufofascialis* (Stephens); *Pachyzancla bipunctalis* (Fabricius); *Glyphodes pyloalis* Walker; *c*) sub-fam. *Crambinae; Dicymolomia julianalis* (Walker); *d*) sub-fam. *Phycitinae: Moodna ostrinella* (Clemens); *Homoeosoma electellum* (Hulst); *e*) sub-fam. *Chrysauginae: Clydonopteron tecomae* (Ruley).

13) Fam. *Noctuidae*: (*a*) sub-fam. *Agrotinae: Heliothis* (*Chloridea*) *obsoleta* (Fabricius); *Hil.* (*Chlor.*) *virescens* (Fabricius); (*b*) sub-fam. *Acronyctinae: Bagisara rectifascia* (Grote); *c*) sub-fam. *Erebinae: Alabama argillacea* (Hübner); *Anomis exacta* Hubner; *An. erosa* (Hübner).

14) Fam. *Lycaenidae: Strymon melinus* (Hübner.

871 – **"*Muscardine*" *(Botrytis Bassiana)* Disease attacking Silkworms and other Insects.** — See No. 844 of this Review.

872 – **The Use of Rubber Tents in the Fumigation of Trees with Hydrocyanic-Acid Gas.** — *The India Rubber World* Vol. LXIV, No. 2, pp. 555-556, figs. 3. New York, May, 1921.

For twenty years, the growers of citrus fruits have sought in various ways to check one of the greatest drawbacks connected with the use of tents in the fumigation of trees with hydrocyanic acid, viz. gas leakage through the cotton fabric of which the tents were made; but even the application of a mucilage made from boiled *Opuntia* leaves mixed with linseed oil failed to made the material impermeable to the confined fumes.

After much study, G. HOCKENSMITH, an American expert on balloon fabrics, has succeeded in solving the problem. Having chosen a suitable material, he subjected it to the treatment given to balloons, and dirigibles during the War, the fabric not only being rubberised and made perfectly gas-tight, but also given an aluminium-colour facing, that makes the tent also opaque. The advantage of opacity is, that fumigation may be carried on in the tents, three or four hours before sundown. Experience with the plain canvas tents has proved, that day fumigation gives decidedly inferior results to night work. For some reason not yet explained, sunlight on ordinary tents during the fumigation of trees with liquified hydrocyanic gas often causes peculiar injuries to the fruit and leaves. Hence, the practice of doing most of the fumigation after sunset. It is claimed, that the new rubberised cloth tent will effectually keep out the actinic rays of the sun which are believed to be the rays exerting an injurious effect in conjunction with the gas, thus making daylight fumigation possible.

The new rubber tents are octagonal in shape, the centre being made of the heavy material, and the wings or sides, of a coated fabric which is somewhat lighter. Such construction not only reduces the weight of the tent, but also makes it easier to handle in the field. As might be expected, the cost of the rubberised tents is higher than that of the ordinary type but the advantages more than compensate for the extra cost.

A severe test, not only of the efficiency of the new tents in retaining, gas but also of their durability, was carried out recently at Corona, (California) where they were used for fumigating a thousand lemon trees.

Standardisation of fumigation has hitherto been impossible with such a variable factor as gas-leakage, which may always occur with porous sail-cloth, and is often influenced by weather conditions. To hold a definite amount of gas for a definite time is the very basis of fumigation, and these two essentials can be obtained by the use of gas-tight tenting material; with the latter, exact dosage can now be attained, not only to insure results, but also to avoid any danger to the tree from injury by excess gas, or over exposure. Further, by adopting the new type of tent the dosage for small trees can be reduced by two-thirds, for average-sized trees one half; and for very large trees one quarter. Also the time-exposure may be shortened from about an hour to an average of thirty minutes.

During fumigation, trees must be kept dry. Ordinary canvas tents often allow damp to reach the fruit and foliage; and when the liquified hydrocyanic acid unites with the moisture, serious damage may be done to the tree. Under a rubber tent, the tree may be entirely protected from both damp and wind, which latter also interferes to some extent with the fumigation process.

Even in the time taken for covering a tree, the use of the new tents effects a 50 % saving.

873 - *Tipula simplex* and *T. quaylii* Diptera Injuring Pastures and Grain and Lucerne Fields in California.

— PACKARD C M, and THOMPSON B G, in *United States Department of Agriculture, Department Circular* No 172, 8 pp figs 5. Washington, D. C, May 1921.

Californian pastures, and also the grain and lucerne fields, are often badly injured during the rainy season by the larvae of crane-flies, *Tipula simplex* Doane and *T. quaylii* Doane; which are frequently exceedingly abundant; in certain spots, as many as 300 to the square foot are found They devour all the grain and vegetation in these areas. The injury done by these insects is usually more noticeable during wet winters, such as that of 1920-21, but they occur in large numbers almost every winter in some locality, and a few can as a rule be found every year throughout the area inhabitated by this pest. On large stretches of pasture land, the larvae often destroy in a single year thousands of dollars worth of forage, for lack of which the live stock sometimes die of starvation. Further, they are likely to attack all winterplanted field crops, especially on newly-broken sod land, where the flies have an opportunity to breed and multiply undisturbed through several successive seasons.

The authors describe the habits and the different stages of *T. simplex* which are very similar to those of *T. quaylii*.

So far, the only known method of reducing the damage caused by these two diptera has been more or less continual cultivation This, however, is of no avail to save a crop that has already been planted, and is being destroyed by crane-flies. Cultivation can only prevent possible injury in future years, and cannot be applied at all to large areas of pasture land.

It had however been observed, that the larvae come out at night upon the surface of the ground. This fact, together with the indication that the species in question feeds upon the aerial portions of plants more than is commonly supposed, suggested the possibility that they would be attracted by the poisoned-bran bait commonly used for grasshoppers. During the winter of 1920-21, experiments were made in badly infested areas to determine the efficiency of poisoned bran in destroying the insects.

As a result, from 50 to 90 per cent of the larvae were killed on the experimental plots where several different poisoned-bran formulae were tried. The mixture usually recommended for the control of grasshoppers, which contains molasses and lemons added to the bran, Paris green and water, killed an average of 72 per cent of the crane-fly larvae present. Fully as high a percentage of mortality was however obtained on the plots where a mixture of bran, Paris green and water without any flavourings was used, and as this is cheaper and easier to make, the authors recommend a bait made in the following proportions: bran 25 lb. Paris green 1 lb. water (to make a flaky mash) about 3 gallons. The Paris green is mixed thorougly into the dry bran, then the water is gradually added, till an even, crumbly mash is obtained. The mixture can be spread broadcast by hand, or if the area is of considerable size, it can be scattered very easily and rapidly with a horse-drawn grain-seeder. Ten to twenty pounds per acre was the smallest amount that gave a uniformly high percentage of mortality over the entire plot. When less was used, the number of dead insects varied greatly on different parts of the plot, because of the difficulty of making an even distribution of the bait.

Amounts larger than 20 pounds per acre did not increase the efficacy of the bait, though when this is spread evenly and smoothly with a grain-seeder, good results can probably be attained with smaller quantities than if more or less unevenly sown by hand. The poison should be scattered broadcast over the entire infested areas, rather than in strips, because the larva of the crane-fly does not ordinarily travel far in search of food. The cost of this poison, made as recommended above is not great, and it is an efficacious practical remedy, that can easily be applied to crops attacked by the larvae of either *Tipula simplex* or *T. quaylii*. Precautions must be taken not to allow the poisoned bait to fall into lumps when spreading it on the field, and to avoid leaving quantities of it in places to which children and animals have access.

This bait has, however, been spread many times where cattle and sheep have been grazing, with absolutely no injury to the stock.

874 - ***Prodenia litura*, a Macrolepidopteron Injurious to Rice in Goa Portuguese India** (1). — CORRÊIA, ALFONSO, P. P., in the *Governo Geral do Estato da India, Direcção dos Servicos Agricolas e Florestais, Boletim de Agricultura*, Year II, Nos. 1-4, pp. 16-19. Nova Goa, 1920

The rice-fields of some villages of Salcete have recently been attacked by various species of migratory larvae, amongst which — according to the results obtained by artificial rearing — the most numerous were those of the two macrolepidoptera, *Spodoptera mauritia* and *Prodemia litura*.

Three methods of controlling the latter insect were traied (its habits are similar to those of the former):—

1) The use of poisoned baits containing arsenic; 2) catching the caterpillars in a special net swept over the plants attacked, the insects being afterwards killed or buried; 3) covering the surface of the water in the rice-fields with a petroleum emulsion, after passing a bamboo horizontally over the tips of the plants, and thus detaching, the caterpillars, which fell into the water. The third method was the most successful.

There are, however, other ways of combating the pests. On ascertaining the direction in which the caterpillars are proceeding, they can be prevented from reaching the nearest rice-field by cutting all the grass for a space 5 to 8 metres, thus forming a wide isolating band. Thus cut off and deprived of the plants necessary for their sustenance, the caterpillars die before arriving at the opposite margin of the strip that has been mown. The same results can be obtained by digging a sufficiently deep trench running across the caterpillars' path. Spraying with lead arsenate is also advisable, but it should be done at a time when there is no fear of its being washed off by the rain.

If none of these control measures are adopted, the ground should be ploughed deeply, in order to expose the chrysalids to their natural enemies, and to the destructive action of the sun's rays. By taking this precaution, the probability of a near fresh invasion of the insect is considerably diminished.

875 - ***Mineola indiginella* a Microlepidopteron Attaching *Cotoneaster* spp. in New Jersey.** — WEISS H. B. in *The Canadian Entomologist*, Vol. LIII, No. 4, pp. 73-75. Guelph, April, 1921.

For some years past, *Mineola indiginella* Zell. a microlepidopteron normally feeding on apple, quince, plum, cherry, peach and pear, which is rarely troublesome in well-kept orchards, — has been observed attacking various species of *Cotoneaster* especially *C. microphyllla* and *C. horizontalis*, in a nursery at Rutherford (New Jersey).

---

(1) See also *R.* Oct. 1912, No. 1476; *R.* Nov. 1912, No. 1585; *R.* Feb. 1913, No. 193; *R.* May 1914, No. 479; *R.* July, 1914, No. 690; *R.* May 1916, No. 590. (*Ed.*)

The habits of the insect on *Cotoneaster* are practically identical with those noted on apple-trees.

In the spring, the caterpillars open the large ends of the tube-like cases in which they hibernate (these are fastened securely to a twig for their entire length), and web up the foliage in the vicinity of these cases; later they feed on the leaves, flower-buds etc. Many of them feed on the green bark at the mouths of the cases, and sometimes strip it off all round the twig. As the larva grows, it enlarges its case. The larva becomes full grown about the first, or second week of June it then loosely closes the opening of its tube with particles of leaves and silk, and transforms into a pupa. After about two weeks, the moth appears. There is only one brood annually, and the July eggs produce over-wintering larvae. Most of the caterpillars appear to feed at night; they remain in their tubes during the daytime.

Considerable damage can be done to *Cotoneaster* by this insect, which is popularly known as the apple leaf-crumpler; when several larvae are present on one twig, it is soon girdled, moreover the leaves are small and the branches soon stripped.

The author gives a detailed morphological description of the larva of *M. indiginella*. At Rutherford they are parasitised to some extent by *Tachina phvcitae* Le Baron. Arsenic sprays applied early in the season of infested apple-trees, should prove effective.

876 - ***Ctenophora atrata*** **a Dipteron Attacking the Birch in Switzerland.**— BARBEY, A., in the *Bulletin de la Société vaudoise des Sciences naturelles*, Vol LIII, (1920), No. 199, pp 259-262, 1 pl Lausanne, June 19, 1921.

Ctenophora atrata L. was found in September 1915, in the Vallée de Conches (Canton of Valais), on the road leading to the village of Grengiol, at the entrance of the Binnthal (altitude 1200 m.). Holes 4 to 5 m.m. in diameter were discovered on birch-trees of which the wood was partly decayed, though in some cases it was still covered with bark. In the interior of the galleries, together with the larvae of certain polyphagous coleoptera, there were other very characteristic caterpillars, which when reared in the laboratory, proved to be the larvae of *Cten atrata.*

This wood-borer had already been repeatedly found in Switzerland and in Italy (Piedmont); it would also appear to be by no means rare in Belgium where its larvae also attack the birch.

Cten. atrata does not confine itself however to the birch, but also infests the poplar, alder, and lime; it is therefore a polyphagous insect, but probably eschews trees with resinous wood. On account of its large size, and preference for damp ligneous matter, the larva travels but short distances, and does not always leave behind it galleries of a very defined type. An examination of the injuries produced show that the insect excavates its burrows without any particular system. The galleries may be of different diameter, and the passage of the dipteron, as shown by its excreta, can be traced from the phloem to the heart of the decayed or dead branches and trunks. In dry wood which offers a certain resistance, the galleries made by the larvae are long and fairly regular, but this is the exception.

Pupation takes place in July, and lasts from two to three weeks, the process is carried out in an elongated, but irregular cavity situated near the periphery of the trunk.

877 - ***Stilpnotia salicis* a Macrolepidopteron Injurious to Poplars and Willows, Reported for the First Time from Massachusetts and New Hampshire** (1). — BURGESS, A. F., in *United States Department of Agriculture, Department circular*, 167, 16 pp. 7 figs. Washington D. C., May 1921.

The satin moth (*Stilpnotia salicis* L.) — an insect well known in Europe for the injury caused by its larvae to poplars and willows — was reported for the first time in the United States about July 1, 1920. At this date, it was found, that a number of poplar trees (*Populus monilifera* var. *angulata*) on the Malden and Medford line north of Boston (Massachusets) were being defoliated by the larvae of this insect. A hasty examination showed, that the most severe defoliation was in the region where the caterpillars were first reported, and several trees in a small group of *P. pyramidalis*(Lombardy poplar) had been completely stripped.

Observations in the field, in 1920, indicated that the small larvae of *St. salicis* chiefly fed on different species of poplar, those most severely attacked being the Carolina (*P. monilifera* var. *angulata*), Lombardy (*P. pyramidalis*), Balm of Gilead (*P. balsamifera*) and Silver Leaf (*P. alba*).

As regards the distribution of the satin moth in the United States, the insect is now known to occur over an area of 642 square miles, including 60 towns in Massachusetts, and 4 in New Hampshire. Probably a few of the insects had already existed for some years in the locality where they were first observed.

While it is impossible to determine the original source of the infestation it is very probable that *St. salicis* was brought into the United States during the dormant season in crevices of the bark of live or dead trees; bits of infected bark mixed with packing material could easily furnish a means of transporting the insect, for the hibernating webs of the small larvae concealed in the crevices of bark are so inconspicuous as to escape even careful inspection.

The larvae and pupae of the satin moth are effectively attacked by the adult and larval forms of *Calosoma sycophanta*. Another formidable enemy of the larger larvae of *St. salicis* is *Compsilura concinnata* Meigen.

Telenomus californicus Ash. is a parasite that has been reared from the eggs of the satin moth. The prospect of controlling the latter by parasites is encouraging but it may be necessary to import into the United States from Europe some of its enemies that do not at present exist in the former country.

---

(1) See also *R.* May 1921, No 595. (*Ed*)

Time has not permitted experiments to be carried out in the infected area to determine the most effective remedies against *St. salicis*, but from what is so far known concerning the latter — the paper analysed gives the data collected during the summer of 1920 respecting the stages of development and the habits of the insect — the following treatment would seem advisible.

1) Spray poplars and willows as soon as they are in full leaf with arsenate of lead at the rate of 10 lb. to 100 gallons of water, using soft soap to make the remedy adhere to the leaves.

2) If the infestation is severe, it may be necessary to repeat the operation by the middle of June.

3) If egg clusters are abundant on the trees in July, spray again with the same material about August 1.

The experience of a full years work on this insect will proably results in a modification of these recommendations.

INJURIOUS VERTEBRATES

878 - ***Epimys rufescens* and *Nesokia bengalensis* (?), Rodents Attacking the Coconut Palm and Cereals Respectively at Goa, Portuguese India.** — *Govèrno Geral do Estado da India, Direcção dos Serviços Agricolas, e Florestais, Boletim de Agricultura* Year II, Nos. 1-4, pp. 19-22, figs. 3. Nova Goa, 1920.

Epimys rufescens is undoubtedly one of the most dangerous enemies of the coconut, and the fruits, that this rodent destroys may be counted by thousands. It lives in a nest built at the top of the tree. It is capable of breeding when less than a year old, and always produces 5 to 10 young in a litter. There are at least 5 litters a year.

The little pest makes a round hole in the soft part of the green nut, sucks out the milk, and devours the recently formed kernel. Thus damaged, the fruit soon falls from the trees.

The rodent has some natural enemies among birds, reptiles and mammals, but many of these are destroyed by man owing to ill-founded suspicions, and also superstition connected with some of them (birds and reptiles).

Traps and poison are of very little use against *Epimys rufescens.*

In large plantations, in districts where the ground is covered with heath, each tree cannot be treated separately, owing to the great expense this would entail; therefore recourse is had to large fires. Piles of combustible material are placed in the plantation on the side whence the wind blows, and lighted towards evening, when the breeze gets up. Substances with a pungent, penetrating smell (sulphur, incense etc),as well as a little ground pepper, are strewn on the burning heap. The smoke spreads through the plantation, rising to the tops of the palms and drives away the rodents, which never again return. Men and animals must avoid the centres where these fires are kindled.

The preventive control measure which has hitherto proved most efficacious is to surround the trunk of the coco-palm completely at the height of 2 m. or more, from the ground, with funnels made of tin or zinc, and placed mouth downwards. These funnels should be 30 (or better) 15 cm. wide, and previously covered with tar.

Palms provided with these funnels must not be in contact with other unprotected trees, or with the branches of trees, which must be cut back systematically to within a distance of 2 m. from the palm Before surrounding the trunks with the above-mentioned protective apparatus, the tops of the palms should be carefully examined, and any nests found at once destroyed.

The severity of the invasion can be much reduced by leaving sufficient space between the trees, the proper aeration of their summits, and the general cleanliness of the plantation.

Another rodent, which is probably to be identified with *Nesokia bengalensis,* comes out of its nest in the ground at night and destroys cereals either by cutting off the tender plants or by gnawing the ears

The best way of killing these animals in their nests it by means of an apparatus sold under the name of the " White Ant Exterminator. " Naphthaline placed at the entrance of the nests drives the rodents away.

A mixture of 15 gm. arsenic and about 900 gm. of wheat flour should be strewn over the infested fields at night.

YEAR XII — NUMBER 9 SEPTEMBER 1921

INTERNATIONAL INSTITUTE OF AGRICULTURE
BUREAU OF AGRICULTURAL INTELLIGENCE AND PLANT DISEASES

INTERNATIONAL REVIEW OF THE SCIENCE AND PRACTICE OF AGRICULTURE

MONTHLY BULLETIN
OF AGRICULTURAL INTELLIGENCE AND PLANT DISEASES

FIRST PART

Description of valuable Chinese books presented to the Library of the International Institute of Agriculture

By GUIDO PERRIS.

The President of the Chinese Republic has been pleased to offer to the Library of the International Institute of Agriculture a work no less rich than rare — the splendid album descriptive of agriculture and silk-culture in China which was published in sumptuous style by the Emperor K'ANG HSI (1662-1722).

At the same time his Excellency LU-CHÊNG-HSIANG, formerly Minister of Foreign Affairs, who visited the Institute in 1919, expressed the desire to supplement on his own account the magnificent present of his Excellency the President of the Chinese Republic by the gift of a number of classical works on the subject of agriculture, also published in a most artistic form.

In order to testify to their gratitude to their Excellencies, the President of the Chinese Republic and LU-CHÊNG-HSIANG, the Permanent Committee of the Institute of Agriculture decided at one of its recent meetings to direct special attention in the Monthly Bulletin to the importance of this precious gift.

The brief review which follows will, it is hoped, serve to give an adequate idea of the high historic, artistic and scientific value of the works with which the Library of the Institute has recently been enriched.

The *K'ang hsi yü chih kêng ch'ih t'u* (1) or pictures of agriculture and silk-worm breeding published by the Imperial Court of K'ANG HSI may be regarded as a graphic representation of the forms in which agriculture and silk-culture were practiced in China during the reign of the Emperor K'ANG HSI (1662-1723).

---

(1) For purposes of the transcription of Chinese words into Latin characters, the orthography of Sir Thomas WADE, adopted by GILES in his *Chinese-English Dictionary* has been followed. Consonants and groups of consonants are always sounded as in English while vowels are pronounced as in Italian. A reversed apostrophe (') signifies that the consonant to which it is prefixed should be aspirated.

The somewhat curious history of this work dates back to the XIIth Century. In 1145 LOU SHOU, Governor of Yu ch'ien, presented the Emperor KAO TSUNG (1127-1162), the first representative of the Southern Sung dynasty, with a collection of drawings and poems entitled "*Kêng chih t'u shih*", i. e. Poems and pictures of agriculture and weaving." The drawings were intended to represent the methods of field work as practised at the time and the songs to express the sentiments of the country people. The present greatly pleased the Emperor and the work was engraved on stone in 1210 under the direction of a nephew of the author and remained popular for a long time. But though the songs have come down to us, the pictures have been almost entirely lost and it was only recently that a reprint of the book was discovered in Japan. The reprint was made in the XVIIth century and contains reproductions of the original illustrations.

The Library of the Institute already posesses a copy of the *Kêng chih t'u shih*, " Poems and pictures of agriculture and weaving, " by LOU SHOU, which appears in a volume included in a collection of rare works belonging to different dates and of a different character. This was published by the Emperor CH'IEN LUNG (1736-1795) with the title of: *Chih pu tsu chai ts'ung shu* and bears the date of 1781 (1), and includes two others works on agriculture, both important and rare. Of these the first is the *Nung shu* (handbook of agriculture) of CHÊN FU, a small treatise published for the first time in 1149. This work is divided into three chapters (*chüan*), the first of which deals with agriculture proper and includes twelve numbered sections followed by two that are not numbered; the second deals with cattle breeding, contains a preface and two numbered sections; the subject of the third is the rearing of the silkworm and the culture of the mulberry, with a preface and five numbered sections. There is also an author's preface followed by notes which provide interesting information on the importance and the history of the *Nung shu*. This is followed by a short disquisition on silk-growing, the *Ts'an shu*, written by the celebrated littérateur, CH'IN KUAN (1049-1101), which was probably printed for the first time in 1214. It consists of nine brief sections, each containing short instructions on the rearing of silkworms, and of three interesting notes on the objects and origins of the industry.

Two important notes by WAN TSO-LIN, a writer of the CH'IEN LUNG period come next and are followed by a reproduction of LOU SHOU's *Kêng chih t'u shih*. Only the text, however, is given, consisting of 21 poems on agriculture and 24 on weaving. Immediately after the poems and on the back of the 8th and the front and back of the 9th folios appear the observations of Lou Hung, the nephew of the author, bearing the date of 1210, which are of great importance for the history of Lou Shou's work. This is followed by an appendix entitled *Kêng chi t'u hou hsü* with observations by another nephew of the author, called Lou Yo (1137-1213), who held high office in the Empire and was a writer of repute. The whole concludes with some brief remarks by Lou Shao grand nephew of Lou Shou, dated in the first year of the reign of Chia Hsi, about 1237.

---

(1) This book contains a final note which makes it possible to establish its date. The note states that on the 19th day *jên ch'ên* of the first month of the year *hsin ch'ou* (1781) of CH'IEN LUNG, a certain FANG P'U of Jên Ho finished his task of transcribing the 18705 monosyllables which make up the volume.

These various comments, which provide interesting details with regard to the origin and vicissitudes of Lou Shou's work, at the same time testify to the interest and enthusiasm aroused, even in the days of the Sung Dynasty, by the publication of Lou Shou's collection of pictures and poems about agriculture and weaving. The work is in brief a glorification of agriculture, inspired by the respect and veneration with which it has always been regarded by the Chinese Nation.

Wan Tso-lin's remarks (the first dated 1738), to which reference has been already made, acquaint us with the fact that the three former works were offered by certain literati in the Chiangnan (1) to the Emperor K'ang Hsi who was travelling at the time in the Southern Provinces. The copies offered to the Emperor were based on all the rarest editions of the Sung epoch.

The *Kêng chih t'u shih* of Lou Shou at once interested the Emperor very deeply, so much so that he desired to have a second edition made and illustrated by drawings more in accord with the contemporary spirit. He entrusted the celebrated artist Chiao Ping-chêng with the carrying out of the drawings, and himself wrote for each picture a poem descriptive of the subject.

The work was published in 1696 in an elaborate form with a preface by the Emperor, emphasizing its importance and scope. Below is given a translation to indicate the lofty political interest with which the Emperor was inspired in the deep veneration which he cherished towards agriculture, which in fact during the whole period of his reign received every possible encouragement.

Preface by the Emperor K'ang Hsi.

" Morning and night my thoughts turn to the state of the Empire and my heart is full of anxiety for the future. When I consider the foundations on which rest the life of my people, food and clothing appear to be the most important of all. Moreover I have read the Chapters " On the Customs of *Pin* " (2) and " The Precepts against Extravagance. "

---

(1) The actual provinces of Chiang-su and Anhui.

(2) The chapter " On the customs of *Pin* " (*Ping fêng*) is the fifteenth book of the first part (*kuo fêng*) of the *Shih-ching* "Book of Odes", one of the sacred books of China, and consists of a very valuable collection of odes and popular songs, recited and sung on different occasions, and dating back to different periods between 1769 and 600 B. C They were

The recommendations therein contained on the subject of seed time and harvest, the rearing of the silkworm and the cultivation of the mulberry are full of interest and at the same time complete. At all periods in the past, these subjects have been handled to the sound of the flute and the accompaniment of the harmonies of stringed instruments as well as discussed in laws and edicts. It is the duty of whosoever presides over the well-being of the Empire to reflect continually on these questions.

The laws of the Western Han Dynasty (1) which so nearly approach antiquity say " Injury to agriculture gives birth to famine, confusion in women's weaving work causes suffering on account of the cold. " They say again that " Old men shall die after a long life and young people shall reach an advanced age. "

If a man attempts to realize these precepts while neglecting the fundamental laws on which they depend, all his labour with be nothing worth.

Every time that I have travelled about the provinces and have heard the sound of the voices of the country people, I have been rejoiced to note the signs of agricultural labour, the condition of the land in the North and in the South, the preparations for the sowing of millet and rice, the

selected and classified by Confucius himself. *Pin* is the name of the capital of a small feudatory state belonging to the family of the Chou before it took possession of the throne. This chapter on the customs of *Pin* deals with the subjects of agriculture and weaving in a style that has become classic, an object of admiration and a model for all Chinese literati and poets, who seek its inspiration every time they compose poems dealing with agricultural work.

This ode, which depicts with a sentiment profoundly religious, the conditions of life among the people of *Pin*, their field work varying in accordance with each month of the year, the prosperity which the inhabitants enjoyed as a result of the beneficent institutions of a wise Government, is always referred to with sorrow and regret, as the far-away picture of the type of prosperity that a tiny state had been able to obtain, thanks to the wisdom and piety of its rulers many centuries before our era.

In thus alluding to it, K'ang Hsi makes evident his intense interest in agriculture and the well being of his people.

" The Precepts against Extravagance " (*Wu i*) are found in the 15th Chapter of the *Chou shu*, " historical records of the Chou dynasty, " which is itself the fifth part of the " *Shu ching* " or Book of History, another book regarded as sacred by the Chinese nation, which covers a period dating from the middle of the XXIVth century B. C. to the year A. D. 721. Agricultural work is praised in this chapter also, and the Emperor's reference to it has the same motive as that to the chapter " On the customs of *Pin*. " Both chapters are ascribed to the Duke of Chou (Chou Kung, d. B. C. 1106) brother of the first Emperor of the CHOU dynasty and renowned throughout the ages for his wisdom and virtue.

(1) The Western or Former Han Dynasty was in power from B. C. 206 to A. D. 23. It is therefore considered by the Chinese as very closely approaching the period of classical antiquity which is taken as a model of good government and morals, and embraces a period, which starts with the beginning of Chinese history and lasts till the fall of the Chou dynasty in the 3rd Century B. C. The precepts quoted by the Emperor K'ang Hsi are to be found in an edict of the Emperor Ching Ti (B. C. 156-140) published in B. C. 145 to call upon the people and magistrates to devote the utmost attention to agriculture in order to avoid the risk of famine. This edict which is reproduced in the History of the Western Han Dynasty is likewise quoted in the *Shou shih t'ung k'ao*, book 43, fol. 1, back.

variety of the seasons and the measures taken to destroy the locust. It has been for me a true pleasure to seek and obtain exact information on all such matters.

When busy with affairs of state, I discuss the problems with Ministers and Officials on the borders of the " Well-watered Garden " (1), wherein are many cultivated plots while the peasants allow the water of the stream to run freely in the furrows, and the eye rests upon a succession of rice fields, and the ear is filled with the clatter of buckets. The peasants can safely reckon on the ripening of an abundant crop consisting of many thousands of *chung* (2). Mulberry trees are planted on the borders and all along the footpaths and close to them huts have been built for the rearing of the silkworm. The cocoons are washed and the silk is wound and so the work proceeds exactly as though under the thatched roof of peasant's cottage. Moreover I have built the Pavilion called " The Knowledge of Agriculture " and the " Kiosk of the Autumn Cloud " in order to be able to observe all the processes in detail.

It was a saying among our ancients : " Let him who is clothed in silk think of the cold from which the weaver woman has suffered : let him who eats the loaf remember the weary labours of the peasant. " On these maxims my thoughts dwell deep and long. For this reason I have ordered the " Pictures of agriculture and weaving " to be designed, each subject being illustrated by 23 drawings.

To each of these pictures I have added a poem of my own composition, and these I have written so that they may be used as songs to beguile the labour and the weariness of the field.

The pictures represent the weary toil of the peasant, which raises hard places on his feet and hands, and the harsh life of the women who rear the silkworms and have the care of the cocoons, the silk and the weaving. The field work is depicted in most complete and minute detail from beginning to end.

I have ordered new plates to be engraved in order that these pictures may be handed down to posterity and that our sons and grandsons, and our subjects of all classes may learn that the wheat, which is their staff of life, is cultivated with toil and pain, and that the raiment they wear is no less difficult to provide.

In the *Shu-ching* (Book of History) is written this precept: " But love the good gifts of the soil, and you will be pure in heart. "

Of a truth these pictures contain much to stir the heart. But my chief desire is that they may serve throughout my Empire, to give each a pride in his own work, in order that he may be able to devote himself to it with all his strength and live sparingly, so that the fruits of the earth may ever more and more increase.

---

(1) " The Well-watered Garden " (*Fêng tsê yuan*) was in the grounds of the Imperial Palace at Pekin. It was laid out by the Emperor K'ANG HSI and contained several *mou* of rice-fields, many rows of mulberry trees and many nurseries of silkworms. In the *Shou shih t'ung k'ao*, book 51 fol. i (front and back) and fol ii (front) a description of this garden is given in the form of a poetical essay by the Emperor CH'IEN LUNG, entitled *Fêng tsê yuan chi.*

(2) An ancient Chinese measure of capacity, equivalent to 6 *hu* and 4 *tou.*

When there is enough and to spare of food and clothing, each citizen will be able to reach the realm of peace and concord, prosperity and long life. Such is my heartfelt prayer in my profound desire for the well-being of the mass of my people.

Composed and written by the Imperial hand in the 35th year of K'ANG HSI (1696) in the second month of spring, on the 5th day dedicated to the Divinity of the Earth (1) ».

The work which has been presented to the Institute by His Excellency, the President of the Chinese Republic, is of exceptional rarity (2) and a perfect treasure-house of Chinese typographic art. CHIAO PING-CHÊNG's plates are dry point engravings on wood and handpainted with most remarkable care and exactitude, giving an extreme delicacy of tone and a clear outline of each figure on a rural back ground, treated with a deep feeling for natural beauty. This copy is perfectly preserved and without any defect. It is in fact a fresh edition of the CH'IEN LUNG period made throughout with the K'ANG HSI original blocks, to which have been added poems by the Emperors YUNG CHENG (1723-1735) and CH'IEN LUNG (1736-1795), both of whom desired to follow the example of their illustrious ancestor and to compose a poem for each of the pictures.

The work consists of two large volumes in album form, enclosed in a covering of richly adorned silk with clasps of carven ivory. This in its turn is ingeniously contained in a wooden case bearing the inscription " *K'ang Hsi yü chih kêng chih t'u,* i. e. " Pictures of agriculture and weaving, Imperial edition of K'ANG HSI. " The first illustration shows the casket just described.

Each volume is bound in a double covering of stout boards, the second being faced with a handsome brocade. The second illustration shows the brocaded cover of the second volume. The inscription on the left hand side is in manuscript and the title is identical with that on the casket. The three lines in small characters below the title run as follows *" Hsia ts'ê chih t'u êrh shih san yüeh tê yü chang an kung chieh ho yüan*

---

(1) *Shê jih*, days of sacrifice, coming once in the spring before seed-time, and again in the autumn after harvest. They were sacred to the Earth, personified as the tutelary deity of the soil.

(2) MAURICE COURANT (p. 145 sq. of the second volume of his " Catalogue des livres chinois, coréens et japonais de la Bibliothèque Nationale de Paris ", 1903) describes very briefly certain copies of the *Kêng chih t'u* (nos. 2394-2398) but it does not seem possible that any of these were based on the original plates of K'ANG HSI. They differ entirely from our work in form or other essential points. The same is the case with the copy in the National Museum of Natural History of New York and that in the Konigliche Bibliothek of Berlin. These last are slightly more in accord with our copy, which is however greatly superior both as regards technical execution and state of preservation.

shih ts'ang chên" i.e. "IInd volume, weaving, 23 pictures; which became the property of the Archives of GHANG-AN in the third month of the spring season of 1753 and was preserved among the treasures of. HO YÜAN [pseudonym], (whose red seal is affixed)." The same legend is also to be seen on the cover of the first volume with of course the exception of the number and subject. These markings lead to the conclusion that the work was produced at a date previous to 1753 and probably between 1736 and 1742, that is to say, before the Emperor CH'IEN LUNG gave orders for the engraving of the plates for the edition issued under his control (1). The two albums are 3 ½ cm. thick and almost square is shape, being in fact 28 cm. wide by 26.8 cm. long.

In the first volume two blank pages are followed by six which contain Emperor K'ANG HSI's preface, of which a translation has already been given. This preface is a facsimile, printed in red, of the original hand writing of the Emperor. On the first page (fig. 3) in the right hand lower corner is to be seen a manuscript inscription in black characters, meaning "Preserved as a precious relic in the "Pavilion of Serene Peace," (*An ching t'ing chên ts'ang*). The red rectangular seal (*Kuan fang*) of the command of a western expeditionary force (2) has been stamped by hand over the inscription.

The pictures on agriculture are found immediately after the preface and all are on the page to the right hand of the reader, while the text of the Imperial poems is on the opposite page. Each of the pictures measures 24.5 × 24.7 centimetres, and has a black line border. In one of the blank corners, or, where all the corners are occupied by the drawing, in any available blank space, the original poem of LOU SHOU on the subject of the picture is inserted. The poems of LOU SHOU are in 8 verses of five monosyllables apiece.

The text of the Imperial poems takes up the page to the left of the picture to which it relates and is framed in a red border, 3 centimetres wide. The space occupied by the text is broken up into 8 columns, lettered in red, and is 18 × 19 centimetres wide.

---

(1) A very detailed study of the *Kêng chih t'u* and more particularly of the Edition of *Ch'ien Lung*, has been published by O. FRANKE in a volume entitled: "*Kêng chi t'u, Ackerbau und Seidengewinnung in China,*" Hamburg, 1913. The eminent French authority on China, PAUL PELLIOT, has contributed a masterly footnote to O. FRANKE's important monograph by his erudite article "A propos du *Kêng tchê t'ou*" which is published in the "*Mémoires concernant l'Asie Orientale,*" Vol. I, Paris, 1913.

(2) The same seal occurs on the page of the text corresponding to the 23rd picture in the first part, and on the 1st, 2nd and 23rd pictures and corresponding pages of the text in the second. On the first picture in the second part (fig. 7) the print of the seal is particularly clear and runs thus: *Kuan tai hsi chêng hsüan fêng yang p'ao chang hsü tui shih kuan fang,* which may be roughly translated: "Command of the expeditionary force against the rebels of the West. Front line. Regiment of Western Artillery and Dragoons, Official seal." It would be interesting from the point of view of the history of the Album to be able to identify the various persons into whose possession it came, following the line of the various inscriptions referred to above.

The first column to the right indicates the section, the number of the picture in the series and its title. The second and the third columns contain the poems of the Emperor K‘ang Hsi in 4 verses of 7 monosyllables apiece. In the fourth, fifth and sixth columns is given the poetry of the Emperor Yung Chêng in 8 verses of five monosyllables a piece following exactly the model of Lou Shou. The poems of Emperor Ch‘ien Lung, which are in the same metre as those of K‘ang Hsi, are to be found in the seventh and eighth columns, but none of the poems bears any indication of the author. At the end of the first volume in the lower corner to the right in picture 23, immediately after the verses of Lou Shou, is inscribed the name of the painter, Chiao Ping Chêng, who styles himself Secretary of the Imperial Bureau of Astronomy. The same inscription is to be seen in the lower left hand corner of picture 23 at the end of the second volume. The pictures and the text in the second volume are arranged in the same manner as those in the first

The first volume is devoted to agriculture (*kêng*) or, more correctly, rice-culture, from the period of sowing to that of Harvest Thanksgiving. The second volume is devoted to weaving (*chih*) that is to say the rearing of the silkworm and the completion of the fabric.

Below are given the titles of the various pictures with brief notes of explanation.

First Part. — AGRICULTURE (*Kêng*).

1. *Ch‘in-chung*	Immersion of the Grain.
2. *Kêng*	Ploughing.
3. *P‘a-nou*	The first harrowing, by a rigid harrow with three rows of teeth, ridden by the worker.
4. *Ch‘ao*	The second harrowing, by a harrow with a single row of teeth and a vertical frame held in the hand.
5. *Lu-tu*	The third harrowing, by a light harrow with three rows of teeth.
6. *Pu-yang*	The sowing.
7. *Ch‘u yang*	The first sproutings.
8. *Yü-yin*	Manuring. As soon as the shoots appear, a small trough attached to a rod is used for this purpose.
9. *Pa-yang*	Raising the seedlings.
10. *Ch‘a-yang*	Pricking out the seedlings.
11. *I-yün*	First weeding.
12. *Erh-yün*	Second weeding.
13. *San-yün*	Third weeding.

14. *Kuan-kai*	Irrigation, by a hand-windlass.
15. *Shou-i.*	Cropping.
16. *Têng-ch‘ang*	Grinding.
17 *Ch‘ih-sui*	Threshing with double flail.
18. *Ch‘ung-tui*	Pounding with pestle and mortar
19. *Shai*	Sifting.
20. *Po-yang*	Winnowing
21. *Lung*	Cleansing.
22. *Ju-ts‘ang*	Storing in the granary.
23. *Chi-shên*	The Harvest Thanksgiving.

SECOND PART. — WEAVING (*Chih*).

1. *Yu-ts‘an.*	The bathing of the silkworms' eggs.
2. *Êrh-mien*	The second sleep.
3. *San-mien*	The third sleep.
4. *Ta-ch‘i*	The great awakening.
5. *Cho-chi*	Maturity. The fully developed worms are taken out by means of nets, and the weaklings are rejected.
6. *Fên-po*	Bedding-down.
7. *Ts‘ai-sang*	Plucking the mulberry leaves.
8. *Shang-tsu*	Mounting the silkworms.
9. *Chih-po*	Heating the trays.
10. *Hsia-tsu*	Extracting the cocoons.
11. *Tsê-chien*	Sorting the cocoons.
12. *Chiao-chien*	Care of the cocoons.
13. *Lien-ssŭ*	Winding off the silk on the frames.
14. *Ts‘an-ê*	Mating the moths.
15. *Ssŭ-hsieh*	Thanksgiving to God.
16. *Wei*	Making the weft.
17. *Chih*	Weaving.
18. *Lo-ssŭ*	Making the skeins.
19. *Ching*	Making the warp.
20. *Jan-sê.*	Dyeing.
21. *Pan-hua*	Weaving embroideries.
22. *Chien-po.*	Cutting up the finished silk.
23. *Ch‘êng-i*	Garment making.

A few reproductions of the drawing with the text of the accompanying poems are appended.

The first picture in the first part of the *Kêng chih t'u* (fig. 5) represents the watering of the seeds, the first task of the agricultural year. In the early days of April, baskets containing the seed are dipped in the stream flowing past the peasant's cottage in order that the action of the water may develop its power of germination. In the left hand corner is LOU SHOU's poem of which the following is the text and a translation.

CH'IN CHUNG

Ch'i t'ou yeh yu tsu
Mên wai ch'un shui shêng
Yün lan ch'in ch'ien pi
Chia ku ch'ou hsin mêng
Hsi ch'ou chiang yu shih
Lei ssŭ sui ch'ên hsing
Chih chi chi kou mang
Tsai pai ch'i ch'iu ch'êng

IMMERSION OF THE SEEDS.

" Last night on the mountain, whence springs the stream, were rains abundant.
At our door the spring floods have swelled the brook.
Now plunge we our frails in the shallow green waters.
So that the bountiful seed may send out its tender shoots
In the fields of the West toil now begins,
And the ploughshare follows the course of the rising sun.
To the God of Spring we sacrifice a cock, (1)
And pray once more that in the Autumn time we may reap rich harvest. "

Fig. 4 gives a reproduction of the page of the text corresponding with Picture I. It contains the poems of K'ANG HSI, YUNG CHÊNG and CH'IEN LUNG of which a rough version is given:

K'ANG HSI's poem:

Hsüan ho chieh hou chao nung kung
Tzŭ t'zŭ ch'in lao ch'i ch'u t'ung
Tsao pien tung t'ien t'ung lu chung
Ch'ien shang shê shui ch'in yün lung

" The toil of the field begins as mild, and balmy grow the days.
Now all around with equal zeal men start to work
Early in the day, for the Eastern fields seed slow and quick of growth is chosen
The peasants barelegged step down into the stream to dip their frails. "

---

(1) " KOU MANG " is the protective Genius of the Spring

YUNG CHÊNG poem:

Pai ku i chia chung
Hsien nung chu mou kung
Ch'un hsüan êrh yüeh hou
Hsiang ch'in i ch'i chung
Chung lu sui i pien
Yün lung yung li t'ung
Mei to hsien fu lao
Chan chieh shih nien fêng

" The fruitful seeds given by last year's crops
Safeguarded by the Divine *Shên Nung*, (1)
In the third month, in Spring's warm days,
Are plunged in the sweet-smelling stream.
The slow growths and the quick are chosen,
And all together grasp the frails,
What time the village grey beards
In fullness of knowledge predict a year of abundance."

Poem of CH'IEN LUNG:

Ch'i pu ching yang tsao hua kung
Tung chiao shu tsai wan fang t'ung
Ch'i liu ch'in chung ju yu lu
Shêng i han ch'un hsiu sê lung

" The creative influences of Spring are spreading through the air.
Eastwards in the country round about the city, field work is on all
sides beginning.
The grain is being dipped in the stream, flowing down from the
mountain and now green as oil.
Spring's joy is all pervading and the grain frails are fair to see ».

Fig. 7 depicts the first process in silkworm rearing, the bathing of the eggs before hatching out, which takes place in mid-April.

LOU SHOU's poem, which is to be seen in the upper right-hand corner, and the page of text corresponding with the picture which contains the poems of the three Emperors on the same subject may be rendered as follows.

---

(1) SHÊN NUNG (2852-2737 B. C.), the Divine Husbandman, was one of the five first legendary rulers of China. Tradition ascribes to him the discovery of the plough, and also the instruction of his people in the art of cultivation and the use of medicinal herbs He is regarded as the tutelary Divinity of Agriculture.

LOU SHOU's poem:

YÜ TS'AN.

Nung sang chiang yu shih
Shih chieh kuo chin yen
Ch'ing fêng kuei yen jih
Hsiao yü yü ts'an t'ien
Ch'un shan chüan kao mei
Pên ch'ih lung ch'ing ch'üan
Shên kung hsiang chai chieh
Kung sang shuai min hsien.

THE BATHING OF THE SILKWORMS'EGGS.

" The field worker's and the silk worker's toil is now beginning,
For the days when no fires may be lit are past (1).
When gently blows the breeze and the swallows return,
And lightly fall the spring showers, then is the time to cleanse the silkworms' eggs.
So turn back the sleeves of your white Spring garments,
See how the water in the vessel gleams crystal-clear.
In the Imperial Palace strict fast is kept,
And, for an example to his folk, the Emperor himself tends the mulberries "

K'ANG HSI's poem:

Pin fêng ts'êng chu shou i pien
Ts'an shih sh'u hsing ku yü t'icn
K'êng k'ao kung sang ch'uan li chih
Hsien i yu chung hsiang ch'ing ch'uan.

" As hath been already set forth in the chapter " on clothing " in the " Customs of PIN "
Silkworm rearing begins on the " Ku yü " day (2)
Moreover it is laid down in the rules of the Book of Ritual (3), in the passage on the Ducal mulberry trees,
That the first task is to plunge the eggs in the sunlit waters of the stream. "

---

(1) "*Chin yen*", i. e. the period when no fires were allowed, came round towards the end of spring or at the end of the 3rd month of the Chinese year. For several days the lighting of fires and all cooking were forbidden.

(2) "*Ku yü*" (literally "grain rains") is a solar term corresponding with the 20th of April when the Sun enters the Constellation of Taurus.

(3) The *Li Ki*, or Book of Rites, is one of the texts of the teachings of Confucius in which is collected all the information relating to the ceremonies, rites and customs, both civil and religious, practised by the Chinese of ancient times.

YUNG CHÊNG's poem:

Men to yang liu fêng
Ch‘i chang t‘ao hua shui
Ts‘un chiu yun yang kao
Ch‘un kuei yu ts‘an tzŭ
Hsien hsien lung ts‘ui p‘ên
Ch‘i ch‘i juan hsiang chih
Hsüeh chien yu ping ssŭ
Fu kung ts‘ung tz‘ŭ shih.

"When among the willows before the house the breezes blow gustily
And the steamlet issuing from the mountain is swollen and noisily flow its waters, now coloured as the peach bloom,
The village keeps solemn festival with lamb's flesh and wine,
While in the rooms of the women the silkworms' eggs are cleansed.
Then fair hands hold the basin, turquoise green,
And in it are poured the eggs from the scented packet.
Later from the cocoons all snow white, silk icy white will be woven,
Now the tasks and the toils of the women begin."

CH‘IEN LUNG's poem:

Ts‘êng tu pin fêng ch‘i yüeh pien
Ch‘ih ch‘ih jih ting li kuang t‘ien
Hsin ts‘an wei ch‘i hsien i yu
P‘ên man ming pi jên man ch‘uan

"It is written in the chapter "on the 7th month" in the "Customs of PIN",
When the shadows grow longer and the sky shines bright,
The yet-unhatched and tender silkworms' eggs are cleansed
In basins filled with the clear waters of the stream, where all the folk are gathered round."

A characteristic picture representing a stage in rice-culture, the pricking out of the seedlings, has also been chosen for reproduction. From the most remote age this practice has existed in China, though with us it has been followed in quite recent years only and is not as yet general. The poem of LOU SHOU on the subject is to be seen in the upper right-hand corner. It runs as follows:

CH'A YANG

Ch'en yü mai ch'in jun
Wu fêng huai hsia liang
Ch'i nan yu ch'i pei
Hsiao ko ch'a hsin yang
P'ao chih pu t'ing shu
Tso yu wu luan hsing
Wo chiao ch'a yang ma
Tai lao min mo wang.

PRICKING OUT THE SEEDLINGS.

" In the mouth of May the dawn showers bathe the soil,
And the South Wind keeps the summer days cool as it rustles the acacias.
To South and to North of the streamlet that comes down from the mountain,
With jest and song the country folk prick out the rice-seedlings.
Stooping to earth and never remitting in their toil,
They move steadily to right and left.
I will teach you to do the work with a tool of wood:
This will lighten your toil; give heed to my instruction." (1)

⁂

The works presented by his Excellency, M. LU, form a worthy complement of the gift of the President of the Chinese Republic. They comprise:

1) *Nung chêng ch'üan shu*
2) *Ch'in ting shou shih t'ung k'ao*
3). *Chih wu ming shih t'u k'ao.*

A brief summary of these three works follows.

The *Nung chêng ch'üan shu* is a complete treatise on Agriculture in sixty volumes (*chüan*) and the classical work on agriculture for the Ming dynasty (1368-1644). The author was HSÜ KUANG-CH'I (1562-1633) the famous pupil of the Jesuit father, Matteo RICCI, under whose influence he was converted to Catholicism.

From the biography of the author which appears in the History of the Ming Dynasty (book 251, folio 15), we learn that HSÜ KUANG-CH'I held a very high place in public life. Hence it is not surprising that his conversion raised the highest hopes among the missionaries, who at his baptism wished to give him the name of Paul, to indicate the

---

(1) A description of this tool as used in the rice-field is given in the *Nung-chêng-ch'üan-shu*, book 21, 19th folio (front and back).

Apostolic service that they expected from him in China. Their hopes were however doomed to disappointment for Hsu Kuang-ch‘i remained for all time the only example of a Catholic convert among high Chinese functionaries. However in his writings he gave currency to the European scientific knowledge that he had acquired as a result of the instruction he had received from his Jesuit instructors

Hsu Kuang-ch‘i died before he had quite completed his treatise on Agriculture which was not published till 6 years after his decease. Although according to the History of the Ming Dynasty (Ming shih, book 251 folio 17 front) the question of an Imperial Edict ordering the work to be printed was raised, no Imperial Edition of the book has been discovered. Probably the internal struggles which a little later brought about the fall of the Ming Dynasty prevented the carrying out of the Imperial order. The fact remains that the *Nung chêng ch‘uan shu* as appears from the Imperial Catalogue of Ch‘ien Lung (*Ch‘in-ting-sŭ-k‘u-ch‘üan-shut-sung-mu*, book 102, folio 15 back) was printed by Ch‘ên Tzû-lung, who received it from one of Hsu’s uncles, Chang Kuo-wei and Fang Yo-kung, who were all high State dignitaries. The first edition made its appearance in 1639. It contains the preface and the notes of the three editors named above, who were contemporaries of Hsu-Kuang-ch‘i. He himself was a native of Shanghai, close to which is to be found even to this day a famous Jesuit Community in a district which takes its name from the Hsu family (*Zikawei* [Hsŭ-Chia-Wei] = Villa of the Hsu family).

Hsu Kuang-ch‘i’s work, which is truly a monumental record of Agricultural science in the days of the Mings, has had an enormous circulation throughout China and has run into numerous editions.

The copy presented to the Institute by his Excellency was printed in the first half of the year 1800.

The library of the Institute possesses a second copy, presented by the Chinese Government in 1909. It is a reprint dated 1843 (the 23rd year of the reign of Tao Kuang) edited by T‘ai Yuan Shih and published by the house of *Shu-hai-lou* at Shanghai.

The *Nung Chêng ch‘üan shu* is in effect a most carefully produced Encyclopaedia of Agricultural Science. In it the subject is considered in its scientific and practical aspects, not merely as affecting the agriculturist alone, but rather from a wider and more general point of view as a form of Political Science, the base and foundation of a complete system of government. Herein lies the most original and important characteristic of the work of Hsu Kuang-ch‘i, who, taking as his standpoint the old classical idea that “ Agriculture is the basis of the Empire and the greatest and most useful of the Arts ”, considers that a treatise on agriculture viewed generally should keep in view the realisation of the well-being and comfort of the people, and aim at guaranteeing their freedom from disturbance and the maintenance of a Government resting on solid foundations

A brief summary of the contents of the treatise shows that the first

3 books (*Nung-pên*) deal with agricultural literature from the earliest down to the author's own period. It contains numerous quotations from the classics and also from the scientific publications of the most famous writers. A historical study is also given, showing the great importance paid at all times by the different Chinese Dynasties to questions relating to Agriculture in general.

Books 4 and 5 (*t'ien-chih*) deal with the land-systems and the distribution and classification of estates.

Books 6 to 11 (*nung-shih*) describe field-work.

Books 12 to 20 deal with Hydraulics and Irrigation. Here for the first time European hydraulic science is referred to in a Chinese book. HSÜ KUANG-CH'I gives a partial reproduction of the treatise on hydraulics which he himself wrote at the dictation of Father SABATINO DE URSIS which had already been published in six volumes under the title of *T'ai hsi shui fa* (1). Part of the 4th, and the 5th volume are omitted as being purely speculative and theoretical.

Books 21 to 24 (*nung-ch'i*) contain a complete description of the various agricultural implements and machines with explanatory matter and numerous drawings.

Books 25 to 30 (*shu-i*) treat of the cultivation of the chief crops; cereals, vegetables, fruit-trees, etc.

Books 31 to 34 (*ts'an-sang*) describe at length the cultivation of the mulberry and the breeding of silkworms. In particular in books 33 and 34 are to be found a number of drawings of the "plant" used in silkworm breeding and also for spinning and weaving the silk.

Books 35 and 36 (*ts'an-sang-kuang-lei*) give a detailed account of the modes of cultivating cotton, hemp, flax and the fibres of *Pueraria Thumbergiana*. Book 35 has been translated into English in the "Chinese Repository" (vol. XVIII, 1849) pp. 449 under the title of "Directions for the cultivation of cotton."

Books 37 to 40 (*chung-chih*) have reference to forest-trees, such plants as tea, chrysanthemum, bamboo and those used for dyeing.

Book 41 (*mu yang*) is on the subject of cattle-breeding, while book 42 (*chih-tsao*) treats of the conversion of agricultural produce into foodstuffs, oils and alcoholic beverages.

Books 43 to 60 (*huang-chêng*) are devoted in great detail to general policy with regard to the distribution of foodstuffs and in particular to the measures that should be taken to avoid and to combat famine and other calamities resulting from natural causes.

A section of book 44 on the subject of locusts has been translated into Italian by Alfonso ANDREOZZI, who published at Florence in 1870 a little volume with the title: "Sulle cavallette, considerazioni estratte dal *Nun' cen'-ziuen-sciu*, ossia Trattato completo sull' Agricoltura. — Firenze, 1870."

This Section of the treatise contains complete lists of all the grasses,

⁂

The *Ch'in ting shou shih t'ung k'ao* is the chief work on Agriculture produced by the Ch'ing Dynasty (1644-1912) following the example of the treatise of HSU KUANG CH'I. It was set on foot by the Imperial decree of the Emperor CH'IEN LUNG (1736-1795) through an official committee, with a Prince of the blood royal as President, consisting of fifty members of acknowledged scientific eminence, among whom were to be found some of the chief dignitaries of State.

By an Edict of the 14th of May, 1737, the Emperor CH'IEN LUNG gave orders that the work should be carried out in order to give an impetus to agriculture in the Empire and to demonstrate to his people that it was a matter of the deepest concern to the highest authority in the land. The work was finished in 1742 and presented with a note to the Emperor, who himself added a preface.

The title is distinctly characteristic of the Ch'ing period — one of remarkable scholarship, more imposing on account of the vastness of its literary output than of its intrinsic value. While the titles of previous works are clear and comprehensive, it is impossible to understand the title in this case without reference to its original source. In the " Book of History " (*Shu-ching* i, 2), a classic of the highest antiquity, it is stated that the Emperor YAO (2357-2255 B. C.) ordered the astronomers HSI and HO to draw up the Calendar " paying all due respect to the God of Heaven " in such a way " as to make the march of the Seasons quite evident to the folk " (*Ching-shou-jên-shih*).

The treatise opens with this phrase of *Shu-ching's* to be understood in the sense that " the seasons for mankind are the periods for fixed labour and for harvesting " and that " the precise definition of the seasons is the foundation of all agricultural work. "

Hence the title really signifies " Enquiries into the true significance of the seasons ", that is to say, into the types of fixed labour appropriate to the various stages of the year. As regards the actual value of the treatise it hardly appears to be so important as that of HSÜ KUANG-CH'I. In reality it is largely a reproduction of earlier work with certain additional matter but without criticism or originality. It attaches great importance to the encouragement of agriculture by the State and to religious festivals connected with husbandry. The whole is copiously illustrated, HSÜ's designs being supplemented by a large number of modern and original engravings.

The edition which has been presented by his Excellency is undated, but in all probability belongs to the later half of the year 1800.

The Library also possess a second copy of the treatise, the Imperial Edition of 1826 (sixth year of the reign of TAO KUANG), the gift of the Chinese Government in 1909.

Below will be found a short summary of the contents of the 78 Books (*chüan*).

Books 1 to 6 (*t'ien-shih-mên*) deal with the subjects of climate and seasons.

Books 7 to 18 (*t'u-i-mên*) treat in great detail questions relating to the land system and distribution of estates, irrigation, etc.

Books 19 to 30 (*Ku-chung-mên*) deal with the cultivation of cereal crops and volumes 31 to 41 (*Kung-tso mên*) with various forms of field-labour and harvesting, illustrations of the implements and machines employed being also given.

Books 42 to 53 (*ch'üan-k'o mên*) describe the different forms of encouragement given to agriculture by the Government, various Imperial edicts, poems, public ceremonials in honour of agriculture, etc. In volumes 52 and 53 are reproduced the drawings of agriculture and weaving given in the *Kêng chih t'u* described in detail above.

Books 54 to 57 (*hsü-chü-mên*) contain much interesting information upon the State granaries, which in general should serve, not only for charity or for dealing with famine conditions when they arise, but also for regularizing the market.

Books 58 to 71 (*nung-yü-mên*) deal with the crafts subsidiary to agriculture, such as horticulture, sylviculture and cattle breeding.

Books 72 to 78 (*ts'an-sang-mên*) are concerned with silkworm-rearing and the cultivation of the mulberry. They have been in part translated by STANISLAS JULIEN in his well known book entitled « Résumé des principaux traités chinois sur la culture des mûriers et l'éducation des vers à soie », published in Paris in 1837.

⁂

The *Chih wu ming shih-t'u k'ao*, or Illustrated Index to the Vegetable Kingdom, is the work of the famous botanist WU CHI-'CHÜN (d. 1846) of Ku-shih, in the province of Honan.

This Catalogue gives a careful classification and a very detailed description of all plants.

Before publication, the whole work was carefully revised by another celebrated botanist LUNG YING-KU of Mêng-tzu in the province of Yünnan.

The edition presented by his Excellency, LU CHÊNG-HSIANG bears the date of 1919. It was issued by the Official Printers of Shanhsi, the province of which the author was viceroy for many years, but was originally written in the first half of 1800. The Library possess a second copy, which was printed in 1866.

The treatise is in 38 volumes, with an appendix of 22 additional volumes.

SECOND PART

ABSTRACTS

AGRICULTURAL INTELLIGENCE

GENERAL INFORMATION.

879 - **The Progress of Agriculture in the Republic of Cuba During Recent Years.** — *Communicated by* DR. F. F. FALCO, *Delegate for Cuba to the International Institute of Agriculture.*

General Statistical Information. — The following data have been furnished by the special Bureau of Information of the Ministry of Agriculture, Commerce and Labour of the Republic. The demographic and commercial portions relate to the year 1920.

The Island is about 750 miles long, and the area is 45 881 sq. miles. The sea coast of Cuba is about 3700 km.; it has more deep-water ports than any other country in the western hemisphere. The mean temperature in January is 21.3° C; and in July 28° C; extremes vary from 17° C to 39° C. The average rainfall is 137 cm., the climate is dry in winter, but there is heavy rain in summer. There is a population of 2 900 000 inhabitants; or a density of about 24 per sq. km.

Excess of births over deaths	45 000
Average annual immigration	45 000
Average annual increase	90 000

74 % of the population is white, 26 % coloured.

Foreign Trade: — Total	$	890 000 000
Exports	»	590 000 000
Imports	»	300 000 000
Balance of trade in favour of Cuba	$	290 000 000
Balance of trade per head	»	100
Re-exports from Cuba per head	»	203
Imports into Cuba per head	»	108

[Information N° 879]

In normal times more goods enter and leave the Port of Havana than any other Western Hemisphere port except New York.

The value of the sugar crop of 1918-19 was $524 000 000, and the estimated value of the sugar crop 1919-20 is $1 080 000 000. The total tobacco crop was valued at $50 000 000.

Citrus plants, pine apples, vegetables, cocoa and honey produced $4 000 000. Cabinet woods and dyewoods yielded $1 000 000. Cattle, hides, etc., yielded $3 000 000, and iron, copper manganese and asphalte $12 000 000.

Since the establishment of the Cuban Republic (1902), the foreign trade has increased by over 700 %, and the exports have increased by 228 % since 1915.

The cost of land depends on the situation, quality and size of the lot. Prices vary from $15 to $500 per acre.

Sugar cane. — The chief agricultural product of Cuba is the sugar cane, The annual production is as much as 4 000 000 tons, divided among about 200 factories called *centrales* and *ingenios.*

Almost all the sugar cane is grown without artificial irrigation, but for some time taking water from the sub-soil and using it for irrigation have been in successful operation and in several plantations more abundant crops have thus been obtained.

Compared with other countries where sugar cane is grown, Cuba has the advantage of having plants of exceptional longevity. Sugar cane planted on virgin soil in Cuba can be cropped for 30 successive years without having to replant, and in any case the cane-fields remain productive for 6 to 20 years ; total replanting is not required and it suffices to replace plants which die from time to time.

The cane is propagated by cuttings, that is to say by pieces of cane with three eyes buried horizontally in furrows made 1.50 m. and 2 m. apart ; the cuttings are placed 1 m. apart in the furrow.

The cane is cut in winter. It ripens with the first cold and dry weather. In summer the rainy season and in winter dry weather are the most favourable conditions for its cultivation in the Island.

Largely owing to the strong impetus given by the Experimental Agricultural Station of Santiago de las Vegas, the sugar industry makes ever increasing progress.

Tractors and the most suitable machinery for reducing the cost of production and improving the quality have been introduced.

At the State Agricultural Station itself many new varieties of sugar cane have been produced ; they have been obtained from seed, i e., sexually, and even by hybridisation.

In the western provinces of the Island, where the soil is partly exhausted, fertilisers are used. Their use is very widespread in the Island of Cuba giving the most up to date scientific development to the agriculture of the country. Close to the sugar factories there are large establishments that prepare compound fertilisers, which are then supplied, on credit, to the growers (*colonos*) depending on the factory itself who agree to pay the amount only after the harvest.

In everything relating to the growing of the cane and to the sugar industry — chemistry and technology of manufacture, agricultural mechanics applied to tilling the ground and plant breeding — the measures taken by the Government, especially during the recent world war, show an extraordinary eagerness to realise the maximum production.

The production of sugar cane was valued at $800 per acre for the past year.

Tobacco. — Next in importance to sugar cane comes tobacco, which continues to justfy its reputation as the finest tobacco in the world. Tobacco is planted, grows and is gathered in 90 days. Cuba is always in advance of other countries regarding the growth, study and treatment of the diseases of this plant, the chemical processes and methods of industrial elaboration which are used to prepare it for the market.

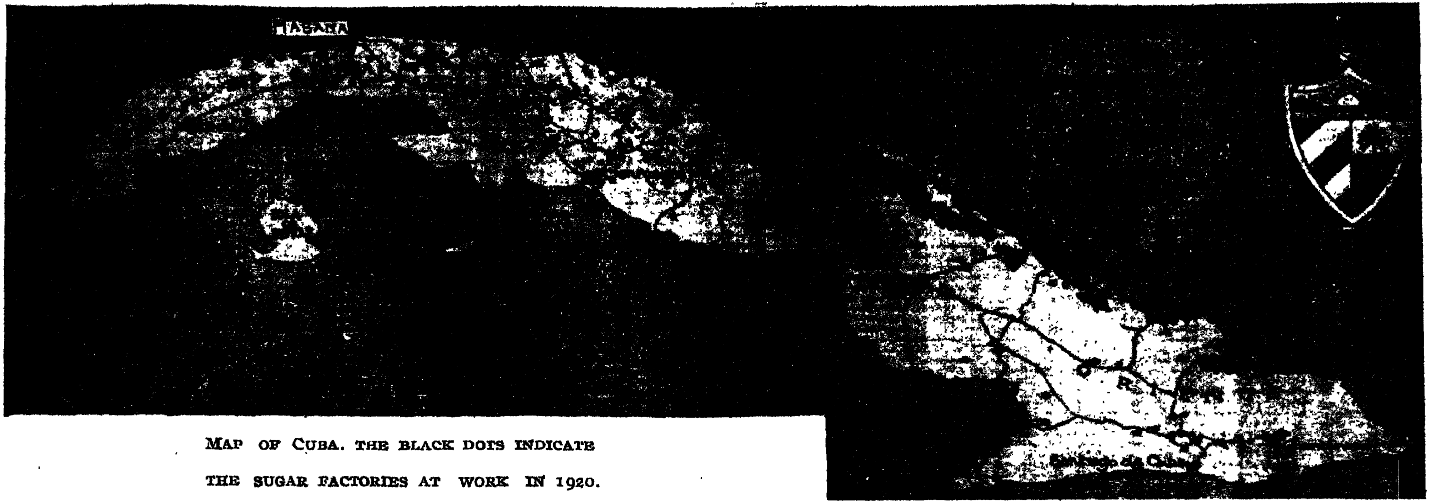
Owing to the marked specialisation of the cultivation of these two plants (sugar and tobacco) which absorb almost all the agricultural energy of the Island, the world war might have caused serious consequences to the economy of the country and in the first place have increased the difficulties of importing from abroad goods of prime necessity. But the Minister of Agriculture of the Republic managed by an active propaganda, to minimise the disadvantages accompanying the growth of a single industrial crop, and favoured by all means in his power promiscuous crops by indicating technical rules for growing food crops which could be intercalated in the cane fields, especially along the paths separating the fields (*guardarayas*) which act as firelines and facilitate the harvesting.

Cereals. — Associating himself with the plans of General E. SANCHEZ AGRAMONTE, Minister of Agriculture, and thanks to the generous and effective cooperation of the illustrious Prof. N. STRAMPELLI, Director of the Royal Italian Station for wheat cultivation, the author was able in the spring of 1918, to obtain, for despatch to Cuba, fine selected varieties of wheat seed and one of barley, specially suited to the climate and soils of the Island. The above mentioned Agricultural Experimental Station of Santiago de las Vegas made the trials; the "Carlotta Strampelli" variety in particular has given results promising well for the future.

The result will be the eventual emancipation of the Island, so far as supplies of the most indispensable cereals from abroad are concerned. At the same time world economy will have the advantage of being relieved of Cuba as a purely passive consumer and the Island will become, in time an active factor in the balance sheet of the production of wheat.

Amongst other cereals, Cuba has long grown maize, of which in normal conditions two crops are grown each year; recently the production has even been intensified. During the war a stronger impetus was also given to the growth of hill rice with good results.

Other crops. — Among crops of minor importance "boniato" (*Ipomoea batatas*), or sweet potato, occupies a place in the first rank as food for the inhabitants: it is very commonly used and its varieties are numerous, some



MAP OF CUBA. THE BLACK DOTS INDICATE THE SUGAR FACTORIES AT WORK IN 1920.

having great nutritive value. There is also the yuca (*Manihot palmata aipi*), the tuberous roots of which, when a year old, have an exquisite flavour. The Indian bread of old time, *casabe*, was made from this tuber. Cuba also produces the common potato, and various species of bananas; one of the latter sometimes is substituted for bread.

The cultivation of citrus plants is very widespread. Oranges, according to their degree of maturity yield from $50 to $500 per acre.

Kitchen gardens can yield everywhere a revenue of about $100 to $400 per acre.

Besides the crops already named those of other tropical products, such as coconut, cocoa, coffee, yam, sorghum, etc., are not neglected in the Island.

Tractors and fertilisers. — The use of tractors and of a fertiliser very rich in phosphoric acid, bat guano, which is found in large quantities in limestone caves in the Island, were of great use to Cuban agriculture in the most critical moments of the war to make up for want of manual labour and fertilisers. Thus Cuba was able, through to its abundant production of sugar, to provide for the pressing needs of European nations during the war by supplying sugar at prices that were relatively moderate, especially if the increased cost of production at that calamitous time is considered. Consequent on the impulse given to agricultural production by the State Central Agricultural Station, at present managed on scientific lines by Dr. CALVINO, an Italian, supported by the Government of the Republic, there has been fruitful initiative in the introduction of many new plants, especially forage plants of great nutritive value for feeding cattle, caucho, etc., as well as an increasingly thorough study of the special diseases of the plants of the Island and the means best suited to their treatment.

On this last subject, I propose shortly to make a more detailed communication (1).

880 - **The Agricultural and Forestry Experimental Station of Phu-tho (Tonkin).** — GILBERT, H., in *Le Moniteur d'Indochine*, Year II, No. 67, pp. 5-8, figs. 7. Hanoi, April 10, 1920.

The Agricultural and Forestry Experimental Station of Phu-tho was created by an order dated June 21, 1918 of the High Resident at Tonkin, on the proposal of M. CHEVALIER (Head of the Permanent Mission of Agriculture and Forests of the Colonies) then charged with the Inspection of Agriculture and Forests in Indo-China and in agreement with the opinion of the Director of the Agricultural and Commercial Services of Tonkin.

Its object is to proceed with the acclimatisation and the study of all plants having an agricultural and forestry interest, notably researches relating to coffee, tea, trees producing oil, lac and paper in Tonkin, and to give practical instruction to the students of the College of Agriculture and Forestry of Indo-China (1).

---

(1) See No. 955 of this *Review*.

The object to be attained being very vast, land was required served a railway or a river, both if possible, and not too far from Hanoï. M. CHEVALIER wished to make it the central Station of Tonkin and to install there the Direction of the Agricultural and Commercial Services with its various branches. The search was somewhat prolonged as large areas of uncultivated land are scarce in the central region of Tonkin.

The Administration finally chose land situated at 6 km. from Phu-tho at the junction of the Phu-tho—Phu-doan, Phu-tho—Viétri, and Phu-tho—Lemy roads. The lands are composed of tree-clad, bushy or grassy round hills intersected by low-lying rice fields or swamps. Their diversity allows all possible crops of the country to be tried; and they were selected for this reason combined with their exceptional situation near to Phu-ho and within a few hours of Hanoi.

The area appropriated to the Station is roughly 1500 ha., of which 300 are under forest, 400 under rice fields and 800 bushy round hills; the greater part of the land was already in the forest reserve.

Work was commenced on July 21, 1918. Straw huts as quarters for the workmen and the native supervisor had first to be erected, the land to be brought under cultivation had to be cleared and worked, and roads traced. At present 120 ha. are worked of which two thirds are planted, and there are 10 km. of 4 m. roads to open them up.

The first business of the author was to make a nursery for coffee plants Since 1917 M. CHEVALIER, through the Governor General, has been in correspondence with all the scientific establishments in the world, and they have sent to the Station numerous lots of seeds of coffee and later of tea. The French Colonies have contributed to this work, but Buitenzorg (Java) has sent most of the coffee seed and the Indian Tea Association. whose Experimental Station is at Cinnamara (Assam), has furnished the Assam and Ceylon tea plants. The Phu-tho Station has numerous lots of various species and varieties under acclimatisation tests, each lot comprising from 100 to 400 plants. By observing the plants during the course of their growth it will be possible to pick out those which are worth keeping. Besides the experimental plantations which cover about 5 ha. and are enlarged by the author according as the Station receivves new seeds, experiments on shading, spacing and manuring have been undertaken with acclimatised *Coffea arabica*, *excelsa* and *liberica* on about 7 ha.

In Tonkin, where the dry season is fairly long and where the heavy summer rains cause ravines and carry off the greater part of the fertilising principles of the soil, it is necessary, especially on hilly ground, to provide a remedy. Thus at the Station the growth of coffee shrubs on terraces 7 m., 4 m., and 3 m. wide has been tried. No doubt these terraces will prevent the formation of ravines, will retain the rain water and enable it to sink into the soil and preserve its humidity so that the coffee shrubs will not suffer during the dry season.

---

(1) Regarding the creation of the College see *R.*, Oct 1918, No. 1068 (*Ed.*)

The work which these experiments require is done as economically as possible under the same conditions as those of a private owner so that the account may be published in a few years and will enable planters to know and to give a good direction to their work.

Regarding tea bushes, the author has endeavoured first to get together all the local varieties. The Station has the following:—

Ordinary Tonkin tea; Haigiang, sector of Than-thung tea,; Haigiang, sector of Lao-Khang tea; Wild tea of the Tiên-yên region; Wild tea with large leaves of mount Bavi; Wild tea with small leaves of mount Bavi; Wild tea of the Thanh-ba region; Cochin-China tea.

In comparison with the Indo-China teas, various Indian teas are studied at the Station, viz., varieties of Ceylon, Assam, Calcutta, etc.

The tea plantations cover 6 ha. and will be enlarged in the course of the year, for when the planters of Tonkin learn to prepare tea in a suitable way they will no doubt dispose of their crop at remunerative prices. The cultivation of tea is also receiving attention as well as that of coffee.

The trees which produce oil are known and their seeds are extracted by the natives; but up to date neither the natives nor the European planters have made them the object of regular cultivation and it is impossible to say with any certainly what the growth of these trees would bring in. With the object of throwing light on this question the author has made plantations of the following species:—

Garcinia tonkinensis	3.5	hectares
Bassia Pasquieri (Than-hoa oil tree)	2.5	»
Aleurites moluccana	3.0	»
Aleurites montana	1.5	»
Aleurites Fordii (from Quang-Tung)	2.5	»
Camellia drupifera	2.5	»
Illicium verum.	4.0	»

These experiments take a long time and cannot be conclusive for some ten years, as the trees do not produce seed before they are 5 or 6 years old.

The Station nursery is 1.5 hectares in area; all trees and shrubs of any value are collected and it is renewed each year. Besides the plantations made at the Station the plants for which come from this nursery, it has been possible to distribute to natives, European planters and for the avenues of Phu-tho, 1000 coffee plants, 3000 oil-producing trees or avenue trees and 3000 tea plants. Some experiments with annuals such as tobacco, groundnuts, flax and rice, have been commenced.

Fruit trees have also had attention; the best varieties of local and Yunnan fruit trees, such as peach, apple, pear, orange, etc. have been collected. The orchard is 3 ha. in area. The herd at present comprises 102 head of cattle and has been doubled in the course of 1920. The marshy flats which are drained to transform them into hay meadows will permit the animals to be kept in byres and the introduction of animals of foreign breeds to improve the local breeds.

From a forestry standpoint nothing has been done up to the present, but shortly it will be possible to proceed with the installation of the arboretum ; two wooded round hills of an area of 30 ha. are reserved for this purpose. The forest after being cleared of under growth will be divided by lanes which will give access to it. Each division will include one family of plants ; the well-grown trees at present standing will not be sacrificed but labelled differently so as to indicate to visitors that they are not in their logical place. By degrees by means of plantation, as many species as possible will be introduced into the arboretum, its object being to furnish material for study to the European Forest Officers commencing their career and to the students of the College.

The forest itself will be penetrated by communicating roads and divided into experimental and working felling areas. This work, carried out methodically for some ten years, will cause the Station to possess a forest property of real value.

881 - **Results of Agricultural Experiments in Iceland.** — HELGASON, E., and SIGURDSSON, S., in *Búnáðarrit* 34 *Aarg* Reykjavik; summarised in *Nordisk Fordbrugsforkning*, Part 4, pp. 146-147. Copenhagen, 1921.

Results of a series of researches undertaken at the two principal Agricultural Stations of Reykjavik and Akureyri ; they relate to: — Manurial experiments, especially with fertilisers, the growth of root crops, potatoes, forage grasses, cabbages and other kitchen garden plants, arboriculture, the raising of ornamental plants, etc.

It appears from the manurial experiments that the Icelandic soils are generally poor in nitrogenous material and in phosphoric acid, whereas they have abundance of potash ; in any case, the use of potassic fertilisers is always to be recommended with potatoes or when basin irrigation is employed.

Regarding the forage grasses and leguminous forage plants the following species are recommended:— *Poa trivialis, Poa pratensis, Festuca rubra, Phleum pratense, Alopecurus pratensis, Bromus inermis, B. arvensis, Agrostis alba, Aira cespitosa, Trifolium repens,* and *Vicia cracca.*

Trifolium pratense and *T. hybridum,* however, gave negative or partly negative results.

At the Reykjavik Station, *Phleum pratense* produced on an average, for 18 years, 4800 kg per hectare, and at Akureyri Station it also gave a good yield of hay. The *Poas* on average for several years gave a little over 4000 kg. per ha.

On moraine soils that are sufficiently warm and moist, *Alopecurus* stands first of the forage grasses ; it was surpassed on one occasion by *Bromus arvensis,* which yielded 9600 kg. per ha.

Oats, barley, and winter rye also gave a good yield ; and it would be erroneous to say that the growth of rye for grain has been completely given up. Among the varieties which have given the best results the authors mention :— for oats, Grenaa and Mesdag ; for barley, Early Svalöf, 6-row barley and Bjorneby barley.

The best kinds of forage root crops yielded an average of 30 000 kg. per ha. ; White Globe, Fynsk Bortf, Grey Stone, Red American turnip are in the first rank.

Among the turnip cabbages may be mentioned Bangholm, Troudpjem and Icelandic ; the latter has given the heaviest crops (it is a Bangholm acclimatised since the time of the " Landfysicus " [Land doctor] SCHIERBECKS).

In the course of researches undertaken at Reykjavik, 100 varieties of potatoes were investigated ; the 10 following gave the best results :— Harbinger, Remarkable, Beauty of Hedbom, Agnelli, Early Goldstream, Dr. v. Eckenbrecker, Prof. Dr, Orth, Bodopotet (Bodo potato) Aeggeblomme and Wonder of the World.

The following, in round figures are data relating to the best varieties for the decennial period 1904-1913, at Akureyri Station :—

	Yield per hectare	Percentage of starch
Mossrose	15 650 kg	8.9 %
Helgu hamms (Icelandic)	15 600	10.6
Akueyrar (Icelandic)	15 200	10.8
Prof. Maercker	14 800	9.2
Bodopotet	14 500	9.9

882 - **Organisation and Scope of the Department of Agriculture, Dominion of Canada.** — *The Agricultural Gazette of Canada*, Vol. 81, No. 1, pp. 7-13. Ottawa, Jan.-Feb. 1921.

The following is a statement in summarised form of the organisation of the Department of Agriculture for Canada and of the work performed by the Department.

The Department of Agriculture is divided into a number of branches, each of which takes charge of certain activities or administers certain legislation pertaining to one particular line of agricultural industry The branches of the department are as follows :

Administrative Branch
Experimental Farms Branch
Health of Animals Branch
Live Stock Branch
Dairy and Cold Storage Branch
Seed Branch.
Entomological Branch
Fruit Branch
International Institute of Agriculture
Publication Branch
Agricultural Instruction Act Branch.

The various lines of effort of each branch are given very briefly below.

ADMINISTRATIVE BRANCH. — The Administrative Branch as its name implies, has to do with the administration of the whole Department of Agriculture. The major divisions are the Minister's office, the Deputy

Minister's office, the Accountant's office, where all financial matters in connection with the department are attended to, and the office of the Translator. The Translator's office is responsible for the translation into French of all departmental publications, which are usually written in the English language, and also for the writing of French correspondence for the Administrative Branch when necessary.

EXPERIMENTAL FARMS BRANCH. — This branch is the largest of all the branches of the Federal Department of Agriculture, and is the one which probably comes more closely in touch with the farmers of the country than do any of the others. The experimental Farms system covers a wide field, and gives its service to a wide territory, as the branch Experimental Farms are scattered all over the country, from the Atlantic to the Pacific and from the international boundary line to the Yukon. The centre of the system is the Central Experimental Farm at Ottawa, and there are 20 branch experimental farms and stations at present in operation, located at the following points :

Charlottetown, P. E. I., Kentville, N. S., Nappan, N. S., Fredericton N. B., Ste. Anne de la Pocatière, Que., Cap Rouge, Que., Lennoxville, Que., La Ferme, Que., Kapuskasing, Ont., Morden, Man , Brandon, Man., Indian Head., Sask., Rosthern, Sask., Scott, Sask., Lethbride, Alta., Lacombe, Alta., Summerland, B. C., Agassiz, B. C., Invermere B. C., Sidney, B. C.

Besides the Experimental Farms proper, a number of Experimental Substations are located in the thinly settled districts of northern Alberta and the Northwest Territories where experimental work on a smaller scale is carried on. These Sub-stations are located at Beaverlodge, Alta., Fort Vermilion. Alta., Swede Creek, Y. T., Dawson, Y. T., Salmon Arm, B. C., while experimental work is also carried on for the Experimental Farms Branch at some of the settlements in the Northwest Territories, namely Fort Smith, Fort Resolution and Fort Providence.

Connected whith the Experimental Farms system are two Tobacco Stations, at Farnham, Que., and Harrow, Ont. These Stations are established in a country which has proved itself suitable for tobacco production and their chief line of operation is in connection with tobacco production.

In order to bring the work of the Experimental Farms more closely to the attention of farmers in some of the newer provinces, as well as the older ones, a system of Illustration Stations has now been established. Some 80 of these stations have been established in the provinces of Alberta, Saskatchewan Quebec, New Brunswick, and Nova Scotia, and their influence has already been felt in the surrounding country.

As stated above, the work of the Experimental Farms system is directed from Ottawa, where the work is divided into the following subdivisions. each under the charge of a Chief.

Horticulture
Cereals
Animal Husbandry
Field Husbandry
Chemistry
Poultry
Forage Plants
Botany
Bees
Tobacco
Illustration Stations
Fibre
Extension and Publicity.

As is indicated by its name, the Experimental Farms Branch is mainly occupied in conducting experimental and research work in connection with agriculture along the various lines indicated by the names of the divisions mentioned in the preceding paragraph.

These lines cover practically all the field of practical agriculture, and while each farm perhaps does not carry on work in all these lines, an attempt is made to make each Experimental Farm of maximum benefit to the district which it serves.

The results obtained from experimental work carried on at the Farms are given to the public through the media of press articles, publications, lectures, and addresses, exhibits at agricultural fairs, as well as by direct illustration and demonstration on the Experimental Farms themselves, and at the Illustration Stations, which endeavour to illustrate the methods that have been found to be most suitable on the Experimental Farms proper.

In addition to the experimental work, this branch also has charge of the administration of that section of the Destructive Insect and Pest Act which deals with plant diseases. For the past few years potato inspection has been carried on, and a great deal of investigation into black-rust of wheat and white pine blister rust Plant pathological laboratories have been established at Charlottetown, P. E. I., Fredericton, N. B., St. Catharines, Ont., Winnipeg, Man., Brandon, Man., Indian Head, Sask., and Sakatoon, Sask., as well as the central laboratory at Ottawa, and these laboratories serve as centres for the work of the administration of this Act, as well as for research work into plant diseases.

HEALTH OF ANIMALS BRANCH. — The activities of this branch take, in general, the direction of maintaining the health of the live stock population of the country at the highest possible standard, of safe-guarding the consumers by insuring a supply of wholesome and properly inspected meat, meat products and canned goods, and of research work in animal diseases.

The Health of Animals Branch is divided into three divisions, viz: Animal Contagious Diseases Division, which administers the Animal Contagious Diseases Act. Meat and Canned Foods Division, which administers the Meat and Canned Foods Act; Pathological Division, which conducts research work into diseases of live stock.

A large staff of veterinary inspectors is maintained by the Animal Contagious Diseases Division at ports of entry, as well as other inland points in this country. Their duties consist of the inspection of animals entering Canada, and placing such animals in quarantine if found necessary. There are 85 quarantine stations located at various ports. These inspectors also investigate and enforce control measures for outbreaks of contagious disease of live stock as they occur. A great deal of work has been done during the past few years towards the suppression of hog cholera, and under the present regulations garbage feeders are licensed and their premises periodically inspected, and quarantined if any trace of disease is found. The Animal Contagious Diseases Act also provides for the superintending of the disinfecting and cleaning of stockyards and railway cars used in the transportation of live stock. Regulations have also been put into operation whereby municipalities may obtain inspection for dairy cattle producing milk for sale in the municipality, and last year a commencement was made towards putting into operation the Accredited Herd System which has proved so successful in the United States. Under this system, owners of pure-bred herds can obtain inspection for tuberculosis, and when their herds have been proved to be free from the disease they are placed in the Accredited List and enjoy certain privileges as to export to the United States without further inspection.

The Meat and Canned Foods Division also maintains a large staff of veterinary inspectors and lay inspectors, whose duty it is to examine animals before they are slaughtered in the abattoirs, and also to examine the meat and meat products from these animals before they can be offered for sale for human consumption. These veterinary inspectors are stationed at all the large packing plants throughout the country, and this division also inspects all meat products coming into inspected plants from foreign countries. Another phase of this work is the supervision and inspection of canning factories, jam factories, evaporated milk factories and condensed milk plants doing business in Canada; the testing and reporting on samples of imported and domestic canned fruits and vegetables as well as milk, while just recently new regulations provide for the approval of this Division being obtained as to labels used on canned fruits, vegetables, and milk manufactured and offered for sale in this country.

The pathological Division maintains a Biological Laboratory at Ottawa, a Research Station at Hull, Que., and field laboratories at Agassiz, B. C, and Lethbridge, Alta. At these laboratories supplies of mallein, tuberculin and blackleg vaccine are prepared and tested and these are sold to applicants at cost. A great deal of research work has already been carried on, and is continually being carried on with various live stock diseases such as dourine, contagious abortion, chicken disease, bracken poisoning, while one officer of this division is stationed at Charlottetown, P. E. I., where he is conducting an investigation in connection with the nutrition of black foxes.

LIVE STOCK BRANCH. — The activities of this branch are in general directed towards the improvement and development of the live stock industry by the encouragement of the production of better live stock, and by improving marketing facilities. This work, while carried on under direction from Ottawa, is performed mainly in the producing and marketing districts where officers are stationed to help the producer and the shipper. This branch also administers the Live Stock and Live Stock Products Act.

The chief divisions of this branch are:—

Horse Division, Cattle Division, Sheep and Goat Division, Markets Division, Poultry Division.

The Horse Division administers the policy with reference to Federal aid to horse-breeding associations. Up to a few years ago the department owned a number of pure-bred stallions which were loaned for breeding purposes to farmers' organisations throughout the country. This policy has in the past few years been considerably modified, and the department's holdings of stallions materially decreased. At the present time it pays a grant to farmers' associations using a stallion that has been approved by the inspectors of the Horse Division. This division also makes arrangements for providing live stock judges for agricultural fairs which have received the Government grant, and investigates and gives advice upon transportation matters as affecting live stock.

The Cattle Division administers the policy with respect to the breeding of better beef and dairy cattle. Pure-bred bulls are loaned to farmers' organisations and dairy cows are tested for record of performance.

This division also has charge of the administration of the Freed Freight and Car Lot Policies which give assistance to farmers and others in taking back fron marketing centres animals brought there for slaughter but which are found by the officers to be suitable for breeding or finishing purposes.

The Sheep and Goat Division loans pure-bred rams and boars to farmers' associations under the Distribution Policy, and also supervises the grading of wool and the encouragement of its co-operative marketing by farmers' organisations. A financial grant is made by this division to farmers using pure-bred rams for the first time, while attention is also given to the organisation of ram clubs and sheep-breeding centres. A report is sent out each week dealing with the wool market, and exhibition material in connection with the sheep, goat and swine industries is prepared and shown during the season.

The Poultry Division administers the Live Stock and Live Stock Products Act as it refers to eggs, and provides for export. This division also encourages the co-operative marketing of eggs and poultry, publishes a daily and weekly egg and poultry market report, and gives advice on the transportation, packing and marketing of eggs and poultry. A record of performance for poultry has recently been inaugurated, and inspectors have been appointed to carry on the necessary work in connection therewith.

The Markets Division administers the Live Stock and Live Stock Products Act as it refers to stockyards and live stock exchanges. The part of this division located in Ottawa has largely to do with the preparation and publishing of daily, weekly and monthly market reports dealing with the marketing of live stock. Stockyard agents are stationed in the stockyards at Edmonton, Calgary, Prince Albert, Winnipeg, Toronto and Montreal to obtain marketing information, and assist farmers and live stock shippers. These officers also assist the Cattle Division in the operation of the Free Freight and Car Lot Policies.

Under the Live Stock and Live Stock Products Act the department examines all the by-laws, constitutions, etc. of live stock exchange operating in stockyards under their supervision.

Dairy and cold storage branch. — The Dairy and Cold Storage Branch, as its name implies, has to do with the dairy industry of this country, and also in a small measure with cold storage warehouses. It administers the Dairy Industry Act, the Oleomargarine Act, and the Cold Storage Act.

The chief divisions are the Dairy and Cold Storage Division and the Markets Division.

The Dairy and Cold Storage Division operates a Dairy Station at Finch, Ont., and a Pre-cooling Cold Storage Warehouse at Grimsby, Ont Experiments and investigations into the manufacture of butter and cheese are carried on, and during the past year a Dominion Educational Butter Scoring Contest has been in operation, involving the inspection and rating of samples of butter from all over the country. In order to encourage the farmer to keep only the best producing cows, officers of this division organise and carry on cow-testing work in the various provinces, while last year a commencement was made in the grading of butter offered for export at the port of Montreal. Under the Cold Storage Warehouse Act, the department pays a certain subsidy towards the erection of cold storage warehouses used for public cold storage, and the work in connection with the payment of these subsidies is under the control of this division. Investigations are carried on in connection with the shipment of fruits, dairy products and eggs, in refrigerator cars.

The Markets Division arranges for refrigerator car service for butter and cheese shipments operated by railways under agreement with the Department. Its cargo inspectors also inspect and supervise the loading at Canadian and the unloading at British ports of all shipments of perishable products. Thermographs are placed in all vessels carrying such products and the records so obtained are blue printed and distributed to shippers.

A weekly dairy produce market report and monthly news letter are published by this division, which also inspects butter under the Dairy Industry Act, and administers the Oleomargarine Act.

SEED BRANCH. — The Seed Branch works along the lines of the encouragement of the use of better and purer seed and the production of good seed. During the war years it also had charge of the work of insuring a proper supply of good seed for districts in Canada where there was an apparent shortage. This branch administers the Seed Control Act, and at the last session of Parliament the administration of the Commercial Feeding Stuffs Act was also placed under the charge of this branch.

There are four divisions in the Seed Branch namely:—

Seed Testing Division
Seed Inspection Division
Seed Markets Division
Seed Purchasing Commission.

The Seed Testing Division maintains and operates Government Seed Laboratories at Ottawa, Winnipeg and Calgary, where purity analyses and germination tests of seed samples for farmers, seed merchants, and institutions are carried on. Official samples taken by customs officers from seed importations, by seed inspectors under the Seed Control Act and for special investigations are also tested at these laboratories. A great deal of investigational and research work with seeds has been carried out during the past few years, and some valuable work connected with the micro-analytical tests of feeding-stuffs has also been brought to a favourable conclusion.

The Seed Inspection Division enforces the Seed Control Act. The inspectors connected with this division inspect seed grain and fibre flaxseed received into, and shipped from Government elevators or other warehouses by the seed Purchasing Commission, or other dealers. Certain importation regulations are applied, and general quality standards for the various grades of clover and grass seeds have also been fixed. Samples submitted to the seed laboratories for test are graded and reported on by this division.

The Seed Markets Division compiles and issues semi-monthly seed market reports, and prepares and distributes lists of reliable seed importers in other parts of the Empire and foreign countries. It also supervises the administration of the subventions paid by the Seed Branch to the various provinces in connection with seed fairs and field crop competitions. During the war years this division, in collaboration with the Division of Forage Plants of the Experimental Farms Branch, also arranged for the production of a large quantity of field root seed of which at that time it was anticipated there would be a serious shortage. Advertising and other means are resorted to in order to bring about the extension of markets for Canadian seed.

The Seed Purchasing Commission has now been in operation for some four years. It was originally established as a war measure in order to insure a supply of good seed for farmers in certain areas which had been devasted by drought or other causes, and has been in operation since that time. This Commission purchases, stores, cleans and distributes at cost price inspected seed of good quality to those districts where there is a seed shortage. It has already done a business of over three million dollars per year.

The outside work of the Seed Branch is carried on by a field staff of inspectors. For the purposes of administration the Dominion is divided into six districts, each of which has a district seed inspector in charge. The officers in these districts are occupied with seed inspection, inspecting field crops, obtaining market information, judging seed and addressing meetings.

It is anticipated that the new Commercial Feeding Stuffs Act will be put into operation early in the coming year, and this will of course necessitate a large increase in the activities of the Seed Branch.

ENTOMOLOGICAL BRANCH. — The Entomological Branch occupies itself with studies of means of control for injurious insects affecting all agricultural products. It also administers that part of the Destructive Insect and Pest Act which has reference to insect diseases. For purposes of administration the branch has four divisions:

The Division of Field Crop and Garden Insects conducts life-history studies and studies methods of control of insects injurious to field and garden crops. Outbreaks of injurious insects are investigated, and control measures organised. Specimens are identified, and some work is also carried on with investigations in reference to insects in green-houses.

The Division of Forest Insects investigates outbreaks and organises methods of control for insects affecting trees. Forest sample plot areas have been established in various districts so that the study of these insects may be facilitated.

The Division of Foreign Pests Suppression enforces the Destructive Insect and Pest Act as it refers to insects. For this purpose fumigation stations are established at a number of points and all nursery stock imported is inspected and fumigated at these stations. Whenever necessary, quarantines and embargoes are laid against foreign and native insect pests, and enforced by this division. The Division also conducts scouting work in connection with outbreaks of injurious insects.

The Division of Systematic Entomology has charge of the National Collection of Insects. This division does most of the identification work of the branch, and is also occupied in mounting and preparing material for addition to the National Collection.

The Entomological Branch also conducts investigations into insects affecting fruit, insecticides, the colonisation, liberation and recovery of parasites of various insects, as well as orchard spraying and potato spraying experiments.

The field work of this branch is conducted from 10 entomological field laboratories stationed in various parts of the country. Each of these is in charge of a competent entomologist, and from these field laboratories local insect conditions are studied.

FRUIT BRANCH. — The Fruit Branch administers the Inspection and Sales Act as it affects fruit, fruit packages and potatoes. Its work also consists of the general encouragement of the fruit industry, especially the marketing of fruit. Fruit and vegetable crop reports are published at periodical intervals and the officers of the branch assist producers and dealers in buying and selling their fruit. The fruit inspectors also address meetings of fruit growers, and give demonstrations of the proper methods of picking, grading and packing fruit. Special transportation officers are employed to give assistance and advice to shippers as to the proper routing, etc., of fruit shipments. Complaints of improper shipments of fruit are investigated, and improved methods of distribution studied. Matters connected with fruit transportation generally are discussed with railway, express and steamship officials with a view to devising means for improved methods in this regard.

PUBLICATIONS BRANCH. — The distribution of the numerous publications issued from time to time by the Department of Agriculture is carried on by the Publications Branch. Most of the Divisions publish from time to time circulars, bulletins, pamphlets, etc., and the Publications Branch maintains mailing lists and sees that all persons on these mailing lists receive the publications which they desire. This branch also has charge of the publication of the official departmental magazine, *The Agricultural Gazette*, and of other publicity material.

INTERNATIONAL INSTITUTE BRANCH. — The International Institute of Agriculture serves as the connecting link between the Canadian Department of Agriculture and the International Institute of Agriculture at Rome.

This branch obtains and publishes through the Press, and through *The Agricultural Gazette* information on matters pertaining to world agriculture which it receives through the central offices of the Institute.

It also provides the Institute with information with reference to Canadian agriculture, and the Institute Commissioner represents the Canadian Department on the International Institute. The departmental library is also under the control of this branch.

AGRICULTURAL INSTRUCTION ACT BRANCH. — Under the Agricultural Instruction Act the sum of $1 100 000 annually for a period of twenty years was appropriated to assist the provinces in agricultural instruction work.

This branch administers this Act, and makes the necessary grants to the various provinces for the purpose of providing agricultural instruction and demonstration, and agricultural education in colleges, agricultural schools, high schools and elementary schools.

883 - **The International Congress for the Control of Seeds at Copenhagen, Denmark, June 6-11, 1921.** — PETERSEN K. (Director of the State Institute for the Control of seeds), *Official communication of the Danish Government*. Copenhagen, July 4, 1921.

This Congress met at Copenhagen from June 6 to 11 last. The very best relations existed among the delegates from the beginning to the end of the Congress, which was very successful. The Congress comprised 30 delegates of the 17 following States:— Belgium, Canada, Denmark, Finland, France, Germany, Great Britain, Holland, Hungary, Italy, Jugoslavia, Norway, Poland, Rumania, Switzerland, Sweden and Czecho-slovakia.

On the proposal of Sir L. WEAVER, of the British Ministry of Agriculture, and of M. INSULANDER, Director General at the Swedish Administration of Agriculture, the two Danish delegates, the presidents of the Commission for the control of seeds, Prof. W. JOHANNSEN and Director K. DORPH-PETERSEN were unanimously elected to the Presidency of the Congress.

Important detailed discussions on various subjects were followed with the greatest interest.

A proposition, put forward by Sir L. WEAVER, to form an *Association of the European Institutions for the control of seeds* and to appoint a Committee of control to carry out common work settled by the Congress, was adopted unanimously by the representatives of the States represented.

The following delegates were elected members of this Committtee:— K. DORPH-PETERSEN (Denmark), F. F. BRUIJNING (Holland) and A. VOLKART (Switzerland), all three Directors in their respective countries of State Institutes for the control of seeds. A. VOLKART was charged in addition to direct and set going comparative analyses with the object of finding out the places of origin of the seed of red clover (*Trifolium pratense*) and of lucerne (*Medicago sativa*). A Commission was also appointed, composed of Councillor of State von DEGEN (Budapest), Prof. VOIGT (Hamburg), Prof. BUSSARD (Paris), Director VITEK (Prague), and Director ENESCO (Bucharest). This Commission was given the task of making the fullest researches regarding the presence of the seed of the parasitic plant dodder (*Cuscuta* sp) and to seek means of controlling it.

Besides the meeting of the Congress, the delegates and guests met at an official dinner on the invitation of the Minister of Agriculture, who was present. In a series of speeches emphasis was given to the opportuneness of the Congress and its great success. An excursion to the State fields for the control of seeds, to the Museum of Agriculture and to the old farms of Lyndgby was followed by an informal gathering at the Hotel des Bains at Skodsborg.

On June 12, after the close of the Congress an excursion was made to the State Experimental Station at Tystoft, where LINDHARD, the Head of the experiments, demonstrated the work of plant improvement. An invitation from the British Government, transmitted by Sir WEAVER, to hold the next Congress in England in 1924 was unanimously accepted.

Prof. VOIGT, Sir L. WEAVER, Prof. BUSSARD and Director General INSULANDER at the close of the Congress expressed in very warm terms their thanks for such interesting, instructive and pleasant meetings. The Congress was agreed on the importance of teaching and carrying out the analysis of seeds. All were agreed in expressing the wish that the directing staff might have the opportunity of working for a certain time in the more important institutions for the control of seeds in foreign countries.

One of the Divisional Heads and one of the Assistants of the Office of Seed Control in London (which is to be transferred this autumn to a large new building at Cambridge) have worked during June in the State Institute for the control of seeds at Copenhagen in order to learn the method employed in Denmark for the examination of the purity of grass seeds, a method which is to be employed in Great Britain as from August of this year.

CROPS AND CULTIVATION

884 - **Effect of Altitude on the Appearance of Different Phases of Growth.**— PFAFF, W , in the *Phänologische Mitteilungen*, Year 37, No 26, pp 31-38, Darmstadt, 1920,

Results of a detailed study on the effect of altitude on phenoscopic phenomena.

The materials used in these researches were the phenological data collected during 3 years, simultaneously, and with absolutely uniform methods at Bozen-Gries and at Ober-Bozen, two localities which lend themselves very well to the object of the research. In fact, except for the difference of altitude (about 920 m), all the other conditions are practically uniform. The distance as the crow flies between the two points is only 5 km. ; the geographical constants are therefore practically identical; the soil is the same, for porphyritic formations from which the vegetable soils are derived by disintegration and washing, are found over the whole of this district; the two localities are situated on slopes, facing south, and are protected on the north by ranges of mountains; the exposure to wind is therefore the same for both. The rainfall is also distributed in a similar manner at the two stations, as indicated in the following Table, where the monthly rainfall is given as a percentage of the total annual rainfall.

	Jan.	Feb.	March	April	May	July	Juli	Aug.	Sept.	Oct.	Nov.	Dec.
Bozen.	3	3	6	8	10	11	13	13	10	11	7	5
Ober-Bozen . . .	5	3	6	7	12	11	14	12	10	10	7	3

On account of this uniformity of conditions it may be admitted that each of the stages of growth should be influenced by factors whose intensity and character vary precisely with the altitude.

These factors are:— 1) Temperature; 2) length of time the snow lies on the ground; the distribution and intensity of frosts; 3) the duration of the period of vegetation; 4) the length of the day, light, and insolation.

TEMPERATURE. — The Table of monthly and annual means in degrees centigrade is as follows.

	Jan.	Feb.	March	April	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.	Year
Bozen . . .	0.0	3.0	7.5	12.7	16.6	20.4	22.5	21.5	18.0	12.2	5,5	0.9	**11.7**
Ober-Bozen	—2.7	—1.1	1.1	5.3	8.9	13.1	15.3	14.4	12.0	7.0	1,7	—1.5	**6.1**

The difference between the annual means is thus 5.6° C.; the smallest difference, 3.10 C., is found during the winter months, December-February; the greatest differences are found in spring (March-May) and in summer (June-August, 7.2°).

SNOW AND FROSTS. — At Bozen snow covers the ground only temporarily and interruptedly; on the other hand at Ober-Bozen the soil is covered with a layer of snow which is often very thick during at least 4 months.

At Bozen the mean daily temperature is below zero for 5 days in the year only (January 10-15), while at Ober-Bozen the period of frosts is 96 days (November 26 to March 2).

DURATION OF THE PERIOD OF VEGETATION. — During this period there is a difference of about 2 months in favour of Bozen. As far as these three factors are concerned, of which the two last are closely correlated with the first, namely with the temperature, the conditions at Ober-Bozen are much less favourable to the growth of plants than those of Bozen.

LENGTH OF THE DAY: INSOLATION, LIGHT. — At Bozen and Gries about 25 % of the sky is hidden by the outline of the mountains; at Ober-Bozen hardly 10 %. In this last locality there is therefore at least an hour more sunlight each day. For the same reason the light is also more feeble, as well as the intensity of the sunlight, because of the atmospheric dust which collects over the valleys.

Let us now inquire into the phenological data:—

I. — BEFORE SPRING ("Vorfrühling"). — The commencement of flowering of *Corylus Avellana* and *Tussilago Farfara* is considered as the sign of the beginning of this season. These plants flower on an average 38 ½ days earlier at Bozen than at Ober-Bozen.

II. — SPRING (*first half*) ("Erstfrühling"). — The average time of the appearance of the leaves of *Aesculus Hippocastanus, Betula verrucosa, Betula alba, Tilia parvifolia, Quercus pedunculata*, and of the commencement of flowering of *Acer platanoides, Prunus spinosa, Ribes rubrum, Betula verrucosa, Prunus avium, Pyrus communis, Prunus cerasus* and *Pyrus Malus* have been adopted as data indicating the beginning of this season (see the following Table).

Commencement of the first half of Spring.

	1916–1918 Bozen	1916–1918 Ober-Bozen	1916–1918 Difference relative to Bozen	
Aesculus Hippocastanus, **B O**	29 III	8 V	+ 40 (1)	Commencement of the first half of spring at Bozen 37 days earlier.
Acer platanoides, **b**	1 IV	7 V	+ 35 (2)	
Prunus spinosa, **b**	3 IV	9 V	+ 36 (3)	
Betula verrucosa, **B O**	1 IV	9 V	+ 38 (4)	
Betula alba, **B O**	—	—	—	
Ribes rubrum, **b**	2 IV	12 V	+ 40 (5)	
Betula verrucosa, **b**	3 IV	6 V	+ 33 (6)	
Prunus avium, **b**	4 IV	11 V	+ 37 (7)	
Pyrus communis, **b**	5 IV	14 V	+ 39 (8)	
Tilia parvifolia, **B O**	8 IV	18 V	+ 40 (9)	
Quercus pedunculata, **B O**	6 IV	—	—	
Acer platanoides, **B O**	9 IV	15 V	+ 36 (10)	
Prunus Cerasus, **b**	9 IV	—	—	
Pyrus Malus, **b**	12 IV	18 V	+ 36 (11)	
			410 : 11 = 37 (see following column)	

B O = in leaf; **b** = in flower; I-XII = January-December.

The difference in days is calculated for each of the phenoscopic data relating to Bozen and Ober-Bozen; the differences are then added and the total divided by the number of phenological values considered. The quotient represents the difference in days between the commencement of the first half of spring at Bozen and Ober-Bozen.

III. — SPRING (*second half*) ("Vollfrühling"). — The difference between the two localities is 31 days, as regards the foliation of *Fagus sylvatica,* and the flowering of the following species: — *Syringa vulgaris, Aesculus Hippocastanus, Lonicera tatarica, Berberis vulgaris, Crataegus monogyna, Crataegus Oxyacantha, Cytisus Laburnum, Sorbus Aucuparia, Euonymus europaea, Sambucus nigra, Robinia Pseudacacia, Cornus sanguinea,* and *Symphoricarpus rae.*

IV. — EARLY SUMMER ("Frühsommer"). — There is a difference of 44 days if the flowering of *Ligustrum vulgare, Tilia grandifolia, Tilia parvifolia* and the commencement of the ripening of fruits of the following plants:— *Ribes rubrum, Lonicera tatarica, Lonicera xylosteum, Symphoricarpus racemosus,* and *Sorbus Aucuparia* are regarded as standard.

V. — FULL SUMMER ("Hochsommer") begins at Bozen 45 days before Ober-Bozen in correspondence with the ripening of the fruits of *Viburnum Lantana, Sambucus nigra* and *Cornus sanguinea.*

VI. — EARLY AUTUMN ("Frühherbst"). — The difference is 21 days based on the ripening of *Ligustrum vulgare* and *Aesculus Hippocastanus.*

In the cases investigated so far the season commences much earlier at Bozen.

VII. — LATE AUTUMN ("Spätherbst"). — To mark the commencement of this phenological season the moment is taken when the leaves turn and fade. This phenomenon takes place first at Ober-Bozen, so that the seventh season, differing from those preceeding, commences first at Ober-Bozen, with a difference of 18 days, if reference is made to the following plants:— *Acer platanoides, Tilia parvifolia, Betula sylvatica,* and *Quercus pedunculata.*

According to these data and with reference to the altitude, it is reasonable to deduce that: — Per 100 m. altitude there is a delay of 4.19 days for the period just before spring; 4.08 for the first half and 3.91 for the second half of spring; 4.78 for early summer and 4.89 for full summer; 2.34 for early autumn. On the other hand, the turning of the leaves takes place first in the mountains, where instead of a delay, there is an advance of 2.06 days per 100 m.

These results agree with those already obtained by the authors and by FRITSCH, DRUDE, and HOFFMANN.

885 - **Influence of Periods of Drought on the Growth of Plants.**— PFEIFFER, T., RIPPEL A., and C. PFOTENHAUER, in *Die landwirtschaftlichen Versuchs-Stationen,* Vol. XCVI Parts V and VI, pp. 353-363. Berlin, 1920.

HELLRIEGEL, WOLLNY, PFEIFFER, with BLANCK and FLÜGEL have already noted that intercalated waterings, when water is lacking, are harmful to the growth of plants, and even a large quantity of water after a period of drought is not sufficient to repair the injury which the plant has suffered so that, especially for spring crops, an average frequency of watering is much more suitable.

E. GAIN has observed, however, that a certain quantity of water applied after a slight drought gives better results than permanent moisture even when optimum; the extreme case of injury caused by permanent moisture and a distinct advantage from interrupted waterings even occurred with the thorn-apple.

The authors have therefore considered it desirable to take up the question again by making pot experiments with lupins and spurrey as xerophilous plants, and with barley and oats as hydrophilous plants; these two last crops were, however, attacked by *Erisiphe graminis*. One series was kept at a constant humidity (60 % of the capacity of water) by replacing every day the water evaporated; the other was left in suspense up to a certain degree of humidity (30 % of the capacity of water), then a quantity of water equal to that which had been applied in the meanwhile to the first series in several waterings was applied during 26 periods. The yields in dry matter obtained were as follows: —

	Constant humidity gm.	Alternate drought gm.
Lupins	35.0 ± 0.27	24.5 ± 1.21
Spurrey	28.1 ± 0.88	21.1 ± 0.81
Barley	14.6 ± 0.21	14.4 ± 0.40
Oats	32.4 ± 2.07	28.0 ± 0.59

The deduction from these results and from other observations is that, at least for the plants in the experiment, the greatest possible constant water content of the soil gives better results, or, at worst, not inferior results to those which are obtained by using the same quantity of water intermittently. A temporary dryness of the soil, not exceeding a certain limit, causes injury of various degrees to the growth of all plants, and the reason is found in their different aptitudes for adaptation to drought relatively to their greater or less power of reducing the consumption of water; spurrey and lupin, for example, require a long time to reduce the humidity of the soil from 60 to 30 % of the capacity of water, and in the light of the experimental method adopted, these plants suffer more injury if they remain exposed for a long time to drought; barley comes next and lastly oats which make the greatest demands on the moisture in the soil.

The consumption of water per gram of dry matter produced is less with alternate periods of drought, and this is all the more noticeable with plants which adapt themselves better to the conditions of humidity of the moment, by regulating evaporation.

886 - **The Carbon Dioxide of the Soil Air.** — TURPIN, H. W., in *Cornell University Agricultural Experiment Station, Memoir* 32, pp. 319-362, figs. 16, Ithaca, N. Y., April, 1920.

Carbonic acid has long been recognised as an important soil solvent, but from the data available, it is not yet clear what are the chief factors controlling the production of carbon dioxide in the soil; although it is generally considered, that a large proportion is due to the action of micro-organisms, the part played by plant-root excretions in this connection has not been determined. With a view to deciding this question, the author carried out a series of pot (the plants being grown in iron cylinders) and greenhouse experiments, a special arrangement for estimating the carbon dioxide being employed. The soil was a heavy clay loam rich in silt, and brought up to 30 % moisture content on the oven-dry basis.

It was found by these experiments, that oats increased the production of carbon dioxide in the soil. This increase became marked after the first month from the time of sowing, and increased to a maximum just before or after the plants headed; then there was a gradual decline. Millet (*Setaria italica*), behaved in much the same manner, but the production of carbon dioxide by each plant was approximately half as great, and the most marked rise in the carbon-dioxide content of the soil occurred at a later period of growth than in the case of the oats. The cropped soil, after harvest, maintained a higher percentage of carbon-dioxide than was found in the uncropped soil. This was probably due to the decomposition of the plant roots left in the ground. The correlation existing between carbon-dioxide production and transpiration would seem to confirm the theory that increased plant growth is accompanied by more intense formation of carbon-dioxide. Fluctuations in the amount present in the uncropped soil were accompanied by similar fluctuations in cropped soil only after the removal of the crop and before the plants had made much growth. There appeared to be no definite connection between the soil temperature at the time of sampling and the carbon dioxide in the cultivated soil, or that assumed to be produced by the crop (determined by subtracting the carbon-dioxide in the bare soil from that in the cropped soil). In fact, the carbon dioxide content of the former was usually high during warm weather, and low when the temperature decreased; further, very low atmospheric pressures were usually accompanied by an increase in the amount of carbon-dioxide in the uncultivated soil.

The carbon-dioxide produced presumably by the plants appeared to be independent of the initial carbon-dioxide content of the soil, which would seem to indicate that plants and soil organisms act independently in the production of this substance.

In conclusion: it may be assumed, that the plant itself and the micro-organisms present in the soil produce most of the carbon-dioxide. At the period of its most active growth, the plant produces much more carbon-dioxide than the soil organisms, and the excess carbonic acid in cropped soil is due to the respiratory activity of the plants rather than to the decay of root particles, from the crop growing on the soil at the time of analysis.

887 - **The Concentration of the Soil Solution Around the Soil Particles.**— Y J. BOUYOUCOS (Michigan Agricultural Experiment Station), in *Soil Science*, Vol XI, No. 2, pp. 131-138. Bibliography of 3 Works. Baltimore, February 1921.

On account of the supposed adsorptive property of soils, it is generally believed that the soil solution in immediate contact with the surface of the particles has a greater concentration than the remainder of the solution. This opinion has however never been confirmed, and the author indeed holds the opposite view, namely that the concentration of the solution around the soil particles is lower than elsewhere. The experimental evidence brought forward in support of this conclusion is briefly as follows:

a) The diminution of the freezing-point lowerings of soils by successive freezing and thawing; *b*) the liberation of unfree water from soils subjected to this treatment; *c*) the abnormally greater increase in the freezing-point depression of soils as the moisture content diminishes; *d*) the equality in the freezing-point lowering between the supernatant liquid and the soil which it bathes.

The first phenomenon may be explained by the fact that the soils have the power of causing a certain quantity of water to become unfree. This water may be in the soil either as capillary-adsorbed, or chemically combined, or both; it is less concentrated than the solution which freezes at the first time It is liberated from the capillaries by the process of freezing, and in this way, the freezing point is lowered, as stated in *b*. The dilatometer method also showed that the unfree water decreased with repeated freezing and thawing.

The depression of the freezing-point of soils tends to increase in a geometrical progression as the moisture content decreases in an arithmetical progression; this proves, as is said in *c*, that the concentration of the soil solution increases at the expense of the soil particles, which retain the water alone.

As regards soils bathed in the solution, they should if the generally received opinion be correct, have the power to fix a greater amount of salts than the supernatant solution, and hence would show a greater lowering of the freezing point than the latter. This has not been found to be the case (see *d*); indeed, frequently there was a depression in the freezing point of the supernatant liquid, and consequently an increase in its concentration, which points to the conclusion that the solution around, or in immediate contact with the surface of the soil particles, is less concentrated than the mass of the solution. It therefore appears very doubtful whether there really is a physical adsorption of dissolved mineral solids by soils.

A correct knowledge of this particular point is of far reaching importance for the proper understanding of both the soil solution and its utilisation by plants.

888 - **Preliminary Notes on the Microbiology of the Soil and on the Possible Existence of Invisible Organisms in it.** — Rossi, G. (Istituto di Batteriologia Agraria della R. Scuola Sup. d'Agricoltura, Portici), in the *Annali della R. Scuola Superiore di Agricoltura in Portici*, Series II, Vol. XV, Notizie per alcune serie di lavori di microbiologia in corso, I, pp. 3-7. Portici, 1920.

The microbial flora (Schizomycetes, Blastomycetes and Hyphomycetes) of the soil is very little known, not only from the standpoint of the enumeration of the species there present, but especially from that of its signification. The principal reason is the great uncertainty which surrounds the methods of research and among the various aspects of the problem due to this lack of method and of criticism, the author indicated :—

A) The uncertainty arising from the counting of the organisms of the soil, as a slight change in method entails a very great change in the numerical result.

B) The obstacles arising from the antagonism which can be exerted between number and quality during growth; in most cases the number of germs which can be developed by the soil by means of isolating cultures diluted in agar and gelatin, is inversely proportional to the quantity of the soil infusion used ; for example with $1/_{25}$ cc. of soil infusion a greater number of organisms is generally obtained than with $^1/_{10}$ cc.

C) The influence of methods employed for the isolation of the species of micro-organisms in the soil. As has been proved by the experience gained during many years by the author the investigation of the species present in the soil is related to the method of isolation employed and especially to the nutritive medium selected ; agar, gelatin, or even potatoes, however they are prepared, never give different results with *mesentericus, radiciformae, fluorescens,* coloured *cocci, Streptothrix,* moulds, etc., and the soil always contains some germs which, like *B. mycoides,* are always present and of which a small number suffices to prevent the development of all other species.

D) The insufficiency of the methods for isolating certain species ; for example, after having spent much time in isolating nitrifying bacteria it seems clear that WINOGRADSKY, MIGULA, and WARINGTON were right in affirming that their presence was absolutely accidental; often by inseminating up to 8-10 flasks of elective nutritive solutions with soil no nitrifying organisms developed in any of them.

E) The enormous difficulty of sterilising the soil absolutely ; it is well known that the autoclave and KOCH's steam stove do not sterilise soil within a reasonable time ; the same is true of direct roasting with fire and the hot air stove has still less effect. Now, given the great complexity of the chemical and physical structure of the soil, the presence in it of hydrosols which are coagulated by heat, as well as the existence of a circulating solution, which may be considered as the actual medium of the soil, where the micro-organisms act, bringing about reactions and submitting to its influence, it is clear that any sterilisation, chemical or physical, must profoundly impair the powers of so sensitive a medium and falsify the results of eventual experiments.

F) The lack of sensitiveness of certain chemical methods, which are the only methods available for observing the reactions caused by the microbes is also an obstacle. The following are two examples :— The lack of sensitiveness in the determination of nitrogen, necessary for the study of nitrogen fixers, for which so far nothing better has been discovered than KJELDAHL's method and its modifications and which only shows the quantities calculable in mgm. ; the difficulties of the research of nitric acid in the presence of large quantities of nitrous acid, for which, even qualitatively, we have nothing more sensitive than the insensitive method of LUNGE-LUVOFF.

To sum up it must be admitted that there is reason for much hesitation before the whole microbiological mechanism of certain processes of the soil are considered as known, such as those of nitrification and the fixing of nitrogen ; it does not suffice for their explanation to have succeeded in isolating from the soil germs which nitrify or fix nitrogen *in vitro*. All this throws much uncertainty on that which is known, not of the biochemical power of many micro-organisms, but rather regarding their actual value in the soil. Besides what has already been noted, it should also not be forgotten that many of the theories on the processes of the soil are founded on phenomena which have taken place and are studied with germs which are indeed isolated from the soil but which are made to act in artificial solutions which certainly cannot be compared with the circulating solution of the soil.

It is then the insufficiency of the microbial flora recognisable in the soil to explain many phenomena which are produced in it which has led the author to search for the presence of an eventual or ultra-microscopic flora, or better, invisible germs, in the soil. The method employed was a direct method, by filtering soil extracts through a CHAMBERLAND filter and by submitting the aseptic filtered liquid to the principal reactions attributed to visible germs, e. g., putrefactive (ammonia, indol, phenol), nitrifying, nitrogen fixing. As the filtered liquid contained ammonia and nitrites, indol was searched for in a nutritive liquid containing peptone, but the result was negative, while there was an abundant formation with the non-filtered extract. The sterilised filtered liquid also caused no increase of nitrites in a saline ammoniacal solution also sterilised.

According to these results the presence of invisible germs in the soil should be excluded, but this is not sufficient; it will therefore be interesting to follow the results, whatever they may be, of the experiments still in progress.

889 - **Modern Commercial Fertilisers in China.**— REISNER J. H. (Dean, College of Agriculture and Forestry, University of Nanking, Nanking, China) in *The American Fertilizer* Vol. LIV, No. 10, pp. 54-57. Philadelphia, May 7, 1921.

The most potent factor in China's maintenance of her present agricultural production is her scrupulous care in the utilisation of everything that has fertilising value. One of the most important of her fertilisers is night soil, the supply of which is cheap, the use of which is well established beyond the pale of objection so far as the Chinese are concerned, and will prove to be the keenest of competitors when commercial fertilisers enter the field. On the basis of a population of 400 000 000 people, an annual production of 1 073.3 lb. per head (data based on European sources), the total production of night soil in China would be 428 120 000 000 lb., of which it is safe to say that two-thirds, or 285 420 000 000 lb., is saved and used as fertiliser to produce crops. Taking the average of Japanese and European figures on the composition of night soil we find that the percentage of fertilising elements is as follows: Nitrogen 0.63 per cent.; phosphoric acid 0.20 per cent.; and potash 0.24 per cent. Calculating on the basis of the above figures, the amount of nitrogen, phosphoric acid and potash that would be used annually would be approximately:

	lb	$
Nitrogen	1 800 000 000	360 000 000
Phosphoric acid	570 000 000	57 000 000
Potash	685 000 000	85 000 000
Total . .	3 055 000 000	502 000 000

These gold values of the fertiliser elements are secured by using the present retail prices of approximately 20 cents per pound for nitrogen, 10 cents for phosphoric acid and 12 ½ cents for potash. These amounts only represent equivalents, but as such they are important in showing the difficulties if not impossibilities attended by the idea of substituting in part or in whole modern commercial fertilisers for night soil.

If we reduce the 428 000 000 000 lb. of night soil produced annually, and the estimated 285 000 000 000 lb. used, to Chinese weights, we would have approximately 2 149 000 000 piculs (picul = 133 pounds avoirdupois). Fresh night soil is usually sold for about six to ten chinese cents a picul, depending upon locality and demand. Taking eight cents as an average, which is admittedly too high, the value in silver would be $171 900 000 (1). This sum would be more rightly considered the money value of the night soil annually used on the basis of the commercial rates at which it is sold. It would be very difficult to determine the total money value of the night soil that was actually sold, or bartered for, but it would probably not be more than one-fourth or one-third the sum above noted, say approximately $50 000 000 Chinese currency. It is estimated that from 75 to 85 % of the Chinese population belongs to the farming classes, and if this is the case, the estimate of the percentage of total production used and entering into barter or sale is not far wrong.

From the above it will be seen that the largest part of the annual production does not enter into trade and is used where it is produced and represents no cash investment. The labor used in collecting, caring for and applying to the soil would not be considered by the farmers as having a money value. It represents clear gain so far as he is concerned and in no sense as costing anything. In other words, about $50 000 000 local currency would pay for all the night soil that is sold and bought annually, and be considered the annual investment in night soil fertilisers.

But to substitute an equivalent amount of commercial fertilisers for the total night soil consumption would require at present prices $502 000 000 gold against 50 000 000 silver currency, which is itself argument enough to prove that the modern commercial fertiliser will not for a long time dispossess night soil from the place it now holds in the maintenance of Chinese soil fertility and production of crops.

---

(1) The Chinese or silver dollar of 100 cents = 72 % of Haikwan tael of about 2 s 6 d or U. S. gold $ 0 61. (*Ed.*)

It has also been pointed out that China instead of exporting vegetable meal fertilisers such as bean cake, rape seed cake, etc., should use them at home. She does use them in very large quantities, but no one knows just how large quantities of this class of fertilisers is used. In 1918, according to the Customs " Returns of Trade " and " Trade Reports," China exported over 16 000 000 piculs of bean cake, having a value of 29 882 829 Haikwan taels. The total exports of all fertilizing materials of this class was over 17 500 000 piculs, with a total value of a little less than 32 000 000 Haikwan taels. Reduced to pounds and dollars, the yearly export averaged $1.92 Chinese currency per 100 lb. Taking the average of several analyses, the chemical composition of soy bean cake gives nitrogen, 6.62 %, phosphoric acid, 2.20 % and potash, 1.80 %. Accepting the relative price for nitrogen, phosphoric acid and potash as before the war as 20,5 and 5 cents per pound respectively, we have a proportion of 4-1-1. Calculating from the above we find that the nitrogen was worth 19.4 cents Chinese per pound, phosphoric acid was worth 14.5 cents per pound and potash, 17.8 cents per pound. Comparing these figures with those found in the same way for night soil at 8 cents per picul, we have nitrogen in night soil costing 6.3 cents per pound, phosphoric acid costing 5.0 cents per pound, and potash 4.1 cents per pound. The following table will serve to bring out the contrasts :

Cost of fertilising constituents in Chinese currency on pre-war basis.

	Prices Nitrogen	(Cents per pound). Phosphoric acid	Potash
	—	—	—
In soy bean cake	19.4	14.5	17.8
In night soil	6.3	5.0	4.1
Present U. S. prices in gold	20.0	10.0	12.5

The objection might be raised on the ground that the customs value would give a higher value than local market prices. This is probably true. Soy bean cake sells in Nanking for from $1.50 to $2 Chinese currency per 100 lb. But if the figures above are changed on this basis, and on the corresponding basis that night soil sells locally at 6 cents per picul, the contrast is still more striking.

The figures given above show again, as in the case of commercial fertilisers, that the use of night soil is much cheaper than soy bean or any other kind of vegetable cake at the same price. More than that, the difference is marked and places a big handicap on bean and other cake fertilisers in coming into greater demand.

The objection is equally pertinent to both vegetable meal fertiliser and night soil that they are both « unbalanced » fertilisers, by which term is meant an undue proportion of one element to the other two. In both, the percentage of nitrogen is too great in proportion to the amount of phosphoric acid and potash, and this has a tendency to emphasise the effect of nitrogen on crops which the effects of the smaller quantities of phosphoric acid and potash cannot counterbalance. The disadvantage of an excessive quantity of nitrogen is, of course, well known, namely, that it produces vegetative growth at the expense of the reproductive parts such as seeds, fruits, etc. The above statements are in large part true for most of the organic fertilisers including farm manures, green manures, composts, etc.

Probably China's greatest need in the fertiliser line is a more abundant supply of phosphate and potash to be used in connection with those she now uses most commonly, the organic fertilisers noted above. The phosphate fertilisers she supplies to a limited extent in the form of bones. However, in 1918 China exported — the largest share going to Japan — 577 388 piculs of raw bones with a value of 1 ⅓ Chinese cents per pound. The export of raw bones should be prohibited and the bone phosphate industry encouraged. Potash is also supplied separately, for the most part in the form of grass ashes. This the Chinese use widely, though it is questionable whether they fully appreciate the care necessary for properly handling, nor the great ease with which the soluble potash leaches away. Hard wood ashes unleached carry from 0.5 to 12 % potash and constitute one of the oldest sources of potash as a fertiliser. Large deposits of both mineral phosphate and potash salts, have been reported but they have never materialised.

Considerable experimental work will have to be done in the whole matter of fertilizers in China, but it seems fairly safe to predict a big need for both phosphate and potash which the farmers will be willing to meet, when once shown they are profitable when used in connection with their present fertilisers. This will create a considerable demand, which will have to be met in some way or other, possibly importation from abroad if the supply cannot be found in China.

It would seem then that China must continue her centuries-old use of night soil to maintain the fertility of her soil, and to keep up her agricultural production; that neither modern commercial fertilisers nor vegetable meal fertilisers can compete with night soil, and that her greatest needs at present are independent supplies of potash and phosphate to use in conjunction with the organic fertilisers, upon which she mostly depends.

Finally, the export figures for China during 1919 indicate the amount of fertiliser material exported from China for this year. Attention should be called to the fact that the largest part by far of these exports, was from Manchuria — and must not be taken as indicating the condition of supply in China proper, where six-sevenths of the population lives on one-third of the area. The fact that in one year China exported over 1 500 000 tons of vegetable cake fertilisers and over 50 000 tons of bones, is impressive, to say the least.

Chinese exports of fertiliser materials in 1919.

	Piculs	Haikwan Taels
Bean cake	20 724 769	14 173 118
Peanut cake	311 231	479 490
Rape seed cake	536 613	737 650
Sesamum seed cake	308	345
Other kinds of cake	1 264 230	2 091 270
Total vegetable cakes	22 836 151	47 481 873

U. S. equivalents: 1 522 460 *tons*: 62 251 616 *gold dollars.*

	Piculs	Haikwan Tael
Bones	808 368	1 066 513

U. S. equivalents: 53 893 *tons*: 1 375 800 *gold dollars.*

What is needed now, so far as the problem of the use of commercial fertilisers in China is concerned, is a careful, scientifically-conducted series of experiments to determine to what extent the use of modern fertilisers would increase production. The China market for commercial fertilisers will always be an unknown quantity until these data are secured. In the meantime the demand for food production in China will increase, not only because of her rapidly increasing population, but because of her rapidly extending industrial development along modern lines.

890 - **The World's Synthetic Nitrogenous-Fertiliser Industry.** — I. WAESER, B., Fortschritte der anorganischen Grossindustrie während des Weltkrieges: Stikstoff und seine Verbindungen, in *Chemiker Zeitung*, Year 44, Nos. 102, 105, 106, 108, 110, 116, 122, 124, 127, 128, 129, 130, 134, 135, 4 figs., Bibliography of 589 publications. Gothen, Aug.-Nov., 1920. — II. MEINGAST, R., Die Fortschritte der elektrochemischen Industrie in den Jahren 1916-1919, *Ibid.*, Nos. 150, 153, 3 figs., Bibliography of 124 publications, Dec., 1920. — III. WICHERN, G., Bericht über die Fortschritte der Düngemittelindustrie in den Jahren 1913-1920. *Ibid.*, Nos. 10 and 16, Bibliography of 141 publications. Jan.-Feb., 1921. — IV. ESCARD, J., Utilisation industrielle de la cyanamide, in *Le phosphate et les engrais chimiques*, Year 30, pp. 110-112. Paris, April 1921.

I. PROGRESS OF THE INORGANIC CHEMICAL INDUSTRY DURING THE WAR:— NITROGEN AND ITS COMPOUNDS. — Interesting review of all the patents and methods of the modern synthetic-nitrogen industry; it contains technical, commercial and agricultural information. Only that portion which relates to nitrogenous fertilisers and agriculture are reviewed here (1). —

---

(1) Nitrogenous fertilisers are at present divided into 3 classes, according to their origin:— 1) Minerals; 2) by-products of dry distillation; 3) Synthetic. The *Review* of July-Sept., 1919, No. 834, has already dealt with the processes of combination of free atmospheric nitrogen; they may at present be divided into 5 groups or principal methods:— 1) Nitric method of direct combustion in the electric arc (BIRKELAND-EYDE, SCHÖNHERR, PAULING, WIELGOLASKI processes); (2) cyanamide method (FRANK-CARO, POLZENIUS, CARLSON), (3) method of azides (SERPECK); (4) method of synthesising ammonia (HABER, CLAUDE, CASALE); (5) Cyanide method (BUCHER).

From ammonia, produced in any way, nitric acid is obtained in great quantity

During the war the requirements of explosive factories and those of agriculture on the one hand and the difficulties of sea-borne trade on the other gave an enormous development to the nitrogen industry all over the world and especially to the cyanamide industry, for the direct ammoniacal method was only employed in Germany and the other methods made relatively little progress. According to W. S. LANDIS of the American Cyanamide Co., the annual production of works using synthetic processes in the whole world has increased from 83 680 tons in 1913 to 271 170 at the beginning of 1916. The recent world-production of all nitrogenous fertilisers expressed in thousands of tons of nitrogen is summed up as follows (2): —

	1919	1918	1917	1914
(1) Chile saltpetre	520	500	372	368
(2) Ammonia by distillation	350	350	461	260
(3) Calcium cyanamide	343	265	186	28
(4) Nitrogen by the arc process	15	15	34	10
(5) HABER ammonia	109	109	114	11
6. Other synthetic processes	—	—	39	—
	1 337	**1 239**	**1 206**	**677**

As regards the productive efficiency of these fertilisers it is known from experiments made in central Europe that in 1914 the surplus due to the effect of Chilean nitrate varied between 15 and 83 %, compared with the crop without nitrate; in 1915 the surplus due to sulphate of ammonia was from 10 to 117 %.

According to GERLACH, sulphate of ammonia has a fertilising efficiency of 89 % of that of nitrates of soda and of lime and from 76-80 % of that of calcium cyanamide. According to CARO, one ton of synthetic nitrogen used as a fertiliser produces an average increased yield of 30 tons of cereals and 100 tons of potatoes. According to BUEB it would produce, in central Europe, the following surplus yields: —

For wheat	18	tons of grain plus	40	tons of straw
» barley	24	» » » »	30	» » »
» oats	24	» » » »	34	» » »
» potatoes	129	» » tubers »	40	» » leaves
» sugar beet . . .	150	» » roots »	199	» » »
» mangels	240	» » » »	75	» » »

---

by catalytic oxidation (OSTWALD-BAUER, FRANK-CARO processes) and from it is obtained the greater part of the synthetic nitrates used as fertilisers. Agriculture employs $^4/_5$ of the nitrogenous compounds at present produced Cf. BOSCH, Nitrogen in economics and technology in *Zentral-Blatt fur die Kunstdunger-Industrie*, Year 25, No. 1, p. 3. Frankfort, Jan, 1921 (*Ed*)

(2) The data for 1917 are quoted from *R.* 1919, No. 834. For comparisons, see — INTERNATIONAL INSTITUTE OF AGRICULTURE, *Mouvement International des engrais et des produits chimiques utiles à l'agriculture.* (*Ed.*)

The great development of synthetic nitrogen has even led to the invention of special machines and a special mechanical construction industry. On the other hand out of 173 Chilian nitre-beds actually in existence, less than 60 were being worked in 1919 and this was as much due to the competition of synthetic nitrogen as to the lack of fuel, the difficulties of commerce and the European political and financial instability. However an *Instituto cientifico e industrial del Salitre* has recently been created in Chile with the object of studying technical improvements and of increasing the possibilities of competition by Chili saltpetre, of which, however, according to WAESER, synthetic products need not be afraid.

Numerous experiments have been made and there has been much discussion to facilitate the inoffensive application and action of synthetic nitrogenous fertilisers. Opinions differ regarding the caustic and poisonous effect of calcium cyanamide in the factories, especially on workmen who consume alcoholic beverages. To prevent injury to the country people who spread calcium cyanamide in the fields a special competition with prizes was held in Prussia in 1915, but without result. CARO affirms that the best method for giving immunity is granulation with 3 to 4 % of heavy oil, since any treatment with water or with hygroscopic salts would have the defect of causing a loss of nitrogen.

WINTERFELD mixed calcium cyanamide with dolomitic sand. NEUSS and STIEGLER add to it peat and the last water of extraction of potassium salts. STEIMMIG adds to it soda salts containing water of crystallisation and WAAGE prepares briquettes and tablets with calcium cyanamide, basic slag or finely ground phosphorites, a potassic solution, molasses, etc.

The granulated Norwegian product contains 1.6 % of nitrogen and only 9 % of dust, whereas calcium cyanamide treated with lime contains 44 %. Other methods of granulation are employed in North America and in France. But mechanical spreading is considered the best means of preserving the health of the workmen.

Much has been written regarding the use and the fertilising power of calcium cyanamide, or simply cyanamide (if prepared by the FRANK-CARO process), or calcic nitrogen (*Stickstoffkalk* if prepared by the POLZENIUS process). According to the author, the analytical determination of the dicyanodiamide (irreversible polymer of chemically pure cyanamide) which is considered to be poisonous, has a special interest (1).

---

(1) The poisonous effect of dicyanodiamide on plants is disputed :— ULPIANI denies it absolutely and also PEROTTI and GUILLIN. From the results of his experiments. ULPIANI concludes that the cyanamide of calcium cyanamide passes early in urea in the soil whenever the soil is not poor in colloids; that opinion is shared by KAPPEN On the other hand the cyanamide would be poisonous when it remains unaltered as in excessively sandy soil. However, it is to be presumed that much of the want of success of cyanamide in these soils, attributed to the poisonous action of dicyanodiamide or to lack of microbial activity, is due to the absence or rareness of colloids. (Cf. SOAVE, *Chimica vegetale ed agraria* Unione tipografica editrice. Turin, 1915, Vol. II, p. 245).

On the other hand, according to the experiments of COWIE at Rothamsted, dicyanodiamide does not decompose in the soil and exerts a depressing action on the ammonification

Cyanamide is now used as a source of ammonia, nitrates and urea, which contains 46.7 % of nitrogen and is already used with good results as a fertiliser and a food. But owing to that high content urea is only applied to the soil, mixed with powdered lime or other inert matter. After having passed in review recent progress and recent works on agricultural chemistry relating to the questions the author sums up the development of the nitrogen industry in the various countries of the globe.

Germany. — The two great syntheses employed in that country are that of cyanamide, usually by the FRANK-CARO process and that of the direct production of ammonia by the HABER-BOSCH process. The direct oxidation of nitric nitrogen in the voltaic arc would require a large consumption of power; therefore very few factories utilise the PAULING process.

The cyanamide industry is oldest in Germany: it was tried before 1904.

The direct synthesis of ammonia developed enormously during the war; it is carried out on a large scale by the *Badische Anilin und Soda-Fabrik* at Oppau and Merseburg using the HABER-BOSCH process, special at present to Germany and which requires cheap coal and not electric power.

The *Badische Co.* prepares sulphate of ammonia (1), by double decomposition with local gypsum, and it also manufactures urea (44.66 % of nitrogen), nitrate of urea (34.15 %), chloride of ammonium (26.42 %), artificial nitre (16.5 %), double nitrate of urea and calcium (35 %), superphosphate of urea, bicarbonate of ammonium, ammonium-potassium nitrate, sodium-ammonium nitrate, nitrosulphate of ammonium, etc. But agriculture has still a certain mistrust of these new fertilisers, and therefore experiments and propaganda are necessary.

The *Nitrogen Syndicate* (Stickstoffsyndikat G. m. b. H.) with a capital of 1 066 500 000 marks was established in Germany on May 8, 1919 under the auspices of the Badische company.

Before the war (1913), German agriculture consumed about 180 000 metric tons of nitrogen combined with artificial fertilisers (400 000 tons of sulphate of ammonia, 560 000 of Chili saltpetre and 15 000 of synthetic products) and imported almost as much nitrogen with forage. In 1919, according to the Syndicate, the annual productive capacity of Germany was about:—

Synthetic nitrogen by the HABER process	300 000	tons
» » » » cyanamide »	100 000	»
» » » » dry distillation	100 000	»

---

of protein matter, on nitrification and on vegetative growth (*R.* Oct., 1919, No. 1098). LEMMERMANN concludes from pot experiments that granulated cyanamide was injurious on account of its dicyanodiamide content which generally counteracts the power of assimilation (*Chemischer Zentralblatt*, Year 91, Vol. 3, No. 26, Wissenschaftlicher Teil, p. 940, Berlin, Dec 29, 1920). (*Ed.*)

(1) This association of synthetic ammonia with the SOLWAY soda process in the great work shops of Oppau, is, according to PARTINTON, who described it, one of the most interesting. Cf. *Journal of Chemical Industry*, v. 40, N. 6, p 99 London, March 1921 (*Ed*)

It is true, however, that in 1919 the real production was only 100 000 tons, which owing to difficulties in importing, caused a great decrease in the consumption of nitrogenous and phosphatic manures in Germany (1).

The German water-power resources are estimated by HALBFASS at about 11 400 000 H.P. of which about 4 000 000 are already developed (2). The largest electric generating stations in the world is being built in Bavaria ; its capacity is 6 000 000 kilowatts ; at present mixed plant, both hydraulic and steam, is used and the station is subsidised by the State. For storing power UNRUH has proposed to electrolyse the water and transmit the gas by means of a system of pipes to the place of consumption.

Austria-Hungary. — The *Economic Union of the Fertiliser Industry* was founded in 1918 at Trieste with factories spread over the old Austrian-Hungarian Empire. In the same year a factory was already working at Jablonica (Bosnia) and another at Bory (Galicia) ; the latter utilised the MOSCICKI process and produced annually 225 wagons of ammonium nitrate (3).

Bulgaria possesses one factory that makes carbide and chemical fertilisers at Poruschtiza.

Russia. — In 1917 a Company for working the BIRKELAND-EYDE process was formed at Petrograd, and the construction of a factory on the White Sea was proposed. A Russian Commission was sent to Germany to study there MEINER'S new process in the Skoda works.

Finland. — The proposed utilisation of the falls of the Imatra would yield 118 000 H.P. and those at Wych 600 000. A special Commission will decide whether the HABER process or the American cyanamide process will be adopted.

Norway. — This is the country of the arc process. The available water power totals 7 500 000 H.P. of which is 1.34 million H.P. is easily ultilisable and capable of furnishing about 5 000 000 kilowatts.

The cost of installation varies between 250 and 400 *crowns* (1 *crown* = 1.101 *shillings* at par) per kilowatt and the cost of working, including amortisation, between 10 and 15 % of the former. The current thus costs from 45 to 60 *crowns* per kilowatt year. In 1918, the *Norwegian Nitrogen and Hydro-electric Power Company* at Notodden, formed mainly with French capital, produced 350 000 H. P., which it intends to increase to 515 000 ; it is therefore the most powerful electric group in Europe. Another large company, the *Norsk Hydro Elektrisk Kvaelstof Aktieselskab* of Telemarken can produce annually 100 000 to 120 000 tons of synthetic nitric acid by the BIRKELAND-EYDE process ; a very large portion of it is transformed into *Norwegian saltpetre* (nitrate of lime with 13 % of nitrogen), nitrate of soda and nitrate of ammonia, the production of which tends to exceed that of Norwegian saltpetre. In addition, Norway produces annually 700 000 to 800 000 tons of cyanamide lime and the factories of Odda, since 1915, carry out granulation with satisfactory results.

---

(1) That is why an active propaganda was undertaken for the fixing of nitrogen by biological means with leguminous plants chiefly lupins. See *R.*, Feb., 1921, No. 119. (*Ed.*)

(2) For the utilisation of water-power, see also *R.*, Oct., 1919 No. 1096. (*Ed.*)

(3) Two large cyanamide factories also exist at Sebenico and Spalato (Dalmatia) : their annual capacity is 56 000 tons (*Giornale di chimica industriale ed applicata*, Year 3, No. 1, p. 22. Milan, Jan. 1921). (*Ed.*)

In Norway, English and German companies, are also making synthetic nitrogenous products. The Norwegian-Icelandic Titan has also been formed for utilising hydraulic power in Iceland.

In 1918, the *Consumers' Union of the Norwegian Agricultural Society*, which has branches in Sweden and Denmark, founded at Bjölvefos, a co-operative factory with 43 000 H.P.; its annual production is 36 000 tons of cyanamide and 6000 of sulphate of ammonia. Recently the *Norsk Nitrid A.-S.* of Eydehavn has undertaken the manufacture of aluminium nitride by the Serpeck process.

Before the war Norwegian agriculture consumed 6000 to 7000 tons of nitrogenous fertilisers; in 1919, it consumed 80 000 tons of synthetic nitre, 2500 of granulated cyanamide, 43 000 of superphosphate and 2500 of cyanamide powder, used as a weed destroyer and made by the *North Western Cyanamide Co.* of Odda (1).

Sweden. — The production of cyanamide is especially developed in Sweden; the amount at present produced is 21 000 tons. The first large factory for atmospheric nitrate is expected to start working in 1923, and should produce 33 000 tons a year.

In 1919, the consumption of cyanamide was about 100 000 tons; for this reason the State is giving subsidies to favour home production.

United Kingdom. — The British Empire has water power reserves estimated at 50-70 million H.P., and it is proposed to establish an *Imperial Water Power Board.* Hydraulic power in Scotland could be obtained at a cost of £40 per H. P, or $\frac{1}{8} - \frac{1}{5}$ d. per kilowatt-hour.

The *Nitrogen Products Carbide Co.* a long time ago founded on important factory at Dagenham where it nitrifies ammonia derived from Scandinavian cyanamide. After 1915 the *Nitrogen Products Carbide Co.*, which amalgamated in 1919 with the *Alby United Carbide Factories Ltd.*, established a large cyanamide factory at Workington, intended to render England independent of Chile saltpetre. As there was a lack of nitrate during the war it was constantly necessary to manure with sulphate of ammonia and now the use of cyanamide is suggested to remedy the injury caused by prolonged use of ammonium sulphate.

The *Nitrogen Committee*, appointed in June 1919 with the object of promoting the installation of synthetic nitrogen factories in England, has taken up this interesting question and recommended, meanwhile, the foundation of the large factory of Billingham for the production of ammonium nitrate. Manchester has a nitric nitrogen factory which burns directly air in the electric arc, according to a direct process of the *International Nitrogen and Power Co.* of London, considered as very economical, in spite of the high cost of electric current in England. The experiments made to introduce the HABER process have had no results up to date (1) (2). The *Nitrogen Committee* ended its report by recommending strongly the creation of a rational synthetic nitrogen industry and the unification of English electric services.

---

(1) In 1920, Norway exported in round figures 117 thousand tons of *norge*, 18.6 of nitrate of soda, 20.2 of nitrate of ammonia (*Chemical Trade Journal and Chemical Engineers*, Vol. 88, No 1770, p 359 London, April 1921. (*Ed.*)

Denmark. — The need for fertilisers has increased considerably in Denmark. Since 1918 the Government and the *Danish Society* have encouraged the installation of an experimental synthetic factory. But much Danish capital is employed in the *Fosseakeieselskabet Island*, which proposes to use the Thingvalla falls to furnish power to a factory which will supply Iceland and Denmark with synthetic nitrogenous fertilisers.

Holland. — Before the war, this country consumed 100 000 tons of Chile saltpetre and 40 000 of sulphate of ammonia. The restrictions imposed during the war have turned public opinion towards independence of foreign nitrogen. The Dutch Commission which dealt with the question concluded its report by recommending a preliminary investigation regarding the possibility of collecting organic waste (urine and peat litter), and the creation of factories to use the cyanamide or cyanide processes. The *Naamboze Vennootschap Stickstofbindings-industri*, of Dordrecht with a capital of 10 million *florins* (1 *florin* = 1.652 shillings at par), is to produce, by means of an American process, 2500 tons of fixed nitrogen at a price fixed by Government, which is subsidising the Company. In addition, 12 500 tons of sulphate of ammonia will be obtained by the cyanide process. There are no cyanamide factories.

France. — France is very rich in hydro-electric power the reserves being estimated at 10 million H. P. In 1914 only 805 000 H. P. was utilised, representing a capital of 350 million francs. At present about 1.5 million are used derived from rich alpine hydraulic reserves, which are utilised by two important French synthetic establishments, that at Notre-Dame de Briançon, which produce cyanamide lime by the FRANK-CARO process, and that of Roche-de-Rame, which produces nitric acid by the PAULING process. During the war only cyanamide was made, the production rising from 8000 tons in 1913 to 100 000 in 1918; however, since 1909, there has been an aluminium-nitride factory at Mulhouse, working on the SERPEK process, the patents of which now belong to the *Société d'aluminium française.*

In France nitric acid is generally made by catalytic oxidation rather than by direct combustion. In 1915-1916 the French Government requested the Anglo-Norwegian *Nitrogen Product and Carbide Co.* to instal in France factories to make cyanamide, nitric acid and nitrates by the processes worked out at Alby and Odda. It was intended to use the BIRKELAND-EYDE process in the Pyrenees. In 1919, among many French companies was founded the *Company for the investigation of nitrogen*, with the object of dividing between the associated Companies the HABER patent, obtained from Germany under the Peace Treaty.

---

(1) At present, however, the English *Cumberland Coal, Power and Chemical Co., Ltd.*, which controls the English rights of the CLAUDE process, which uses higher pressures than the HABER process is about to instal works in Cumberland (*The American Fertilizer*, Vol. 54, No. 1, p. 76, Philadelphia, Jan., 1921. (*Ed.*)

(2) A modification of the HABER process is being worked by BRUNNER MOND and Co., but with what results is not yet known. (*Ed.*)

Recently G. CLAUDE, who synthesises ammonia at high pressures, has proposed to prepare chloride of ammonia with synthetic ammonia, by the SOLWAY soda process, in place of the sulphate, so as to obviate the high cost of sulphuric acid.

According to TISSIER the requirements of nitrogenous fertilisers in France in 1913 was 70 000 tons.

Switzerland. — According to AGTHE production by the HABER process is not economical in Switzerland; the same is true of the arc process and FIERZ thinks that the same applies to the SERPEK process. On the other hand the cyanamide process is economical. WINTELER estimates that the average cost of installation in Switzerland is 500 fr. per hydraulic H.P. and consequently a cost for current is 62.50 fr. per H.P.-year, or 1 centime per kilowatt-hour, a cost which will bear comparison with that in Norway.

Switzerland produces much calcium carbide but only 10 000 tons of cyanamide, of which 8000 tons. are consumed in the country. At Chippis and at Bodio nitric acid is made for the army by the PAULING process.

Italy. — This country was the first to start the real cyanamide industry by the FRANK-CARO process. In 1918 the old *Società Italiana dei Prodotti Azotati* of Piano d'Orte raised its capital to 9.9 million *lire;* it had produced 14 000 tons in 1914. The Firm of ROSSI of Legnano, which raised its capital to 20 million *lire* in 1920 makes nitric acid by the PAULING process and nitrate of potash and ammonia. An important electric establishment will be created at Domaso (1).

---

(1) PARSONS states that the Italian chemical industry will be very successful (*The Journal of Industrial and Engineering Chemistry*, Vol. 12, No 9, p. 907, Easton, Pa., Sept., 1920) Five cyanamide factories are at present working in Italy; they produced, in 1919, 16 800 tons of this product (Ministry of Industry and Commerce, *Annuario per le industrie chimiche e farmaceutiche*, V. 2, pp. 112 and 113. Rome, 1919) and 28 000 in 1915. A sixth factory is under construction at Domodossola and the productive capacity of the 6 factories is estimated at 80 000 tons of cyanamide.

The two factories of the Firm of ROSSI produce nitric acid.

As in many other countries, the important question of synthetic nitrogen has led, also in Italy, to the creation of a *Commissione per l'azoto*, appointed in December, 1919. After its return from Germany it made the following recommendations:— that the national production of synthetic nitrogen should be increased so as to meet the requirement of 50 000 tons forecasted for a few years hence; that the synthetic ammonia method should also be used by the use of electrolytic hydrogen (*Giornale di Chimica Industriale ed applicata*, Year 3, Nos. 1 and 2, pp. 20 and 64. Milan, 1921). A new elementary synthetic ammoniacal process of CASALE, based on the same catalytic synthesis as that of HABER, but preferable to that of HABER and CLAUDE on account of its economy and simplicity, is being discussed in Italy; it has already been tried with success by the *Idros* Co at Terni: the patent has been bought abroad but with reservation of the right of manufacture in Italy. (*Il Coltivatore*, Year 67, No. 16, p. 499. Casalmonferrato, June 10, 1921). (*Ed*)

Spain. — The *Compañia Navarra de Abonos Quimicos* of Pampelune, founded in 1918, projected the construction, at Viana, of the first factory of atmospheric nitric acid and its derivatives, working on the NORSK-HYDRO patents: the river Ebro supplies 8000 H.P. The second factory (75 000 hydraulic H. P.) is to be installed at Lerida and the third at Corcubion.

In 1918, Spain consumed 60 000 to 70 000 tons of sulphate of ammonia, chiefly in the ricefields of Valencia.

United States. — The development of industrial synthesis in the U. S. is of special interest. The first products were manufactured by the *American Cyanamide Co.*, founded in 1907, which produced in 1913, with power furnished by the Niagara falls, 64 000 tons of cyanamide by the FRANK-CARO process. During the war the great industry of catalytic ammonia oxidation using ammonia obtained from cyanamide and coke ovens developed to such an extent that 5 big works capable of producing 225 000 tons of nitric acid annually were working in 1918. In 1917 the above mentioned company and the Government founded the *Air Nitrates Corporation* with the object of creating large cyanamide factories; in 1918 the Muscle Shoals factory on the Tennessee, in Alabama (Nitrate Plant No. 2) was working; it cost $18.6 million (1 dollar = 4.86 shillings at par), employs 34 000 workmen, and produces, with 90 000 kilowatts, 110 000 tons of nitrate of ammonia annually. The American Government spent another $20 million on the factory at Sheffield, Alabama, which can produce 220 000 tons of nitric fertiliser by the *General Chemical Co.*, process, based on that of HABER, recognised as unexceptionable by PARSONS.

The BUCHER cyanamide process, favourably reported on by PARSONS, has recently become very important; it is worked by the *Nitrogen Products Co.* and produces cheaply by the thermic method. Cyanide of ammonia, urea, and, with the help of current, oxamide, a substance almost insoluble in water which forms, according to BUCHER an excellent fertiliser, are obtained. Recently the U. S. Government has devoted $70 million to the installation of synthetic nitrogen works, and has established a Nitrogen Commission. PARSONS estimates the cost of production of 1 ton in America as follows (page 1123).

The hydraulic power utilised in the United States up to 1917 amounted to 4.4 million H.P. But the *American Cyanamide Co.* also works on the Canadian side of the Niagara Falls and in the port of New York, where the *Ammo-Phos-Corporation* will prepare phosphate of ammonium (*Ammo-Phos*) by the WASHBURN process.

The arc process is little used. There are 3 small factories, subsidised by Government, which produce 2 000 to 3 000 tons of nitric acid by the WIELGOLASKI process.

One third of the total production of synthetic nitrogen in the whole world is furnished by the United States, where the production is more than three times the requirements of the country, in spite of the still very considerable imports of Chile saltpetre.

Canada. — Estimates of the water power vary between 14 and 18.8 million H.P. Of these, 2 million H. P. is already developed and another million is being developed. It is proposed to use the gassy springs of pure nitrogen in the Fraser valley, in British Columbia, and those of the islands in the gulf of Georgia, for the manufacture of cyanamide. In British Columbia, which possesses 3 million hydraulic H.P., of which only 250 000 are utilised, the *American Cyanamide Co.* produces cyanamide from which it makes nitric acid, nitrates, urea, phosphate of ammonia, etc. A factory is also to be constructed to produce 2000 tons by the WIELGOLASKI process.

South America. — No factory is known to be already working. In the Argentine there is talk of using the Iguazu falls, which resemble those of Niagara. In Brazil there are 10 large falls which could supply 26 million H.P.

Asia. — Turkey does not possess any establishments of the kind. In Japan for some years now the *Nippo-Tisso-Hyrio-Kabushiki-Kaiska* (Limited Company of Nitrogenous Fertilisers), of Osaka, has produced cyanamide by the FRANK-CARO process. The same applies to another electrochemical company. A new factory was installed at Fukui in 1918, so that Japan also is progressing towards real or potential economic independence as regards nitrogenous products. Up to the present the arc process is not used industrially, but the Government is constructing a factory to use the HABER process or its American modification.

There is also talk of constructing a fertiliser factory in Korea.

In British India the projected factory at Burhar should supply 5000 tons of cyanamide per annum, to be used directly or to be transformed into ammonia salts, especially for manuring ricefields and sugar cane, the relative production of which is very low compared with that of the neighbouring Dutch Colonies.

Africa. — In the south there are two English companies which produce 2000 tons of sulphate of ammonia and work the local mines of nitrate of potash. Another company, was formed in 1919, to produce fertilisers in Egypt. In the Canary Islands large quantities of fertilisers are used for the banana crop.

Oceania. — Already nitrated lime has been produced in Oceania.

II. — PROGRESS OF THE ELECTROTECHNICAL INDUSTRY FROM 1916 TO 1919. — This is another interesting review of the whole electrotechnical industry during recent years, with information regarding new inventions and patents. The following is an abstract of the parts most interesting from an agricultural standpoint avoiding repetition of the information already given above.

Contrary to the opinion of DOLCH, MEINGAST considers that the Swedish CARLSON process is the best for the preparation of cyanamide. LIECHTI and TRUNINGER are of opinion that to estimate the commercial value of cyanamide, at least as much importance should be attached to the determination of dicyanodiamide as to the determination of the total nitrogen. Numerous contradictory experiments made with cyanamide could, according to MEINGAST, be probably explained by the different content of the cyanamide in dicyanodiamide, which is considered to be poisonous. The experiments of the Swiss Establishment of agricultural Chemistry at Berne-Liebefeld that TRUNINGER has reported, have shown, according to the author, that dicyanodiamide has a specially poisonous effect on oats. For spreading cyanamide in the fields, HUSEN recommends that the workman should be powdered or greased.

In Germany the Nitrogen Syndicate has fixed the proportion 8 : 9 : 10 between the unit prices of cyanamide, ammoniacal and nitric nitrogen.

ANDRIESSENS deals theoretically with the voltaic oxidation of nitrogen and shows that the greatest yield is obtained with a mixture of equal parts of nitrogen and oxygen ; this is why the synthesis of cyanamide should exist in the industry side by side with voltaic oxidation.

III. — REVIEW OF THE PROGRESS OF THE FERTILISER INDUSTRY FROM 1913 TO 1920. — WICHERN gives information regarding the progress made by the potassic, phosphatic and nitrogenous fertiliser industries. We restrict ourselves here to nitrogenous manures, for which the author refers to the previous review of VAESER.

Artificial nitre, unlike natural nitre, does not contain injurious chlorates. Nitrate of ammonia, a concentrated fertiliser, cannot be transported because it is explosive and hygroscopic. Ammonium-potassium nitrate with 15 % total nitrogen, half nitric and half ammoniacal, and with 25 % of potash, and ammonium-sodium nitrate, with 19 % of nitrogen, has not the same obnoxious proporties as nitrate of ammonia. Nitro-sulphate of ammonia (1), with about 27 % of nitrogen, and chloride of ammonia, owing to their novelty, have not yet obtained favour with farmers who remain faithful to sulphate of ammonia. Urea, with 47.6 % of nitrogen is the richest of nitrogenous fertilisers ; it is generally prepared industrially by the reaction of ammonia in carbonic acid in a closed heated chamber and then distilling the product at 80° C. But the hygroscopicity of urea prevents its use as a fertiliser, so nitrate of urea and calcium is prepared, which contains 34 % of total nitrogen (7 % in nitric form), is easy to spread and to store (1). Bicarbonate of ammonium is also prepared (2).

---

(1) Germany ceded this fertiliser to Belgium, including it in the war indemnity (*Journal de la Société Nationale des agriculteurs de Belgique*, Year 3, No. 17, p. 121. Brussels, Apr. 1921). (*Ed.*)

In spite of the development of the direct synthesis of ammonia the cyanamide process is still very important, because it supplies a directly utilisable fertiliser which does not require subsequent transformation. The principal drawback to cyanamide is its extreme fineness of division and to obviate this, treatment with neutral oil is used and will continue to be used successfully. It would be interesting to find a means of neutraising the calcium oxide without altering the cyanamide.

If bricks of cyanamide are prepared a granular product with only 9 % of dust (against 44 in the oiled product) can be obtained but the process is very expensive.

A new nitrogenous superphosphate has been obtained by mixing superphosphate with synthetic urea. It is very hygroscopic but several patents have been taken out to obviate this defect; its richness in nitrogen renders it easily negotiable and exportable. Mixtures of superphosphate and cyanamide are not recommended owing to the reversion of the phosphoric acid.

If superphosphate is saturated with ammonia, GERLACH ammonium phosphates are obtained. This contains on an average:— 2.42 % hygroscopic moisture; 33.71 % sulphate of ammonia; 2.74 % bicalcium phosphate; 30.1 % tricalcium phosphate; 22.55 % calcium sulphate; 2.96 % phosphates of iron and aluminium; 4.26 % silicates, etc. The phosphoric acid of the original superphosphate is effectively retrograded, but 16.27 % (out of 16.73 % total) is soluble in a 2 % citric-acid solution. Of the ammoniacal nitrogen 6.47 % (total 6.61 %) is soluble in water.

Cultural tests, using equal contents of nitrogen and phosphorus, have proved the equality in fertilising efficiency of GERLACH ammonium superphosphate and the ordinary mixture of superphosphate and ammonium fertiliser. Another similar product has been prepared by WILLSON with double superphosphate and ammonia gas.

The GERLACH process, which is not yet used industrially, has against it the fact of phosphoric reversion. But KLINGBIEL concludes from one of his investigations that the method of estimating superphosphate used at present in Germany, which is based exclusively on the estimation of the water-soluble acid, requires to be modified. This is so much the case that since August 1, 1919 (thus satisfying an old desire of local manufacturers) citric-soluble phosphoric acid is just as dear in Germany, which is all the more opportune because at present German phosphorites, rich in iron and aluminium, are increasingly exploited (1).

---

(1) Urea affords great promise as a fertiliser for tobacco. See *R.*, May, 1921, No. 394. (*Ed.*)

(2) As well as BURKEISER's salt, which is a mixture of sulphite and sulphate of ammonium (GREGOIRE, Les engrais nouveaux, in *Annales de Gembloux*, Year, 27, Nos. 3 and 4, Brussels, 1921 in which all the synthetic products are clearly reviewed). (*Ed.*)

IV. — INDUSTRIAL USE OF CYANAMIDE. — Review of a recent book by ESCARD (2).

Cyanamide, in powder, easily carried away by the wind, requires transformation. The most simple operation is granulation. Modern granulation processes allow granulated cyanamide to be obtained at a high strength (19-20 % of nitrogen) with a high content of calcium oxide which facilitates a return to the dusty state as soon as it is incorporated in the soil. This product is sold in tins containing 75 kg.

Ordinarily, cyanamide is granulated by kneading it with a little air. Sometimes clay soil, casein and water are added. In the SAVÈS process, the cyanamide is mixed with a solution of potassium silicate, then dried ; granular cyanamide is obtained having 12.10 % of nitrogen and 1.62 % of potash or other strengths, and is applied in autumn.

The SINCLAIR process of granulation consists in the addition of hot water followed by drying the product during shaking. Briquettes are made by kneading followed by drying and breaking into granules.

Cyanamide oiled with 4 % of heavy oil is then granulated and has the advantage of not being hygroscopic ; 15 % of tar can also be added to cyanamide.

Cyanamide is also valued for its content of lime, iron and manganese. It is suitable for all soils, except soils rich in nitrogen and very sandy soils : it has given excellent results in ricefields. Its effect lasts over a year and it nitrifies slowly. It can be mixed with basic substances, but not with ammonium salts and not even with superphosphate.

891 - **The Mechanism of the Decomposition of Cyanamide in the Soil.** — COWIE, G. A. (Rothamsted Experimental Station, Harpenden), in *The Journal of Agricultural Science*, Vol. X, Pt. 2, pp. 163-176, figs 5, bibliography of 10 works. Cambridge, May 1920.

In a preceding investigation the author showed that cyanamide readily breaks down, yielding ammonia in normal clay and sandy soils. The experiments here discussed confirm the view held by ULPIANI as a result of his later work, namely that cyanamide breaks down by a purely chemical change to urea which is then converted into ammonia.

In the experiments carried out by ULPIANI, culture solutions of various concentrations and at various temperatures were employed, whereas the author conducted his experiments in soil under natural conditions, using amounts of cyanamide comparable with those used in practice. No appreciable amount of ammonia as a result of the decomposition of cyanamide in sterile soils was evident (heated to 120° or 135° C.). The addition of the urease of soya-bean, however, produced considerable quantities of ammonia in these soils which indicated the presence of urea, later confirmed in the laboratory. Further experiments demonstrated that urea actually remains stable in soils heated to 120° C. The addition of cyanamide to sterile soils thus leads to an accumulation of urea, which persists as such in consequence of the suppression of the necessary urea decomposing organisms. Similarly the addition of cyanamide to soils heated to 100° C does not lead to immediate production of ammonia but yields urea, which decomposes after the recovery of the appropriate organisms. There is on the other hand, evidence of a rapid and progressive production of ammonia arising from the decomposition of cyanamide in unheated normal clay and sandy soils. However, examination of these soils revealed in the initial periods the presence of appreciable amounts of urea.

---

(1) According to NEUBAUER, who has dealt with GERLACH ammonium phosphate, the fertilising effect of dicalcium phosphate, soluble in 2 % citric acid, is almost the same as that of water-soluble monocalcium phosphate, except for a soil very poor in phosphoric acid or for plants with a reduced root system, as in young beet plants (*Die landwirtschaftlichen Versuchs-Stationen*, Vol. XCVII, Nos. 1 and 2, p. 20. Berlin 1920). (*Ed.*)

(2) *Production industrielle synthétique des Composés nitrés et leurs dérivés.* Dunod, Paris. (*Ed.*)

The cumulative evidence thus leads to the conclusion that cyanamide in the soil is normally converted by a purely chemical process into urea and independently of the activity of micro-organisms. The urea is then broken down into ammonia by means of soil organisms. Cyanamide appears to behave in this way in both clay and sandy soils, but the decomposition seems to be more rapid in the former case. The experiments have conclusively shown that cyanamide does not decompose into urea in ordinary impure quartz sand; whatever the decomposing agent may be it is not present in pure sand. In one special case sand has been shown to contain a constituent resembling a zeolite. In any case cyanamide does not appear to decompose in the manner above indicated in peat and fen soils; in these it gives rise to a relatively small production of urea under normal conditions.

892. — **Assimilation of Phosphoric Acid and Reaction of the Soil** — See n° 894 of this *Review*.

893 — **Fertiliser Tests in Iceland.** — See n° 881 of this *Review*.

894 – **Factors influencing the Assimilation of Fertilising Matter by the Plant.** — WRANGEL, M., in *Die landwirtschaftlichen Versuch-Stationen*, Vol. XCVI, Pts., 5 and 6, pp. 209-262, 3 pl. Berlin, 1920.

In a preceding work (" Ein estländisches Rohphosphat und seine Wirkung auf verschiedene Pflanzen ", *Die Landw. Versuchs-Stationen*, XCVI, 1), the author has shown that different plants use the phosphoric acid of slightly soluble phosphates, in very unequal quantity. To study this phenomenon, cultural experiments were undertaken and the assimilation of phosphoric acid by the plants relatively to a different reaction (alkaline, neutral, acid by inorganic and organic acidity) of the soil solution and of the soil itself was observed.

With this object, fertilisers were used in mixture which had a neutral reaction; but if care was taken to supply equal quantities of fertilising foods, they were given in a different form and assorted so that a first group of tests remained neutral, the second became alkaline, the third acid had a citric acidity and the fourth acid a sulphuric acidity; moreover, a certain number of parallel tests were treated with calcium carbonate in quantity exceeding that necessary to neutralise the acidity which might eventually develop. The reaction of the soil, or rather of its solution, was controlled during the whole experiment and the effect of it on the assimilability of phosphoric acid, tricalcium phosphate, dicalcium phosphate and natural phosphate was studied first in a preliminary series of experiments with maize, then in a second with mustard. The soil used consisted of quartz sand but contained 0.097 % of lime, partly as carbonate and partly as silicate, which was neutralised, in the first group, by $^2/_3$ of sulphuric acid and $1/3$ of nitric acid, in the third group by citric acid, and in the fourth group by sulphuric acid, while the second group was used untreated. Each pot contained 6 kg. of this sand, and the fertilising substances were applied in quantities of 1 gm. per pot for each of the elements (nitrogen, potash and phosphoric acid) and 5.9 gm. for lime in the form of various salts. The MERCK tricalcium phosphate used contained 40.43 % of phosphoric acid, of which 2 % was soluble in citrate of ammonia; the dicalcium phosphate contained 40.24 % of phosphoric acid (38.8 % soluble), and the natural phosphate (Esthonian oolite) 20.37 %, of which 3 % was citric soluble. The pots were kept at 10 % of moisture; the sand used contained 0.01 % of manganese, traces of iron, aluminium and sulphuric acid, as well as a certain amount of potash.

The results obtained showed that the maize used only the slightly soluble phosphates when there was an acid reaction due to complementary manuring that was physiologically acid; the addition of lime caused the effect of the acidity to cease completely and consequently also the assimilation of phosphates. Mustard however could assimilate phosphoric acid from the slightly-soluble phosphates, even in the presence of a rather alkaline reaction, and this took place also independently of liming and even to some extent of the alkaline or acid reaction except when the intensity of the reaction was such as to give rise to effects that were toxic or harmful in some other way

The maize assimilated the lime relatively to the phosphoric acid in the proportion of 3 molecular weights of one for 1 of the other; mustard, for the same quantity of phosphoric acid, consumes 15 molecular weights of lime; the proportion lime: phosphoric acid enables an estimate to be made of the aptitude of plants to use phosphoric acid and causes, at the end of vegetative growth, a change of reaction in a soil that at first was neutral. The process of dissolution of fertilising substances in the soil appears primarily to differ from an alternate absorption of cations and anions and from the oscillations of alkaline and acid reactions which are thus generated. Normally it appears that there is, at the commencement of the vegetation, an accelerated absorption of cations, favourable to a more intense assimilation of phosphoric acid in the second stage of growth; when basic or acid solutions are added they hasten the appearance of the process of nutrition of the plants to such an extent that they may be considered as catalysts. Nitrogenous manuring has special importance, inasmuch as, if it is applied opportunely, it regulates not only assimilation but also the reaction of the soil solution; in fact, nitrogen may be applied in the form of cation as ammonia, of anion as nitric acid, or else in the form of nitrate of ammonium, which may help to create an optimum reaction for the plant.

Free citric acid is decomposed in a few days in the soil, while the presence of carbonic acid in the soil appears to play an important part in the phenomena of dissolution and transformation.

These statements seem to throw light on several phenomena, such as:— The contradictory results of liming; the exhaustion of the soil and rotations; the sensitiveness of certain plants to lime in spite of a relatively high requirement of lime; the formation of colloids in the circuit of the root system owing to the alternation of the acid and alkaline reaction.

895 - **The Necessity for Establishing a Plant Breeding Station in the Argentine for the Application of Genetics to Agriculture.** — GIROLA, C. D, in the *Anales de la Sociedad Rural Argentina,* Year LVI, Vol LV, No 6, pp 205-212, figs. 2 Buenos Aires, March 1921.

In spite of previous attempts the problem of the selection of wheat in the Argentine is still, according to the author, in the early stages and offers a very large field for research and work to scientists and technicians.

The selection of wheats should be commenced on indigenous or acclimatised varieties, first of all on the *Barleta* (*Triticum sativum* L. var. *Barleta* Gir.) which is still largely represented, although it is rarely met with in a pure state; it has always given good products with respect to quality and quantity. The ease with which it adapts itself to all zones from north to south in the wheat region, facilitates the isolation of subvarieties that are early or late forms which suit different climates and different soils. The following varieties merit, as plant breeding material, special attention: —

Ruso (*Triticum sativum*) L. var. *Ruso* Gir) semi-bearded, which is characterised by its adaptation, its resistance to diseases and to husking, its chemical composition, its productivity, etc. The *Italian* or *Lombard* wheat, bearded, early, good producer, specially suitable for early sowing in fertile soils, though inferior to the two preceding varieties in resistance to husking, should also be selected.

Among beardless wheats the *French* (*Triticum sativum* L var. *Frances* Gir.) is remarkable; it is soft, of excellent quality: among hard wheats preference will be given to *Candeal* (*Triticum durum* Desg. var. *Candeal* Gir.) which owing to the heterogeneity of forms which compose its populations lends itself to opportune selection by pure lines

Good results may be obtained by crossing *Candeal* with *Taganrok* (*Triticum durum* Desf. var. *Taganrok* Gir), the peculiar hardiness of which added to the good qualities of Candeal would doubtless increase the productivity.

Japanese wheat should not be overlooked as, on account of its great earliness, it might be used for the production of kinds suited to the southern regions (with short summer) and also to the northern provinces where late kinds are liable to scorch.

In the preliminary period, however, the work should be limited to a restricted number of varieties, taking as basis the hard wheats " *Barleta* " and " *Ruso* ".

For the complete and methodical realisation of the programme of plant genetics applied to agriculture a large central plant breeding Station is required situated so as to be able to command the greatest possible area under wheat, to ensure the maximum application of the results which may be obtained.

For this a locality should be chosen in the west or north-west of the Province of Buenos Aires, or else in the south or south-west at Santa Fé, or else in the south-east at Cordoba.

The Central Station should be assisted by sub-Stations suitably chosen and situated with regard to climatic and agro-geological conditions in each district.

The varieties of wheat, both Argentine and acclimatised, are increasingly confused and mixed, so that they now form very heterogeneous populations; the improvement in the quantity and the quality of the product which may certainly be expected from selection will largely compensate for the cost of installing the new service.

896 - **Plant Breeding at the Central Development Farm, Weraroa (New Zealand).** — BEVERLEY, L., in *The New Zealand Journal of Agriculture*, Vol XXII, No 5, pp 290-291, fig. 1. Wellington, May 20, 1921.

CLOVERS. — RUNCIMAN's red clover as the result of numerous tests may now be regarded as the only true perennial strain of red clover existing in New Zealand, and it should prove of very great value in the improvement of pastures in the Dominion.

In 1914, several selections, were made in the Auckland district, and further selections were made a year later at Moumahaki, an interesting collection of different types being secured. Recently one of these selections (B95) was isolated and is to be known in the future as "Weraroa white clover." It is distinguished by its active growth, good sized leaves and seed heads, and by its great yield and truly perennial character. This clover promises in a few years to become the standard white clover for New Zealand.

GRASSES. — The Moumahaki cocksfoot (*Dactylis glomerata*) is a pure line cocksfoot obtained locally and noted for its complete immunity to smut. Equally good results have been obtained with *Poa laxa.*

LUCERNE. — A yellow flowered selection of " Chermo " lucerne, characterised by the abundant production of under-ground stems has been given a trial. It has given every indication of great value as a grazing lucerne, but up to the present the form has not been properly fixed.

PEAS. — These experiments were made with a view to producing types of peas giving more than a pair of pods on a stem, i. e. triplet types. Successful results have been obtained with Weraroa Strategy and Weraroa Imperial. Work is proceding to tripletise field varieties such as Early Minto, Egyptian and Partridge.

Owing to the heavy winds in the spring at Weraroa, a pea which branches well at ground level is desirable. Numerous varieties were tested and Sutton's Late Green Marrow was undoubtedly the best, and was crossed in 1918 with a triplet pea. The most forward of these new types are now in the F_3 generation.

897 - **Inheritance of Length of Internode in the Rachis of Barley.**— HAYES, H. K., and, HARRY H. V., in *United States Department of Agriculture*, Bulletin No. 869, pp. 1-26 2 pl. Washington, September 1920.

A series of experiments on the inheritance of the length of the internode in the rachis (density) of barley was undertaken in 1915, in collaboration with the Minnesota Agricultural Station. This character is well suited for such researches for the following reasons:

1) In a pure line, it varies within very small limits;

2) Many varieties present a scale of values as regards length of internode.

The pure varieties examined had three degrees of density, which are also used by systematic botanists in describing 6-rowed barleys (loose, compact and very compact).

Hordeum vulgare pallidum (6-rowed, hairy, awned, white).
Sub-variety *typicum*, lax ear, pure Mandchuria line.
» *parallelum*, compact ear, pure Reid Triumph line.
» *pyramidatum* very compact ear, pure Pyramidatum line.

Hordeum distichon palmella (2-rowed, hairy, awned).
Sub-variety *nutans*, lax ear, pure Hanna and Steigum lines.
» *erectum*, compact ear, pure Svanhals line.
» *zeocriton*, very compact ear, pure Zeocriton line.

Many crosses were effected with these pure lines.

F_1 *Generation.* — Mandchuria (360) × Svanhals (458). The average density in the case of Mandchuria is 3.34 ± 0.01 and in that of Svanhals 2.53 ± 0.01; in the hybrid however we find 2.70 ± 0.01 with the almost complete dominance of the compact over the loose ear.

Pyramidatum (476) × Jet (454); the density of the former being 2.11 ± 0.01, and that of the latter 3.92 ± 0.01, the density of the F_1, was 2.86 ± 0.01. Unlike the preceding case, there were thus some almost intermediate forms (= 3.01).

F_2 *Generation.* — In the second generation the number of plants studied was rather small; it was, however, possible to state that the F_2 hybrids showed much greater variability than the F_1 individuals or their parents.

Thus the coefficient of variability for the F_1 of Mandchuria (360) × Svalhals (458) was 6.30 ± 0.30 whereas in the case of the F_2, this coefficient was 10.20 ± 0.27 (in 1916) and 11.82 ± 0.48 (in 1918.

Though the maximum variation of Pyramidatum (476) was $6.16 \pm 0\ 21$

and that of Jet (454) 6.93 ± 0.39 mm., the maximum variation of the F_2 resulting from Pyramidatum × Jet was 16.44 ± 0.52 in 1916, and 18.38 ± 0.81 in 1918.

F_3 *and* F_4 *Generation.* — In the third generation, the phenomena of segregation show themselves, and groups of descendants appear, which have the same variability as their parents if the line is pure. The careful investigation of the abundant F_4 material proved the purity of some of these F_3 lines. From the cross Mandchuria (360) × Svanhals (458) 32 F_3 lines were bred, which represented all the degrees of density found in the F_2. Five of these lines, or types, transmitted their characters unaltered to the F_4, which proves their homozygous nature. For these 5 types, the values of the average density are as follows:

378 — 1 average density = 2 57 ± 0 01 mm.
378 — 11 » » = 2 64 ∓ 0.01 »
378 — 14 » » = 3.37 ± 0.02 »
378 — 23 » » = 2.55 ± 0.01 »
378 — 31 » » = 2.58 ± 0.01 »

The 378-88 selection gave the highest coefficient in the F_3; 2 fine ears were bred to the F_4, and produced progeny with a density near that of the Mandchuria parent.

Similar cases were met with in the Pyramidatum × Jet progeny; the extracted homozygotes always having densities similar to those of their parents, no intermediate values occurring.

From the crosses Hanna × Reid Triumph, and Hanna × Zeocriton, in the F_3 and F_4 homozygous individuals were obtained having a density intermediate between that of their two parents, and pure homozygotes with a density near the density of their parents.

Analysis of results. — The appearance in the F_3 and F_4 of individuals that were homozygous as regards density, justifies the belief that even the character of the length of the internode in the rachis of barley is governed by genetic factors.

It is not easy to determine the number of factors involved, but from the behaviour of Mandchuria × Svanhals, and of Piramidatum × Jet, it would appear that there is only one.

On the other hand, the results obtained with Hanna × Reid Triumph would seem to show that 2 factors with cumulative effect are at work, their simultaneous presence giving rise to extrinsic types, and extreme values. If either factor is wanting, intermediate values result.

From Hanna × Zeocriton were obtained homozygotes similar to their parents, and 2 homozygotes of distinct intermediate values. The phenomenon can be explained by the existence of 3 independent genetic factors of which each is allelomorphic as regards its absence.

898 - **Observations and Researches on the Sugar Beet.** — MUNERATI, O., in the *Memorie della Reale Accademia dei Lincei*, Serie V Vol. XIII, Part. V, pp. 175-322, 12 Pl., figs. 7 and 274 bibliographic quotations (Bibliography up to the end of 1919). Rome, 1920.

The author considers the problem of improving the sugar beet in the conditions surrounding it in southern countries; this environment is known to be very different, from an ecologic stand point, from that in which the sugar beet was originally improved. For this investigation the Italian Government founded in 1910, a special experiment Station at Rovigo, in the centre of the region in Italy where beet cultivation is most intense. Besides the large resources which the Government has given to it, the Station receives contributions from manufacturers

As the subject, considered both broadly and in detail, is necessarily connected with subordinate and collateral problems, the author investigates, together with fundamental questions, others which depend indirectly on the former and which more or less elucidate them.

The memoir is divided into 12 chapters.

CHAP. I. — PRELIMINARY PART. — After having pointed out that the sugar beet has not yet been thoroughly studied from a genetic standpoint (the bibliography on this subject is fragmentary and uncertain; the species has, in fact, been studied rather from a chemical than from a biological standpoint), and after having considered the direct and indirect difficulties to overcome in the choice of material for selection, the author puts forward several questions. Should the choice of parent plants be made where the beets are generally richest? Is the crop more assured in southern countries when seed from the north is used? And, on the other hand, do the high power of germination and the remarkable initial vigour of young plants raised from seed of southern countries constitute sufficient qualities for the seed of the south to be preferred to that of northern countries? Are there real differences in the hereditary attributes of commercial varieties of sugar beet?

With regard to the first question, perhaps the most important from a practical point of view, the author remarks that selectors have always had a strong tendency to concentrate the choice of parents in regions which have the finest beets. Thus in Central Europe most firms which are engaged in selection have preferred the regions where the beets contain the greatest percentage of sugar, such as Saxony, Anhalt, the plains of Bohemia on the Prague side, etc Perhaps one of the reasons why French selectors have had no luck, even in France, is to be found in the prejudice and distrust, both of sugar manufacturers and growers who sell by density, against seed collected from beets such as they are in France, always poorer than those of Central Europe. The author naturally places the problem in the long list of those attaching to the *vexata quaestio* of the heredity of acquired characters. Can a modification produced by environment be transmitted? In this special case, can the capacity of a beet to accumulate more or less sugar in its root, in consequence of the special conditions of environment in which the plant happens to grow, become a hereditary attribute? Can the environment, by a cumulative process through a succession of a greater or smaller number of generations, determine the formation of new genetic factors, or at least, modify pre-existing factors? Or else, can the stimulus of certain external conditions give rise to new forms (mutations), which the selector can thus obtain? Now, up to the present, the support of experimental researches instituted purposely to reply to these questions has been wanting; it must even be added that a perfect experiment of this kind is not easily made, inasmuch as it would be extremely difficult to estimate all limiting factors and to define every possible cause of error, even admitting that a pure type has been taken as a starting point — which is not easy to prove.

Regarding change of seed, can it be said that it has been proved experimentally that the use, in a given region, of a seed produced under different climatic conditions can act as stimulant on the said seed? Certainly the " degeneration " of types and the declared necessity for changing seeds generally have been much exaggerated, and, in any case, the attribution to change of climate of certain presumed modifications of form and colour of the roots, tendency to bifurcation, etc., facts only attributable to phenomena of false adaptation or of proximity, must be excluded absolutely. But on the other hand there is equal exaggeration when the qualities of seeds obtained in southern countries are extolled for their strong germinative power; it is in this case an attribute that is agronomic or environmental rather than genetic.

Lastly the author is inclined to admit an equivalence among the " varieties " of sugar beets, which, instead of being so designated, ought to be called " trade brands ".

CHAP. II. — STUDY OF CORRELATIVE VARIABILITIES. — The subject necessarily attracted from the commencement, the whole attention of the experimenter. Observations were made on: — The appearance and aspect of the foliage; the foliage as a quantitative whole; the tendency of beets to grow out of the ground; the length and other external characters of the roots; the sugar content relative to the weight, etc. As most of the study undertaken in this respect in regions where beet is grown in the northern countries, cannot serve as a guide to experimenters in southern countries, it is concluded that, except in very special cases, the selector seeks in vain to find means of guidance from the biometric examination of the material which he possesses. On the other hand, the study of numerous correlative variabilities, which might be a real help if the choice of beets was made exclusively according to external characters ceases to have any practical value from the moment when, by a polarimetric determination, the domain of conjecture is left and support is given by the solid ground of figures.

CHAP III. — THE SUGAR BEET IN ITS RELATIONSHIP TO THE ITALIAN CLIMATE. — After having dealt at some length with the more important contributions to the question by previous investigators, and especially by H. W. WILEY in the United States, the author considers the Italian centres that are most characteristic from a climatologic standpoint and dwells on the most difficult problem of the growth of beet in southern countries, which is the phenomenon of retrogression.

If retrogression, he concludes, is chiefly the expression of a problem of distribution of rainfall or of economy of water, other causes may act at the same time cumulatively or independently; loss of sugar in beets is always connected with renewal of growth after summer and autumn rains; the reserve of sugar in the roots can also decrease without the intervention of rain and consequently without the necessity of the phenomenon of a sudden renewal of vegetation. "It will certainly be possible, by the help of intelligent expedients, to diminish the consequences of a rapid retrogression, industrially intolerable, and it is also not altogether improbable that types may be found in which the tendency is found in a slighter degree; but until the contrary is proved, the lowering of the percentages is considered, under the climatic conditions that hold in the valley of the Po, as absolutely inevitable."

As the biologist tends to adapt given races to fixed conditions of environment, the author asks himself whether, in research work on local races, the selector does not find himself sometimes in the presence of factors so stubborn as to render his work extremely difficult. For example can the principle of the wide expansion of the leaves (universally accepted as a basis of selection) be rigorously applied in climates where high temperatures, scarce rainfall and strong sunshine cause the leaf system to transpire enormously? And cannot a race whose above-ground system is reduced, present in its turn other serious drawbacks? Further, considering that in the region in question the sugar seasons run from August to September and not towards the end of the autumn, the author has been led to adopt as an indication in the choice of material for selection the method of analysis of the parent plants in August-Septemher, whereas for the preservation of the selected beets until the following spring, the method adopted is that of replanting in the ground, where the beets very soon take root and put forth new and abundant foliage.

CHAP. IV. — SHOULD *Beta vulgaris* BE INCLUDED AMONG PLANTS WHICH ARE INCAPABLE OF SELF FERTILISATION? — The author remarks, firstly, that until recent years no-one had raised doubts on this question (DARWIN, for example, who however included *Beta vulgais* among those plants that were more vigorous when cross-fertilised, not only did not include the species among those which are incapable of self fertilisation, but even declared it to be very self fertile). The author then discusses the thesis put forward in 1916 by H. B. SHAW, according to which there is in the beet an almost absolute self-incompatibility; and after having quoted a number of his observations on the subject, before and after 1915, he concludes by stating that if SHAW's assertion is not completely acceptable, it nevertheless deserves the greatest consideration. However this may be, fresh research is required to clear up several points which still remain obscure.

CHAP. V. — ON DEGENERATION DUE TO INBREEDING (INZUCHT). — This is one of the most largely developed chapters.

The author first quotes the opinion of those who have previously dealt with the question (C. DARWIN, 1876; W. BARTOS, 1897; E. LAURENT, 1902; H. BRIEM, 1904; K. ANDRLIK and his collaborators, 1908-1909; H. VOGELSANG, 1895-1907; H. METTE, 1908; SESSOUX, 1909; G. FRÖLICH, 1911; H. CRON, 1912; B. KAJANUS, 1913; TRITSCHLER, 1913-1915; E. SCHRIBAUX, 1915; E. BAUR, 1919; M. GAILLOT, 1919). Then he correlates the supposed or real degeneration due to self-fertilisation in the beet with the real or supposed degeneration in other plants (maize, rye, etc.) and with the degeneration due to inbreeding in animals. The author wished to approach the question by following the greatest possible number of descendants derived from isolated individuals. In a single year (1913), 1300 beets were placed under isolators, and 1850 in 1915. With so considerable a number of descendants it was logical to expect very large and very complex returns. Among other things, the experimentor denies absolutely the appearence among the descendants of white sugar beets of plants with coloured skin and pulp; every time that such plants appeared they were only the result of an unsuspected cross with the pollen of ordinary beets fructifying more or less distantly, which is easy to prove experimentally. However, the process of self fertilisation entails the weakening or decrease of vigour of the descendants (degeneration in the Darwinian sense); the fresh vigour infused into the degenerated type by intercrossing between different descendants returns then to the ordinary phenomena of heretosis (stimulation by heterozygosis).

No biologist nor anyone who had dealt with genetics had recorded, up to the present, specific observations on beet; this seems strange when one considers that vigour appears in hybrids with a not unusual frequency. The phenomenon is much more apparent and much more remarkable when the produce of the first generation comes from a cross between a cultivated beet and a wild plant.

CHAP. VI. — THE SUGAR BEET AND THE PROBLEM OF SELECTION. — The progress made since the time when MARGGRAF's first analyses indicated a content of 5 % of sugar is scarcely believable. In fact if numerous data since the time of MARGGRAF and ACHARD up to the present are co-ordinated, graphs can be made which brilliantly demonstrate cumulative action in the direction of selection itself for the partisans of the efficacy of selection, and that with the simultaneous movements of whole groups according to GOLDSCHMIDT's scheme. Unless this question should here be asked: — Has selection itself caused the *change in act* of one or several hereditary units, or has it *simply isolated* or brought out pre-existing attributes?

It must be remembered that, from 1811 onwards, ACHARD recorded beets containing 18 % of sugar and that in 1856 VILMORIN recorded specimens with 21 %. Now, if at that time much more rapid methods of individual analysis had been employed, so that some tens of thousands of roots might have been examined in place of some hundreds, would not beets have been found with still higher percentages? If since the beginning of the past century the present system of individual selection and of purifying races had been known, could the jump of averages towards the highest content have been immediate or nearly so? The question has a great analogy with that raised regarding SMITH's work of selection on maize and CASTLE's on *Mus rattus*.

However this may be, everyone is now agreed that the sugar beet has at present reached a degree of perfection which allows it to be included in the category of pure or fixed races, for which individual selection cannot have the importance and the scope which it had when an impure race or a disordered mixture of types was treated. " To invoke, meanwhile, the prodigious success obtained and recorded by Louis Vilmorin in order to praise, as certain writers still do, the virtues of genealogical selection, is to enunciate a problem without understanding the significance and the scope of the values on which an opinion is to be expressed. But if, nevertheless, to follow the descendants of each individual means the possibility of discovering by chance eventual inmost tendencies to deviations from type, and consequently to improve even simple micromutations, this principle always remains the sole weapon which the selector can use. "

The author next deals with the problem of the " sudden degradation " and the " return to the primitive type " of the beet in the absence of selection. After having quoted the opinion of several writers who have studied the question (de Vries, Blaringhem, Costantin, Harris, Pritchard, Saillard, etc.) and determined the sugar-producing faculty of the beet, the author remarks that if selection has simply acted, as is probable, in bringing about the gradual elimination, from the original mixture, of types of less value (" selection by elimination "), the selector has separated one from another, by means of chemical processes, the components of a hybrid and consequently has unconsciously practised mendelism before Mendel himself. If this is so, to speak of " return to the primitive form " would be nonsense. Lastly, the author propounds the terms of the problem of selection relatively to the environment in which he must work, and the observations he has made lead him to admit above all the necessity of following the descendants of the greatest possible number of subjects (over 5000 direct or collateral descendants were followed from 1912 to 1919). Then he draws attention to a new method to which he had recourse with the object of purifying races that were decidedly heterogenous and feebly self-fertile ; it related to the fructification by pairs of subjects derived from the same parent plant presenting similar morphological characters and chemical attributes. The results obtained were interesting and it was possible to separate forms, detached from type that were specially recessive and deviating.

Chap. VII-XII. — Technical conclusions and researches — For a preliminary summary estimation of the beets of each descendant, the experimentor has used, for many years, utilising working on several tens of thousands of roots, the method of immersing the beets in solutions of sodium chloride. This system, as is known, was abandoned by selectors when the processes of direct determination of the sugar was introduced and became general (1860-1865) ; but if the method is in reality insufficient and empirical, it ought still to be considered valuable and reasonable when it is supplemented by the determination of saccharose, by the polarimeter. But the use of the refractometer, by which the density of the juice can be determined with a very small quantity of pulp (a few decigrams), deprives the system of immersion in sugar or saline solution of a great deal of its scope in application.

The problem of preserving the parent beets during the winter has also attracted the attention of the author, in view of the fact that during winters in the region very heavy losses (up to 90 %) had been recorded for beets kept in ordinary silos. After a series of comparative tests, a process was discovered which enabled 95 % of the roots to be saved up to the time of replanting in spring. Regarding the survival of beets at low temperatures, the author has not yet arrived at any exact conclusion, and it has not been possible to confirm W. BARTOS' statement, namely that beets whose young leaves have reddish petioles are more resistant than those whose central leaves have no trace of anthocyanin.

The author next describes a type of isolator which he adopted and in which the fabric portion is replaced by a sheet of glass which enables the beets to profit by sufficient direct rays during the whole period of isolation; this caused an improvement in the glomerules. Regarding cellular isolation ("Häuschen-Isolierung"), the author is in complete agreement with H. B. SHAW and admits that this means does not prevent contamination with external pollen (special experiments undertaken since 1913, in which coloured and uncoloured plants were obtained, prove this clearly); but as the objects which are interesting to follow are chiefly to separate, even roughly, the descendants and to follow the greatest possible number, the method of cellular isolation, carried out opportunely, retains its full value.

A short final chapter deals with the question of shortening the vegetative period (method of the *Wintersteckling*e) in accordance with the directive ideas of G. RATH (1911).

899 - **White Sugar Mangold Selection at the Ruakura Farm of Instruction, New Zealand.** — GREEN, A. W., in *The New Zealand Journal of Agriculture*, Vol. XXII, No. 5, p. 289, fig. 1. Wellington, May 20, 1921.

The selection of white sugar mangold, commenced by W. S. HILL at Moumahaki several years ago, has been continued without interruption, and an excellent crop of this strain was secured at Ruakura last year, the yield being over 73 tons per acre. A further selection of 100 roots has since been made, and 25 lb. of seed has been harvested.

During the farm school held at Ruakura last July (1920) the visiting farmers were much impressed by the weight and quality of this crop and sacks of selected mangolds were distributed to 27 of them for seed production on their own farms.

900 - **Study of Bud variations in the Eureka Lemon With a View to Citrus-Fruit Improvemente in California.** — SHAMEL A. D., SCOTT, L. B., POMEROY, C. S. and DYER C. L. in *United States Department of Agriculture, Bulletin No.* 813, pp. 1-88 figs. 22. Washington D. C. June 25, 1920.

OBJECT OF INVESTIGATIONS. — To determine the frequency and importance of bud variations in lemon trees of the Eureka variety; to ascertain the commercial value of the various strains originating from bud variations; to discover methods for isolating the best and eliminating the inferior strains through bud selection; to introduce and establish a system of individual tree records with the idea of obtaining reliable supplies of material for propagation purposes or improvement of orchards.

INDIVIDUAL TREE RECORDS. — For each tree: 1) Number; consisting of 3 parts corresponding to the block in which the tree occurs, the number of rows, and the number of trees in the row; 2) Picking; fruit were picked when reaching a certain fixed size, as determined with the aid of special metal rings; 3) Assorting; fruit at each picking were classed in 3 grades: *a*) Green, in which both the light and dark green fruits were included; of commercial value; *b*) Tree-ripe, usually small with thin rinds, an abundance of juice lacking in acidity; *c*) Cull, extremely coarse, and malformed rendering them unfit for the market.

For each grade one fruit was selected and examined to count the seeds and note the characteristics. All the data are registered on special forms for recording the weight and number of the fruit. These forms serve as a register with reference to yield. Other special records are kept with regard to the total annual yield.

NEW VARIETIES ARISING FROM BUD VARIATIONS — Descriptions are given of new strains arising from bud variations.

1) *Eureka Strain* (Open-Productive strain, name adopted because of the habit of growth and the heavy production). — Production is continued and regular throughout the year and thus of commercial value; leaves rounded or elliptical and distinctly contrasting with the sharply pointed ones of some other other strains; fruits oblong in shape, medium in size, thin rind, abundance of juice, solid, with about 7 seeds.

2) *Small-open Strain.* — Fruits more nearly globular and smaller.

3) *Shade-tree Strain.* — Thus named owing to its spreading habit of growth with luxuriant foliage, very pointed, which at certain seasons when there is a scarcity of fruits give them an aspect of ornamental trees. The main crop is borne during the autumn and winter. Fruits are oblong, rind very thick, pulp coarse and juice not abundant. Another characteristic of this strain is the large number of imperfect flowers produced with pistils rudimentary or absent, pollen scarce or with low vitality, etc.

The production and quality of the fruit of *Shade-tree* is very much less than those of Eureka On the average 25 % of these trees were found in the orchards.

4) *Dense-Unproductive Strain.* — Inferior as regards quantity and quality of fruits produced. In some ways they resemble the trees of the preceding strain; vigorous vegetative development; imperfect flowers, etc. It is distinguished by its erect and dense habit of growth and by its smaller size.

5) *Pear Shape Strain.* — Characteristics similar to *Eureka* but distinguished by the shape of the fruits which render them of inferior commercial value. The trees are finely branched and abundant presenting a bush like shape; the leaves are small and ovate in shape.

6) *Dense-productive Strain* — Differs from Eureka mainly in habit of growth, branches and density of foliage, and the fruits are largely covered by the protecting foliage and are thus less likely to suffer from climatic

injury or sunburn. This condition makes up in part for the somewhat lower production of the trees of this strain. The fruits are oblong, medium in size, pulp tender, juice abundant and very acid.

7) *Variegated Strain.* — The bark is variegated with stripes of green and straw colour; the leaves are almost entirely green or white, or white and green intermingled; the fruits have also a striped appearance, alternate green and white areas. This variegation combined with the rough texture of the fruits and thin rinds which are liable to split, makes them of inferior commercial value. Certain growers use the trees for ornamental purposes.

8) *Sporting Strain.* — These plants are interesting from the point of view of their multiple and simultaneous bud variations, which produce typical fruits of all the strains under observation and other new types.

Ridged and protruding .									

This strain is very undesirable, not only owing to the mixture of fruits, but also from the danger of trees being used as sources of budwood.

A certain number of individual trees belonging to each of these strains were under special observation for a 6-year period: July 1911 to June 1917.

A detailed statement relative to this period is reported in special tables with reference monthly to the number and weight of fruits belonging to the various categories: *a*) Green; *b*) Tree-ripe; *c*) Cull.

The foregoing table shows the trees of the Eureka strain not only to be of superior quality but also more productive; this is the only strain of real commercial value.

Thus, the selection *ad lib.* of parent trees as sources of bud wood either from vegetative strains, or from the largest trees with the idea that the size of the tree was correlated with production, or yet again from sucker bud wood, all contributed to the diminution in commercial value of the orchards. On the contrary, bud wood and parent trees should both be selected from strains with typical fruits and the danger of propagating the undesirable strains will thus be largely eliminated. Only fruit-bearing bud wood from superior plant trees selected on the basis of their individual production records should be used for propagation or top-working. Table II refers to the average annual crop of several of the important strains.

TABLE II. — *Average annual production per tree during period* 1911-1917.

Number of Trees	Description of trees	Average annual production per tree							
		Total crop		Green grade		Tree-ripe grade		Cull grade	
		Weight lb.	Number	Weight lb.	Number	Weight lb.	Number	Weight lb.	Number
10	Highest producing (all Eureka strain)	299.45	1341	201.71	754	63.83	292	33.92	295
76	Eureka	230.03	1051	144.63	541	57.20	263	28.20	247
2	Dense productive	217.55	980	155.67	576	39.85	183	22.03	220
20	Small Open	179.86	808	119.07	445	41.43	188	19.36	174

10	Lowest producing (irrespective of strain)	89.44	379	68.46	250	13.48	60	7.50	68

901 - **Bud Variations in the Lisbon Lemon and their Importance from the Propagation Standpoint.** — SHAMEL, A. D., SCOTT, L. B., POMEROY, C. S., and DYER, C. L., in *United States, Department of Agriculture, Bulletin* No. 815, pp. 1-70, figs. 14. Washington, D. C., June, 1921.

The same general methods of keeping records in the studies of the Lisbon variety were followed as those governing work with the Eureka lemon. The article in question gives a description of the following distinct strains:

1) Lisbon (standard); 2) Open, named according to habit of growth

3) Dense unproductive; 4) Bull; vigorous vegetative growth with large sharply pointed leaves, coarse fruits with thick rinds and little juice; 5) Variegated; 6) Sporting.

Only the first two strains are of commercial value, and should therefore be worked for propagation purposes and for top working and the reestablishment of orchards.

902 - **International Congress for the Control of Seeds.** — See No. 883 of this *Review*.

903 - **Varieties of Oats and Barley which have given the Best Results in Iceland.** See No. 881 of this *Review*.

904 - **Spur Feterita a New and Distinct Variety with Superior Grain Producing Qualities in Texas, U. S.** — CONNER, A. B., and DICKSON R. E., in *Texas Agricultural Experiment Station, Agricultural and Mechanical College of Texas. Division of Agronomy, Bulletin* No. 275, pp. 1-28, figs. 14, Tables 11, Brazos County, Texas, Feb. 1921.

Spur feterita is the name given to a new and distinct variety of grain sorghum developed by plant breeding work by the Texas Agricultural Experiment Station at Sub-station No. 7, Spur, Texas. The unimproved feterita commonly grown, and introduced into the United States from Sudan in 1909 has proved its worth as a forage plant, but the new variety under discussion possesses a stem with a diameter 27 % larger than that of the former and is less liable to lodging and stands well in the field, even after ripening. It is about 1 ft. less tall than the unimproved feterita, but is somewhat taller than milo or even kafir. The seed head is compact, and well filled with seed at the base giving in 1919 as an average % grain per head 76.68 % compared wth 72.62 unimproved variety; 74.29 kafir and 76.38 milo.

Although the growing season required varies with the time of planting, the average time required for Spur feterita is about 1 week more than for unimproved feterita and 3 days more than for milo. The average length of the growing period in 1919 is recorded as 97.

A series of plantings of Spur feterita, unimproved feterita, milo and kafir were made for the purpose of determining the relative grain yields of these 4 crops. The results from each of the 8 different plantings together with the average results in grain yield are shown in the following table.

Yield of threshed grain in bushels per acre 1919.

Variety name	April 15	May 3	May 15	June 2	June 16	July 2	July 15	Aug. 1	Average
Spur Feterita . .	66.44	63.94	68.00	71.72	49.39	41.59	22.13	14.93	**50.14**
Unimproved Feterita	60.48	57.18	61.77	58.85	56.85	39.95	21.10	8.29	**45.55**
Milo.	55.18	49.23	40.26	37.82	33.11	25.35	23.48	—	**33.05**
Kafir	51.02	45.60	37.02	35.26	33.95	31.06	—	—	**29.28**

Spur feterita has been grown in a comparative way with unimproved feterita at different Substations and the former was found to produce yields superior in quantity to the latter by approximately:— 8 bus. per acre at Spur, 2 3/4 bus. at Lubbock, and 1 1/4 bus. at Temple.

The results at Spur, Texas, are shown as follows:

Table II — *Yield in bushels per acre — General tests.*

	1916	1917	1918 *	1919	1920	Average
Spur Feterita . . .	31.52	22 39	—	50.14	49 29	**30.67**
Unimproved feterita.	21 84	14 32	—	45 55	31 18	**22.78**

* Crop failure on account of extreme drought

In the appendix, tables are given showing the monthly distribution of rainfall for the years referred to in the bulletin at Spur, Lubbock and Temple.

905 – **Treatment of Potato Sets and Arguments For and Against Cutting and Planting Whole.** — I. Cooley, E. W., (Agricultural Extension Dept. International Harvester Co. U. S. A. To Cut or Not to Cut Seed Potatoes in *The Potato Magazine*, Vol 3, No. 11, pp. 8-9, figs. 3, Mount Morris Illinois. May 1921. — II. Schribaux, E, Expériences a entreprendre sur la fragmentation des plants de pomme de terre in *Comptes rendus des Séances de l'Académie d'Agriculture de France*, Vol. 7, No. 4, Paris, Jan 26, 1921. — III. Taylor, W. H., Treatment of Potato Sets in New Zealand in *The New Zealand Journal of Agriculture*, Vol. XXII, No. 4, pp. 227-228. Wellington. April 20, 1921. — IV. Tice C., The Potato in British Columbia Whole versus Cut seed in *Department of Agriculture, Soils and Crop Division, Province of British Columbia, Bulletin* No. 86, pp 24-27, Victoria B. C. 1921.

Some growers declare that seed potatoes should be cut lengthways so that each piece will contain a part of the seed end of the potato, confident in the fact that the seed end sprouts sooner than the stem end or any other part of the potato and that the sprouts will be stronger and the yield larger. Others assert that the seed end should be cut off and thrown away as they consider that instead of sending out one or more strong vigorous shoots, the seed end will produce a number of small, weak ones Then again, some of the most successful potato growers plant nothing but the whole potatoes (I). Experiments made in various countries are therefore well worth consideration in order to come to some more definite conclusion as to the best method to adopt.

I. — In the United States as a result of observation and experiments conducted in Maryland, Michigan, Colorado, etc. it was concluded that most of the eyes on a potato have equal value for seed proposes, and at Michigan Agricultural College Farm it was demonstrated that the stem end piece bore as vigorous sprouts when separated from the seed ends as the seed ends themselves, and when all other conditions were equal, the individual hill yields were also approximately the same. While it is true that the size of the seed piece is more important than the number of eyes, the experiments seemed to indicate that each seed piece should contain at last 2 eyes

A number of seed potatoes from high yielding hills were cut so as to give pieces of approximately the same weight but with varying numbers of eyes Twenty one pieces containing 1 eye per piece showed 61 % germination: 4 pieces with 1½ eyes per piece showed 75 %, 20 pieces with 2 eyes per piece, 4 with 2½ eyes per piece and 7 with 3 eyes per piece, showed 100 % germination The average quantity of cut potatoes used amounted to 10 bushels per acre, but experiments conducted on 360 farms in the State of New York showed that the yield was from 85 to 100 bus more per acre when 18 bus. of seed were planted than when 10 bus were used.

II. — M SCHRIBAUX draws attention to the evident disadvantages connected with cutting sets, and then proceeds to indicate the advisable methods to adopt in order to compare the growth and yield to be obtained from cutting or planting whole, in consideration of the fact that at the Académie d'Agriculture d'Angers, information has been received recommending the cutting method both from the economical standpoint and as regards yield.

As regards the disadvantages, emphasis is laid on the fact that certain varieties (e g Richters' Imperator) when cut, are liable to rot This is, however, an exception and there is no reason to exaggerate the physiological dangers attached to cutting which can to a large extent be lessened and even eliminated. Care should be taken to plant only sets which have been exposed to the air for several days. Secondly, extra labour is involved in the cutting process. There is also a risk of waste through drying which applies also to the period following planting, as cut sets are less resistant to drought, defective cultural operations, etc than whole sets. Even under favourable conditions, success is at present uncertain and the author considers that this is due to the lack of knowledge concerning *a*) the advisable average weight of the cut sets; *b*) the best system of planting to employ.

The author suggests the following plan and but considers that unless the greatest care is taken to observe the details, it should not be attempted, seeing that it is the relative and not the absolute yield which it is desired to determine.

Whole sets		Cut sets					
Distance apart	Number of plants per sq yd	*Small* about 3½ oz, each with 2 eyes		*Medium* about 7 oz		*Large* about 1 oz	
		Distance apart	No of plants per sq yd	Distance apart	No of plants per sq yd	Distance apart	No of plants per sq yd
cm		cm		cm		cm	
50×40	5	50×14	14	50×20	10	50×25	8
50×50	4	50×18	12	50×30	7	50×33	6
50×60	3	50×25	8	50×40	5	50×50	4

[965]

The cutting of small sets above recommended is the method adopted with success by M. Maisonneuve at Angers, who after having removed a good third of the tuber where there are few eyes, cuts the remainder into 6 or 8 parts according to the number of eyes. As regards the large sets, M Schribaux recommends a similar removal of the lower inferior part of the tuber and cutting vertically the remainder into equal parts.

With reference to planting, the author remarks that the cut sets should be planted less deeply than the whole sets: about 3 to 4 cm. deep for the small, 4 to 5 cm. for the medium and 5 to 3 cm. for the large.

At harvest time, note should be made of the failures, the average number of shoots per plant, the yield per plot and per clump; the average weight of tubers and the proportion of large, medium and small. During these experiments, it is particularly important to note carefully all circumstances which tend to influence the quality of the yield in one way or another.

III. — In New Zealand, it has been proved by growers that potatoes may be roughly divided into two classes viz. round varieties on which the eyes are nearly all active at the same time, and kidney shaped (occasional rounds) that have a decided rounded end. If the former be planted with all the buds intact, a large proportion of them will grow into shoots The latter behave differently. One, two or three buds start before the others, and if nothing happens to destroy them they will produce a plant; the remaining eyes will remain dormant. If the tops of these shoots are injured by frost, they make fresh growth lower down. This naturally results in a reduction in the crop, but the latter may still be profitable. A second frost may occur which will entirely destroy the first tops. Other buds, that probably have already broken but not made much headway, then break through and may produce a crop just sufficient to pay costs. This explains why no disbudding is done. The seed tubers are not cut as that would cause decay, and the second set of buds would not be able to continue growth.

The common belief that all the eyes on a set will produce shoots, and that disbudding is necessary to prevent an overplus of shoots which would give small potatoes is, therefore, contradicted.

IV. — Experiments conducted in British Columbia support the claim made by M. Schribaux that in districts where the land is wet or poorly drained, whole potatoes are preferable to cut sets, since the latter rot easily. Also cut sets are more subject to disease, and sprout later. However, the percentage of marketable potatoes has been found in this case to be smaller when whole sets are planted than with cut sets.

When cut sets are used, a 2-oz. piece has been usually found the best. This statement is fully borne out in an experiment carried out by Dr. Zavitz at Guelph. Sets were planted for 5 years weighing $^1/_{16}$ oz, $^1/_8$ oz., $^1/_4$ oz., 1 oz., and 2 oz.; one eye was left in a piece and the pieces planted 1 ft. apart in the rows. There was a variation in yield from 47.5 bushels to 173 9 bus. for 2 oz., of seed Subtracting the amount of seed used, the former gave 46.2 bus. and the latter 132.7 bus. The system of cutting out the eyes of the set is not recommended, as the author considers there is not enough plant food present to support the young shoot till it develops a root. System two eyes to a set is usually conceded as giving better results than even 1 or 3 eyes. Where a larger number of eyes are present the percentage of marketable tubers is greatly reduced; this was found especially true when the seed-end of the potato was planted although the potatoes thus obtained were earlier.

906 - **Varieties of Oats and Barley which have given the Best Results in Iceland.** — See No. 881 of this *Review.*

907 - **Alfalfa Culture in Argentine.** — SCASSO J. M (Agricultural Enquirer and Specialist in Forage Plants, Buenos Aires), in *The New Zealand Journal of Agriculture*, Vol. XXII No. 4, pp 217-220. Wellington, April 20, 1921.

Alfalfa adapts itself readily to the soil and Argentine climate, and its cultivation is greater than that of any other crop, the actual area under cultivation amounting to 7 619 000 hectares. In the years of ordinary rainfall 4 cuttings are made per year of 7000 kg. per hectare per cut (approximately 2 $^3/_4$ tons per acre) making a total of 28 000 kg. per hectare. In the neighbourhood of the large cities, in the Andine provinces and territories of the south, where there are large installations for irrigation purposes, irrigation is much used in the culture of alfalfa, and in these cases naturally the returns are always greater, as much as 6 or 8 cuttings per year of 9000 kg. per hectare per cutting being obtained; i. e 54 000 to 72 000 kg per year per hectare

The production of alfalfa seed is one of the principal resources of commercial agriculture in the Argentine. It is calculated that the proportion of seed utilised annually for the new sowings amounts to 80 %, the other 20 % being the product of other countries, principally Italy, France and the United States. In the case of alfalfa under irrigation, the production of seed is about 600 kg. per hectare It has been proved that the existence of colonies of bees in proximity to the alfalfa fields has resulted in the returns of seed being increased by as much as from 30 to 40 %.

There is a notable variation in the duration of alfalfa fields according to the regions in which the plant is cultivated.

The average duration of the fields in good production is from 12 to 15 years, but there are areas in which alfalfa fields of 30 years standing yield good returns, especially those under irrigation as in the territory of Rio Negro, the province of St. John and other parts. In the provinces of Cordoba (South) and St. Louis, the territory of La Pampa, etc. there are alfalfa fields not under irrigation which have existed for more than 25 years and these still produce abundant crops. This may be explained by the fact that the deep rooted system of the plant utilises the water that flows many metres deep in the soil.

The author gives details of the preparation of the land, methods of sowing and cultivation generally, and of the utility of alfalfa for pasture, hay making and ensilage. The use of fertilisers is not practised, neither is the use of inoculated soils and lime, found to be a necessary proceeding in Argentina, owing to the fact that the physo-chemical composition of the soils allows the normal development of alfalfa.

908 - **Cotton Growing in Natal: Records of Recent Trials.** — WILSON, W. B., in *The Farmer's Weekly*, Vol. XXI, No. 533, pp. 1178-1179, figs. 3. Bloemfontein, May 25, 1920.

In 1914, the Tobacco and Cotton Division of the Union Government set up an office for Natal to conduct co-operative experiments with the farmers and to study the conditions and means of re-introducing cotton growing with a view to establishing the industry on a permanent basis.

During the season 1914-15, 9 varieties of Upland cotton seed, amounting to 446 lb. were distributed to 21 experimental stations, situated chiefly in the New Hanover and Richmond districts of Natal and parts of Zululand. During the second season much better results were produced than in the first and in Weenen and Zululand the crops were very promising.

The results at the first mentioned place showed a yield of 960 lb of seed-cotton per acre, for the "King" var, and 718 lb. per acre for "Cleveland". As this was a very dry season, this establishes the drought resistant properties of these two types.

The following year the same growers planted an area of 46 ½ acres which gave an average yield of 1212 lb. per acre, and a proportionately larger profit was made over an increased acreage. Other growers at Amatikuha, Zululand, showed similar results both as regards increased acreage and price.

Over the whole of Natal, the increased production during recent years as shown by the official statistics and the Cotton Grower's Association, are as follows: 1915, 1110 lb., 1916, 4890 lb., 1917, 23 604 lb., 1918, 396 bales of approximately 250 lb. each; 1919, 843 bales, and 1920, 1418 bales (both of approximately 480 lb. each).

It is evident, therefore, that very rapid strides have been made the last few years. The really serious question affecting the cotton position is probably that of marketing the crop. In 1915 and 1916 the Government had control of the marketing, pooling the entire crop according to its respective grades and selling most of it overseas, distributing the money among the growers after the receipt of the account of sales. This resulted naturally in a very heavy delay before the grower received the amount due for his crop, but in the absence of local buyers, there was no other course open.

In 1917, the crop began to assume commercial proportions and the Government made other arrangements as regards ginning facilities, but the question of uniformity of staple demanded by the market, the best seed for planting, and how the grower is to be paid for the crop are still important questions which still remain to be determined.

As regards uniformity of staple, different varieties have been planted side by side for the purpose of testing the suitability of the respective varieties to South African conditions: the crops from these plots were ginned on the same machines. This resulted in cross fertilisation and mixing of seeds until uniformity of staple was very much lacking — a serious defect from the spinner's point of view. Also, the relatively heavy yields from the shorter staple varieties was an inducement to growers to plant these to a large extent, in spite of the fact that long staple is more in demand. The percentage of different length staple of the 1920 crop of cotton may be stated as follows:— full staple, 1 $^1/_8$ in., 39 %; medium staple, $^{15}/_{16}$ in. to 1 $^1/_{16}$ in., 32.28 %; short staple, $^7/_8$ in. or under, 28.12 %.

On account of lack of uniformity of staple and the large proportion of short fibres, the S. African cotton is at present very much in disfavour. This difficulty is, however, by no means insuperable, as has been shown in Uganda where a similar position prevailed in 1908. The Government there took into its own hands the matter of seed selection and distribution and as a consequence, Uganda cotton is now highly prized by spinners and commands an excellent price.

Up till now very little attention has been given to seed selection by Natal growers, but the Cotton Growers' Association intend if possible to obtain the support of the Government to establish a farm for the production and distribution of seed for the benefit of the industry.

Summing up the facts relative to cotton growing in Natal, the author states: — 1) that long-stapled American Upland varieties have proved to be the most suitable for the conditions while all attempts at ratooning or growing the cotton as a perennial, irrespective of the variety or class of cotton, have resulted in failure; 2) the cotton does best on the rich soils of the low hot valleys, and the best soils of the coastal belt, but not too near the sea and in exposed positions.

It has been proved conclusively that Natal cotton of good quality can be produced, but that satisfactory results are not to be obtained without careful and persistent labour. The industry can now be made permanent if studied closely and built up firmly step by step

909 – **Discovery of a Wild Cotton, *Bassia lanuginosa*, n. sp. in Western Queensland.**—White, C T (Government Botanist, in *Queensland Agricultural Journal*, Vol. XV, No 5, pp. 216-218, pl. 1. Brisbane, May, 1921.

Specimens of a wild cotton plant found by Pether on poor sandstone hills near the Mayne River, Western Queensland, were forwarded in 1921 for identification, to the Ministry of Agriculture.

On examination, the plant proved to belong to a species of *Bassia*, and one apparently new to science, the nearest allied plant known being *B. carnosa*, which occurs in a few coastal localities in Western Australia. The cotton surrounding the seed of the new species is, however, considerably longer than the last named species.

A description of the n. sp. designated by the name of *B. lanuginosa* is herewith given:

Small undershrub about 1 ft. high; numerous erect simple stems arising from a hard branching woody base; stems covered with a dense, long, floccose tomentum; leaves sessile, linear or the uppermost ones more or less ovate, lower ones about 2.5 cm. long and 2 mm. broad; uppermost ones 0.9 to 1.1 cm. long and 3.5 mm. broad, densely covered with long silky or cottony hairs; flowers sessile and solitary in each axil, but crowdded along the upper part of the stem, densely enveloped in long white silky-woolly hairs; fruiting perianth depressed; about 2 lines in diameter without wool, but over 1 in. in diameter with wool teased out, the 5 lobes enclosing the fruit and surrounded by a slightly raised horizontal ridge, but without appendages of any sort; stamens 5, styles 2, united to about the middle; pericarp about 2 mm. in diameter, depressed ovoid, membranous with a few long hairs.

The cotton ripens from the bottom of the stem upwards and falls away as it ripens. As far as it is known, PETHER considers that it would reach maturity in 3 months, but so long as the ground is kept moist, it would keep green, as it appears to grow and ripen much the same as the natural grasses. It will grow, however, where natural grasses would not grow owing to poor quality of soil and there is also no doubt that the plant is hardy.

It has been reported that this is the first example of a native fibre approaching true cotton that has been seen in Queensland, but that, owing to its short staple, its commercial value is doubtful, although it might be used as a substitute for kapok.

910 – **Notes on the Native Bamboos and Varieties introduced into Lower and Middle Belgian Congo.** — VANDERYST, R. P. H., in *Revue Générale Agronomique*, New Series, Year II, No. 2, pp. 47-64. Brussels, 1921.

The native bamboos in Lower and Middle Belgian Congo are scarce, and chiefly belong to the dwarf species, not exceeding 2 m. in height; the actual distribution is as yet unknown, but taken as a whole the value of these dwarf bamboos form the scientific standpoint is negligible.

As regards the varieties imported into the Belgian Congo, the author classifies the species according to the number of stamens and type of fruit, and gives their fundamental characteristics and distribution tendencies.

The following species are enumerated:— ARUNDINARIA: *A. alpina* K. Schum, *A. Simonii* Riv., *A. japonica*, Sieb. and Zucc. PHYLLOSTACHYS: *P. mitis* Riv., *P. aurea* Riv., *P. nigra* Munro, *P. violascens* Riv., *P. viridiglaucescens* Riv. EUBAMBUSEAE: *Atractocarpa olyriformis*, *Puelia Dewevrei* De Wild., *P. guluensis* var., *P. ciliata* Franch., *Gigantochloa maxima* Kurz., *Oxytenanthera abyssinica*, A. Rich. The author gives the principal morphological characteristics associated with bamboos in this country and their importance from an economical standpoint.

911 – **Experiments with Castor Oil Seed Conducted at Sabour, India.** — TAYLOR, C SOMERS (Agricultural Chemist, Bihar and Orissa), in *The Agricultural Journal of India*, Vol XVI, Pt. II. pp. 146-161, March 1921

Report of attempts made to determine whether by chemical selection it is possible to improve the race of *Ricinus communis* from the point of view of its oil-yielding properties.

Remarkable differences in oil-content of seed were observed from the different types obtained from various parts of Bihar, but this may have been due to the varying conditions under which the plants were grown, and fresh selections were therefore made from the highest and lowest yielders of the 1919 crop, which was grown under uniform conditions at Sabour. Fifteen parents of low oil content were taken, and 20 of high oil content. The mean of 11 good plots was 49.6 % for descendant of parents whose mean was 54.2 %. The mean of 10 well grown "low" plots was 48.6 % from parents whose mean was 42.5 %.

There appeared, therefore, to be strong indications that in the majority of cases the plants did not transmit a high or low oil-content for even one generation, but that in both cases the seed showed a mean oil-content, which lies somewhere about 49 %, when the plants are healthy, and a little lower when the reverse is the case. Out of the whole series, two appear to have kept pure as regards oil-content for more than one generation.

A plot has also been observed which shows a splitting up into different varieties which differ in oil-yielding as well as in ordinary botanical characters *viz.* F_1 green 50.9 %. Four distinct varieties, green A 51.8 %; green B 50.6 %; purple A 46.6 % and purple B 50.4 %; weight of seed 4, 12, ½ and ½ oz. respectively. Original analysis 54.7 % oil. Observations on these varieties will be continued.

Results generally may be taken to give a good comparison between different varieties, and afford a good idea of what could be obtained commercially by the modern method of extraction by solvents such as petroleum ether or carbon tetrachloride.

In order to examine how a small sample will indicate the composition of the main bulk, a number of samples were obtained from botanically pure, or nearly pure, varieties of "*bhadoi*" castor. The analysis of 15 samples from a bulk collection of one variety showed in 1920 a standard deviation from the mean of ± 1.04 %, the mean being 49,5 %. Other analyses made in 1921, taking selection from plant to plant in each of these fairly pure varieties, showed a standard deviation of ± 1.5 %, the mean varying from 47.6 % to 50.9 %. From these observations, the probable error in the oil determination of a single sample of any one variety may be calculated at about ± 1.0 %, of the weight of the seed. The "*rabi*" grown crop showed, however, a standard deviation of 2.0 % (mean 52.3 %), but this may be attributed to the effect of different conditions of growth which had a strongly marked effect on the seed obtained from each plant.

It appears probably that variations in agricultural treatment may possibly have more effect on the oil-yield of the crop than actual chemical selection. As the result, therefore, of a considerable amount of work, a few varieties have been selected which appear to be richer in oil than others, and maintain a mean oil-content greater than 49.5 % which may be taken as the mean of all the types tested here. The improvement is not as marked as was hoped. The greatest improvement observed above the general mean this year was just under 5 % in the case of spring sown *bhadoi*, while the autumn sown *rabi* only showed an improvement of about 3 %.

912 - **Cultivation of Coconut Palm in Porto-Rico.** — GONZÁLES, RIOS P., in the *Departamento de Agricultura y Trabajo, Estación Experimental Insular, Rio Piedras, P. R., Circular No.* 35, pp. 20, figs. 4. San Juan, P. R., Feb. 1921.

No exact data are available regarding the actual number of coconut palms in Porto Rico ; in 1917, according to data collected by the " Comisión de Alimentos," 6832 *cuerdas* (47 113 sq. m.) were planted with coconut palms, and about 10 million coconuts were exported. Porto-Rico coconuts are exported chiefly to the United States ; for export the nuts are freed from the fibrous part of the husk (" coir ") and packed in bags containing 75 to 100. The other producing countries — Ceylon, Java, East Africa, Philippines, etc. — export copra, that is, the fleshy part of the nut, dried in the sun or in ovens. In Porto-Rico there are 3 factories, 2 large and 1 small, for the extraction of coir which is used for making rope, brushes, matting, etc., or else as fuel in factories near the palm groves. The ash is very rich in potash ; some samples contain about 20 %.

Large palm groves grow along the coast of the island ; alluvial soils, by the side of streams, suit the coconut palm very well, but are rare in the island. Fine coconut palms, good producers, are also found on compact soils, but such soils can seldom be used for making plantations since the coconut palm likes mellow soils, moist and easily permeable by water.

The selection of nuts for planting is not generally practised, but the author urges that it should be ; he advises against making plantations with young palms bought in nurseries ; and recommends the selection of the finest nuts on the finest palms 12 to 25 years old (during that period they bear the most vigorous nuts for planting), the picking of these nuts when their fibre is dry or has commenced to dry, the cutting of at least one nut per palm, choosing only palms with nuts that have very thick flesh, rather round than elongated in form, the drying of the nuts selected for planting, spread on the ground in a shaded and aerated place. When planting, the tip of the nut should not be pointed downwards, as is generally done, but have an inclination of 45° ; in this way the layer of flesh which the roots have to traverse is thinner and the distance they have to grow before burying themselves in the soil is shorter.

Replanting can take place when the palm has reached a height of either 30 cm or a little more, or of 1 m. In the former case there is the advantage of being able to get out the roots with less risk of injury, but on the other hand there is the drawback that the stem is still feebly attached to the roots.

Final planting should be made at a spacing of at least 8.40 metres apart in squares ; very close planting is responsible for the low production of many of the Porto-Rico plantations. The trenches should be dug 3 months before planting and the ground should be manured if possible, and carefully kept clean between the palms ; the weeds pulled up should be spread on the ground round the stipes, at a distance of about 30 cm. from them in order to keep the soil moist.

During the first few years after planting, sugar cane, maize, cotton, tobacco, sweet potatoes, or preferably leguminous plants, kidney beans, horse beans, etc., can be grown between the lines. After the 4th year, livestock may be allowed to graze in the plantation.

When the plantation begins to bear, it should be carefully cleared of husks, dry leaves, etc., which should be heaped and burnt to destroy the insect pests which nest in them. The coconut palm lives for 75 to 100 years.

A mixture of fertilisers to be recommended is such as will provide 0.5 kg. of nitrogen + 0.25 kg. of phosphoric acid + 1 kg. of potash per palm. Experiments made since 1908 by the "Estación Experimental Federal" of Mayagüez (Porto Rico) have shown that an increased yield is obtained by applying a complete manuring, that is to say a mixture containing 8 % of phosphoric acid, 6 % of nitrogen, 12 % of potash. By the application of 4.5 kg. of this mixture per palm the crop of coconuts was increased by 30 %; by the application of 9 kg. of this mixture it was increased by 60 %. When the nitrogen and the potash were excluded from the mixture there was no increase; on taking away the phosphoric acid there was a limited increase.

DISEASES AND PESTS OF THE COCONUT PALM IN PORTO RICO. — They do not cause serious injury. Of insect pests, the mot feared is the "escarabajo" (*Strataegus quadrimaculatus*) which penetrates the stipes and ruptures it. It is controlled:— By catching it by hand; by burning the dry leaves and detritus in which it nests; by means of luminous traps; by insinuating a wire with a chisel point into the galleries, where it is not possible to catch it by hand, so as to penetrate it here and there; or else by blocking the galleries with a stopper of cotton wool soaked in carbon disulphide. The "gusano blanco del caculo" (*Phyllophaga* sp.) gnaws the leaves, especially those of the young palms.

The "queresas" (*Aspidiotus destructor* and *Vinsonia stellifera*) adhere to the leaves, from which they suck the sap, causing the leaves to turn yellow. They are controlled by emulsions of soap and paraffin.

Rats are also to be feared; the best means of preventing injury by them is by putting a band of tin or zinc round the stem.

The rotting of the terminal bud ("pudrición del cogollo") is not known at Porto Rico, though it is well known in the neighbouring islands of Cuba and Trinidad.

Finally the author gives information regarding the extraction of coir and suitable mechanical apparatus. According to him the Firm which sells the most complete apparatus for extracting and working up the fibre is the Fibre Machinery Co., 20, Bucklersbury, London, E. C.

913 - **Spanish Sage (*Salvia hispanica*) as an Oil-bearing Plant.**— *Boletín de Agricultura, Industria y Comercio de Guatemala, Organo de la Secretaria de Agricultura*, Year I, No. 1, pp. 21-22. Guatemala, Jan. 1921.

The seeds of the Spanish sage (*Salvia hispanica*; synonyms:— *S. polystacha* Ort., *S. Columaia* Benth.) are used in the preparation of certain beverages; if they are steeped in water for 12 hours they produce a great deal of mucilage, which is a very pleasant basis for cooling drinks. The use of these seeds as a source of oil is much less general, although it is remunerative to grow the plant for its oil, as it produces an abundance of seeds which contain 20 to 40 % of a drying oil very much valued in painting for the brilliancy which it gives to colours. This plant is so little exigent that it is almost a weed; it grows perfectly, even in poor soils where it so to say smothers all other plants. It is ripe 4 months after sowing; if sown very thick the crop may attain 12 to 15 quintals per hectare If it is sown on fertile soil, in lines and ridged up (which is very beneficial to the plant), much more abundant crops can be obtained.

Salvia hispanica, apparently originating in California, is cultivated in various parts of Mexico. Seeds from that region analysed by Prof. Mario CALVINO, Director of the "Estación agricola esperimental" of Santiago de las Vegas (Cuba), contained about 7 % of moisture and from 23 to 40 % of oil (extracted with petroleum ether). The oil obtained by pressing the ground seeds is very clear, of a light green-yellow colour, and bleaches spontaneously in the light; it resembles linseed oil not only in odour, but also in all its other characters.

914 – **Cultivation of (*Rhus succedanea* in Tonkin.** See No. 950 of this *Review*.

915 – **Notes on Methods of Cultivation of Camphor throughout the World.** — See No. 951 of this *Review*.

916 – **Commercial Possibilities of the Nipa Palm (*Nipa fruticans*).** — I. Sugar and Alcohol from the Nipa Palm in *Bulletin No. 3, Forestry Department British North. Borneo* reproduced in *The Journal of the Board of Agriculture of British Guiana*, New Series, Vol. XI No. 1 pp. 51. Demerara, Jan. 1921. — II. Commercial Possibilities of the Nipa Palm, in *Journal of the Royal Society of Arts*. Vol. LXIX, No. 3570. pp. 367. London, April 22, 1921.

I-II. — It is stated that the Nipa Palm (*Nipa fruticans*) is one of the very few tropical plants which occur in pure stands over extensive areas in Borneo. In common with many other palms, its sap contains sugar, and laboratory experiments concluded at the Bureau of Science, Manila, indicate that production of sugar from nipa palm sap would be a commercial success. According to these experiments, it is estimated that there would be at least 12 % of recoverable sugar in the sap, and the average annual yield of 4000 gallons of sap per acre of nipa under management should produce about 4000 lb. of sugar.

Although the production of sugar from nipa sap is still in the experimental stage, according to the U.S. Consul General at Singapore, the manufacture of alcohol from the same source is a well established industry. For many years the natives of the Philippines have been producing a low grade distillate averaging about 25 % alcohol, which has been used as a beverage. Lately the crude stills which produced this distillate have largely been replaced by modern distilleries, of which 75 were in operation in 1913. These produced 2 500 000 gallons of distilled spirits. Over 98 % of this production is diluted and used for beverages, and the balance utilised as fuel for lamps, stoves and motors.

The cost of the distillate as at present produced in the Philippines is difficult to determine, as operations are scattered, manufacturing processes are not well controlled and the cost of collection of the sap is not uniform. In a compact and well managed area, it should be possible to collect and deliver to the distillery at a cost of 50 or 75 cents per 100 gall.; and this quantity of sap should produce between 6 and 7 gall. of alcohol which places the cost of raw material at 8 to 12 cents per gall. of alcohol. The plant needed for distillation is estimated at $15 000 for a 500 gallon per day unit. Including wages, fuel, and interest on investment, the estimated cost to manufacture should not exceed 10 cents per gall. of alcohol, and the total cost of production should not exceed 20 cents per gallon. Experts who have operated in the Philippines maintain that a well organised plant near well managed and concentrated areas of the palm can produce at a cost of 14 cents or less per gallon.

The nipa palm grows in dense formation on tidal areas throughout all the eastern tropics. Very extensive areas are to be found in Borneo and the British North Borneo Government estimates that at least 300 000 acres exist at very accessible points throughout their territory. One block of 57 000 acres has already been surveyed on the west coast and certainly another 100 000 acres can be reached within 4 hours by launch from Sanadakan on the east coast and yet another 100 000 acres near Tawan, on the east coast, but farther south.

917 - **The Use of Tea Flowers for Infusing.**— *Boletin de Agricultura, Industria y Comercio de Guatemala, Organo de la Secretaria de Agricultura*, Year, I, pp. 23. Guatemala, Jan. 1921.

The infusion of the flowers of tea is much less known than the infusion of the leaves, although richer than the latter in aroma and equal to it in all other qualities. In view of the facility for fraud in the leaf-tea trade, the flowers offer several advantages compared with the leaves, e. g. easy plucking, no injury to the bush, much greater difficulty in adulteration.

As the teabush flowers very abundantly, it would be profitable to work it for its flowers. Tea made from the flowers could be sold at a higher price than that made from the leaves, for not only is it more aromatic but also sweeter and contains less thein. Recently tea made from the flowers, which up to date had been reserved for the exclusive use of rich people in the principal producing countries, and was not exported, has begun to be imported into Europe.

Tea does well where coffee does well; its growth in Guatemala, with a view to harvesting the flowers, is therefore recommended.

918 - **Cultivation of Saffron (*Crocus sativus*) in Macedonia.**— *Journal of the Royal Society of Arts*, Vol. LXIX, No. 3577. pp. 487-488. London, June 10, 1921.

The autumnal crocus (*Crocus sativus*) is a native of southern Europe, and western Asia, and is extensively cultivated in Spain, France, Italy and Cashmere. The saffron derived from this plant, requires about 4000 of the dried orange-coloured stigmas to make 1 oz.

According to the report by the U. S. Vice-Consul at Salonica, the 3 villages Goblitza, Vanitza and Spourta, in the district of Cozani (Macedonia), at one time produced a crop estimated at 1500 okes (1 oke = 2.82 lb.); but cereal planting has been more profitable lately, consequently the crop is now only from 600 to 800 okes per year, a reduction of abot 50 %.

In planting, the bulbs are set in the ground 10 in. apart and after 6 or 7 years are taken up and separated, each original bulb yielding a new bulb for every year since planting. A feature of the growing of saffron is the possibility of using the same field for an early crop of some cereal which does not require deep planting. For a good harvest it is necessary that the weather be dry.

After the harvest the saffron is packed in a crude state in matting trunks containing about 50 kilos (1 kilo = 2.2046 lb.) each, and transported to Verria, where they are reloaded on waggons and carried to Salonica. Here they undergo a refining process and are then packed and shipped; chiefly to France and to a certain extent to England.

The product is used in various ways, as a medicine, in the manufacture of cordials and liqueurs; as a colouring matter (the red pistils are utilised in producing a red dye); and in parts of Europe as a flavouring and colouring ingredient in cooking.

Cultivators in Macedonia predict that in a few years time the plant will be more highly valued than at present as a result of the improved methods now being introduced.

919 - **Aniseed (*Illicium verum*) Cultivation and Distillation, and Production in Tonking, Indo-China.** – JEANCARD P. in *La Parfumerie Moderne*, Year XIV, No.4, pp 73-75. Lyon, April, 1921.

The author states that the aniseed (*Illicium verum* Hook.) is cultivated in the district north east of Tonking, Indo-China and in Long Tcheou (Chinese province of Kouang-Si). It is localised in the cantons of Lang-Son, That-Khé, Dond-Dang, Vinh-Rat, Halung, and Na-Chaur at an altitude of 200 to 300 m. It is propagated by seed, and transplanting takes place at the end of 3 years. The inflorescence appears the 7th year, but it is only after 10 years that the first fruit is produced, which contains the well known oil, utilised by the Chinese for medicinal purposes, as an anti-toxin.

The average yield per tree (10 to 20 years old) is from 30 to 35 kg.; after this age has been attained, 40 to 45 kg. is counted upon, and the irregularity of yield can only be attributed to lack of cultivation and to insect attack.

Since the cultivation of this plant has come under European control, it is considered probable that the trees will become more vigorous, will fruit earlier and well, and with much more regularity.

As regards distillation, the Chinese alembic is employed which differs distinctly in construction from the ordinary recognised form of alembic. The author gives illustrations and a detailed description of this " Alembic Tho ". The whole operation last 48 hours (continuous) and 180 kg. of fruit is treated each time. The average yield of oil per 180 kg. amounts to 6 or 7 kg., i. e. 3 to 4 %. The value of the oil thus obtained is estimated according to the congealing capacity as regards temperature. This is measured by means of the BECKMANN method.

The author quotes the exports from Indo-China between the years 1897, 1912 and 1918; the maximum was attained in 1913, viz. 230 000 kg. However, these figures do not in any way indicate the total yield, as a considerable quantity is utilised anually in Indo-China and China, etc., The average price obtained on the French market before the war was between 10 and 15 fcs. per kg.

Aniseed oil obtained principally from Russia before the war was the sole product competing with anethol, and seeing that this has not been put on the market since 1914, there are evidently possibilities of development of the aniseed industry in Indo-China.

920 - **The Variation in Composition of the Rhizomes of Bracken *(Pteris aquilina)*, and Food Values** (1). — HENDRICK J., in *Royal Botanic Gardens, Kew, Bulletin of Miscellaneous Information* No. 4, pp. 157-166. London, 1921.

An investigation was started in the spring of 1918 with the intention of taking samples of the rhizomes of bracken at intervals throughout the year to ascertain the variation which took place in their composition with the season, and the best time of harvesting them from the food and starch-production point of view. Amongst others, samples were taken in April from two points on the Experimental Farm of the North of Scotland College of Agriculture in Craibstone, and when analysed, the percentage of nitrogen varied extraordinarily, although the moisture and dry matter content were almost identical. With the development of the fronds, the store of nitrogen in the rhizomes diminished seriously and the percentage in both sets of samples reached a minimum in July when the frond reaches its maximum development. After this, the nitrogen increased again and soon reached a maximum. This has a bearing on the important economic problem of the best time to cut bracken when it is desired to clear land.

The maximum percentage of nitrogen in the dry matter was reached in August in both cases but the outstanding difference between the 2 sets of samples is the radical difference between the percentage of nitrogen all through the season. The soluble carbohydrates and fibre also vary in a somewhat similar fashion. Neither the ash nor the ether extract show special features calling for comment. Why then should the nitrogen content exhibit such a remarkable difference? No botanical differences were found and both appeared to be normal *Pteris aquilina*.

Analyses were also made of the fronds at different periods during summer and autumn, but except for the differences in nitrogen and moistures, no other striking dissimilarity was found between the 2 sets of samples. The composition was found to be as follows:

---

(1) See also "Bracken Rhizomes and their Food Value". *Transactions of the Highlands Agricultural Society of Scotland*, 1919, XXXI, 5th series, pp. 227-246. (*Author's note.*

Samples of the soil were taken from both places to see if they exhibited any remarkable differences in nitrogen content, or otherwise, which might throw light on the existing differences in the bracken. Both soils are typical sour, moorish soils, and the results of a partial analysis % showed respectively for A and B ; loss on ignition (humus, etc.) 42.65 and 26.95; total nitrogen 0.55 and 0.57; nitrogen as nitrate, absent in both cases; nitrogen as ammonia 0.001 and 0.001 ; lime requirement 1.53 and 1.30. There is therefore no noticeable difference as regards nitrogen content. It would require approximately 15.3 tons of carbonate of lime to neutralise " A " and 13.0 tons to neutralise " B ".

The difference in situation is the only real difference which the author suggests as the cause in variation in composition of plants taken from the two places. (" A " on the open hillside and " B " in a well sheltered hollow).

This, however, hardly appears to be a satisfactory explanation for so remarkable a difference in nitrogen content.

921 – **Forage Root Crops successful in Ireland.** — See No. 881 of this *Review*.

922 – **Pineapple Problems in Florida and the Improvement of Pineapple Soil.** — GOODWIN, R. C. and WARREN, A., in *The Florida Grower*, Vol. XXIII, No. 24, pp. 4-5, figs 6. Tampa, Fla.. June 11. 1921.

Pineapples have been successfully grown commercially on the East coast of Florida for over 30 years. Up till 1915 the industry brought in about 1 million dollars annually to St Lucie County, where the plants were resistant to diseases and pests, but after that time many of the fields have become unprofitable owing to the lack of potash fertiliser, an essential element in the cultivation of pineapples which invariably renders them more resistant to cold.

By applying ammoniates without potash, the plants appeared to become tender and very susceptible to injury from frost. The grower was reduced to the use of blood and bone, tankage, etc. owing to the exorbitant price of potash, and the severe frosts in 1917 followed by a dry year in 1918 led the grower to despair of success.

In the meantime, however, the Agricultural Department at Washington and the Experiment Station at Gainesville were carrying on experiments in plant selection, fumigation, soil sterilisation, disinfection of soil and plants etc., and pineapples planted in 1919 show sign of giving a crop this season (1921).

Plots of ground on old fields have been steamed, others treated with formaldehyde or carbon bisulphide. The experiments are conducted to prove or disprove many theories that have been put forward, and the information obtained will always be of value to growers in Florida.

Although at present local pineapple plants are very scarce, plants will be imported and it is hoped to build up the industry again within a few years time.

In the summer of 1919, experiments were started by SHERBAKOFF in St Lucie County on the A. F. Hoofnagle Estate to discover to what extent the nematode is responsible for the so-called pineapple wilt which has appeared prevalent of late years. Soil was forthwith sterilised with steam, carbon disulphide and formaldehyde, and other experiments were also conducted to show the value of selecting strong healthy slips and also of the fumigation of slips before planting.

Cuban slips gave by far the best results, but as these are difficult to obtain in Florida, it is advised to select with much care the local slips.

The plots where the slips were fumigated with hydrocyanic gas, at the rate of 2 oz. of sodium cyanide to 100 cub. ft. showed superiority over those with the non-treated slips.

With regard to soil sterilisation, it is as yet too soon to draw any definite conclusion, but the plots so far present a very favourable appearance and the plants are growing well

Among further salient points that have been brought out by the experiments the following may be mentioned: —

(1) Restoration of humus in the soil by the growing of some plant resistant to nematode. So far the best results have been obtained with Natal grass (*Tricholaena rosea = Panicum Teneriffae*) (1) and more especially so where it has been allowed to grow undisturbed for 2 or 3 years and only ploughed under before the planting out of pineapples.

2) Necessity of a definite system of rotation. After the 4th or 5th crop of fruit, the field should be planted with some cover crop for one or two years to be ploughed under. This can be so arranged as to maintain a uniform acreage in pineapple each successive year.

Experiments are still in progress in St. Lucie Co. by the Federal

Department, the State Experiment Station, in conjunction with the growers, with a view to ascertaining directly the causes of pineapple wilt.

923 - **Vine Growing and Wine Making in the Province of Mendoza, Argentina.** — CRANNA C. in *The Industrie italiane illustrate*, Year 4, No 50, pp. 14-16, 6 phot., 3 pl., Milan, Dec. 1920.

The author reviews the agricultural development in the Province of Mendoza due to European immigration, from 1885 to the present time.

In 1885, the time when immigration began, the Province had 96 929 inhabitants; it possessed 54 million francs (at par) in heritable wealth and 97 289 hectares of cultivated land, of which 3500 were under vines, and produced 15 000 hectolitres of wine. It exported chiefly to Chile.

According to the census of 1914, the population has increased to 277 535 inhabitants, the heritable wealth to 1400 million francs, of which about 1000 is inverted in landed property. The following Table indicates the agricultural progress made: —

Kind of crop	Area in thousands of hectares in 1914	Products in 1914	Value of products in millions of francs at par	
			in 1914	in 1885
Meadows	85	Hay and pasture	5	11,60
		Cattle and their products	2	
Cereals	45	Cereals	8	1 55
Vegetables and kitchen garden plant	18	Vegetables and kitchen garden plants		
Vine	67	Wine 45 million hectolitres	180	0.85
		Table grapes 5000 met tons	0.5	
Fruit trees	9	Fruits, fresh, dried, preserved	3	1.00
Various	15	Various	3	
			201,5	*15.00*

The vine therefore furnishes the principal coefficient of agricultural development in Mendoza. In 1885 the area under vines was barely 3 % of the cultivated area, while now it exceeds 25 %; in 1885, wine barely reached 7 % of the value of the total production and 2 % of the exports, but at the present time it represent 85 % of the former and 95 % of the latter.

The climate of Mendoza is arid, with 200 mm. of rain annually; the agricultural progress in due to irrigation. The irrigated area, which was 172 000 hectares in 1885, is now more than 625 000 ha. Before 1905 the wine was made by empirical methods; it is now made by good trained wine makers in large establishments which produce up to 350 000 hectolitres of wine a year. The wine-making industry represents altogether a capital of 300 millions francs or less than ¼ of the entire wealth, and it provides for the greater part of the public expenses.

The vineyards belong mostly to Argentine citizens; but $^4/_5$ of the planting and cultivation of the vines is done by Italian immigrants (" contrattisti ") who work by the piece. In 1885, unirrigated vines produced less than 7 quintals of grapes per hectare, but now irrigated vines produce on an average 110 and yields of 320 quintals are not uncommon. The author thinks therefore that the world record of vine production is held by the Province of Mendoza.

924 - **The Importance of the Selection of Cuttings in the Renewal of Vineyards.** — GABOTTO L., in *Il Coltivatore*, Vol. 67, No 16, pp 490-493. Casale Monferrato, June 10, 1921.

The author emphasises the risks connoted by want of care in the selection of cuttings for replanting vineyards attacked by phylloxera. The cuttings of nurserymen are generally, taken here and there in old vineyards without much attention to their parentage and healthiness. The old age of the vines may relate to the stock or to the individual. As the reproduction of the vine has been effected for a very long time by cuttings, it is reasonable to think that the present individuals all belong to varieties which, coming from stocks which are old, are from a biological standpoint, inferior. When these plants, which have in them the defect of coming from a old and worn out organism, are attacked by a disease the results can only be lamentable. Several phenomena which are attributed to a so-called " want of affinity " or a " want of adaptation " owe their origin solely to the congenital old age of the cuttings.

As it is not posible to ascertain the age of the stocks, there is an advantage in taking cuttings from young plants of 3 to 5 years, and particularly from new vines grafted on American stocks. The author recommends the methodical working of cuttings, supplemented by grafts; every nurseryman should watch the success of plantations made with the material which he has supplied, so that he may be able to have recourse for his subsequent supply of cuttings to young vines which have given the best results, choosing among them individual vines that are most commendable for their qualities of affinity, adaptation and production.

925 - **The Timbers of the Ivory Coast from the Industrial and Commercial Standpoint.** — *Gouvernement général de l'Afrique Occidentale Française, Les bois de la Côte d'Ivoire au point de vue industriel et commercial*, 32 pp. pamphlet. Paris, Emile Larose (Publisher), 1920.

France imported before the war about 2 700 000 cubic metres of timber per annum. She now finds herself obliged still to further increase her consumption and the total purchase of timber which she has to make outside France may be estimated at 1 milliard francs per annum. National interests require that these purchases should be made as for as possible in French Colonies which can supply the stocks required by the country. The Ivory Coast Colony offers its timbers which are known, classified, and as good as European timbers. The timbers of the Ivory Coast can replace notably: —

1) The poplar, " grisard ", and tulip tree of America.

2) The pines and firs of France, Northern Europe, Austria and America.

3) The oaks of French and foreign origin, and teak.

4) The beech, plane and hornbeam.

5) The elm, ash and acacia.

They answer the following purposes:—

1) Light furniture, boxes, panelling and interior work.

2) Frame work and joinery.

3) Building, house joinery, frame work, piles, beams, railway material, ship building.

4) Turnery, brush making, paving blocks, tool handles, harness making, chair making.

5) Carriage building, wheelwrights work (naves, fellies, spokes), turnery.

The timbers of the Ivory Coast also include large quantities of kinds used for high class joinery and furniture (mahogany, etc.).

All these timbers come from an immense forest situated along the Atlantic covering an area which is about half that of the Scandinavian forests and greater than that of the French forests. Several rivers flow through it and enter the sea or navigable lagoons. The railway from Grand Bassam to Bonaké traverses its whole width. The difficulties of shipment due to the bar have been remedied by constructing two wharfs at Grand Bassam, which is fourteen days from French ports. There are important forestry businesses, and several sawmills cut up and export the timber. But there still remains on the Ivory Coast $^9/_{10}$ of the forest to be granted in concessions. Large businesses to be successful should:—

1) Make a serious preliminary inspection.

2) Be capable of dealing with all the species which are found mixed up in a tropical forest not under management and requiring it.

3) Invent mechanical means as perfect as possible with a view to reducing human labour to the lowest limit.

4) Study the most economical conditions of transport by land and by water.

It is further very desirable that, in view of the world crisis resulting from the scarcity of wood pulp, the manufacture of pulp or chemical semi-pulp should be studied on the spot by specialists. To sum up, the French home market ought to be widely opened to the direct export of timber from the Ivory Coast, for it is anticipated that within three years from 100 000 to 200 000 cubic metres of timber will be exported from the Colony in place of 52 000 tons in 1913.

A list numbered from 1 to 22, indicates the timbers utilisable in large quantities for the reconstruction of houses destroyed by the war, and including altogether 4 to 50 % of the average stock of the Ivory Coast; a second list, from 31 to 46, indicates the timbers utilisable in small quantities composing about 20 % of the stock.

The results of tests made with the following timber are also republished:— *Entandro phragima* sp.; *Canarium occidentale; Bingeria africana;*

Mitragyna macrophylla; Trichilia Cedrela; Terminalia ivorensis; Chlorophora excelsa; Parkia agboensis; Dumoria Heckeli; Cola proteiformis; Napaga bingervillensis; Farinarium, sp.; *Erythrophleum guineense; Haematostaphis Bartezi; Lophira procera; Pynaerkia occidentalis.*.

LIVE STOCK AND BREEDING

926 – **An Attempt to Induce the Hereditary Transmission of Dourine** (1). — NATTAN-LARRIER, in the *Bulletin de la Société de Pathologie Exotique,* Meeting of May 11, 1921, Vol. XIV, No. 5, pp. 273-277. Paris, May 1921.

Experiments made with female rats and mice with a view to deciding whether the dourine trypanosome, which easily passes through normal mucous membranes (1), can traverse the placental tissue without difficulty, and whether the disease can be produced by *Trypanosoma equiperdum.* Several female rats were inoculated in the peritoneum. After the young were born; some of their blood, taken with every precaution by puncturing the heart, was injected into the peritoneum of a mouse. In most cases the liver and spleen of the same young mice were pounded up and emulsified in a physiological salt solution, and afterwards also injected into the peritoneum of a mouse.

The experiments proved that neither in the case of the mouse, nor in that of the rat, did the dourine trypanosome pass from the mother to the fœtus. Although dourine was thus never transmitted by hereditary contagion, the disease contracted by the mother frequently caused the death of the young mice. In one of the experiments, 1 out of 5 died; in another, all succumbed except one, while in a third experiment, none of the young were alive at the time of birth. As M. LAVERAN had shown that kids born of goats suffering from surra, or debab, *Tr. gambiense, Tr. congolense,* were not immune, even if the mothers had been immunised, the author investigated whether the kids of goats infected with *Tr. equiperdum* could contract the disease. He found that none of them were immune, and even when suckled by a dam actually suffering from the disease, kids acquired no power of resistance to it.

927 – **Note on a Disease of the Horse, Enzootic Haemoglobinuria, in German Austria.** — WIRT (Vorstand der Lehrkanzel für interne Medizin in Wien, in *Der Pferdezüchter,* Year I, No. 7, Part 23. Graz, June 15, 1921.

This disease first appeared in Upper Austria, afterwards in Styria, and has recently broken out in Carinthia. It is known provisionally under the name of "enzootic haemoglobinuria". After the manifestation of certain indeterminate premonitory symptoms, such as fatigue after light work and slight colic, different groups of muscles become swollen and paralysed, and the urine is brownish-red in colour. The animals are frequently unable to masticate and swallow their food. In some cases, the accentuated heart weakness observed in this disease is especially dangerous; often 90 % of the infected animals succumb.

---

(1) See *R.*, May, 1921, No. 519, and *R.*, Aug., 1921, No. 826. (*Ed.*)

The malady chiefly attaks foals and young horses, although older animals are sometimes affected. From bacteriological investigation, it would appear that it is an infectious disease that attacks the nerve centres, and especially the spinal marrow. It was possible to cultivate a certain species of bacterium (streptococcus) from the spinal marrow of horses that have died from the illness. In the opinion of veterinary surgeons, it seems that the bacterium is introduced into the organism of the horse by means of fodder, especially spoiled hay. Hitherto no case of contagion has been observed.

If the animals are properly treated, as soon as the first symptoms appear, it is said that they can frequently be saved. The best prophylactic measure is always to give horses hay that is perfectly sound.

928 - **The Course Run by Camel-Surra in Ponies, Buffaloes and other Animals when Naturally Contracted and Artificially Inoculated.** — CROSS H. E. in *Agricultural Research Institute, Pusa Bulletin*, No. 98. pp. 1-19 and No 99, pp 1-19 Calcutta, 1921.

I. EXPERIMENTS ON CAMELS. — The course run by surra, and still more the probability of curing it, being still much under discussion, the author carried out experiments for the purpose of deciding these questions. He selected 11 army camels which had contracted the disease naturally, and 5 other camels, in which it had been induced artificially by inoculation with 1 cc. of infected blood from a camel.

The animals were kept under the most favourable conditions, and never worked. The results of the examination of their blood and the details of the paroxysms are given in numerous tables.

The following Table (pag. 1165) gives a summary of the conditions of the naturally and artificially infected camels respectively.

These data would seem to show that the duration of the life of camels infected with surra depends largely upon their age, so that it is very probable that the diseased animals when once they are over 6 years of age, and when they are worked, never recover. Whether those that become infected very young, recover, remains to be ascertained.

The paroxysms are for more frequent in the earlier than in the later stages of the disease, when diarrhoea often sets in. In many cases, swelling and suppuration of the inguinal glands are also to be seen. Mange produces very rapid loss of condition in surra-infected animals. When the camels are stall-fed they often feed well during the paroxysms, but if out browsing, they do not browse well, and do not go from tree to tree like camels in normal health. Very often oedema of the belly and legs is observed in camels suffering from surra.

II. EXPERIMENTS ON PONIES BUFFALOES AND OTHER ANIMALS. — In the course of investigations into surra among camels, it has often been found, that in spite of the large number of infected camels and the many *tabanidae*, there were practically no cases of surra among the ponies and mules kept in close proximity to camels.

Experiments were made on ponies, buffaloes, dogs, goats, sheep, rabbits and guinea-pigs, all of which were inoculated with the blood of camels

Age of animals when the disease was diagnosed	Under observation			Results

suffering from surra. The author's opinion that ponies and mules infected with surra did not show the symptoms generally observed in camels affected by this disease, was completely confirmed.

The results of the experiments made in different species of animals, and a summary of the experimental data contined in the numerous tables, are as follows:

1) *Ponies.* — These animals, when inoculated with camel surra, often do not lose condition, and do not always die from gradual emaciation. If they are not worked, their condition may even improve, and they may live for some years. In some cases, especially during the last phases of the disease, the intervals between the paroxysms can be very long sometimes more than a year. Occasionally the hindlegs become paralysed.

2) *Buffaloes.* — There were no fatal cases amongst these animals as a result of experimental inoculation with camel surra; only a few trypanosomes were seen in the blood of buffaloes thus treated. Experiments made on rabbits and guinea-pigs showed that the blood of the buffaloes was infective and therefore buffaloes can act as a dangerous reservoir of surra.

3) *Dogs.* — These animals, when inoculated, manifested very little resistance to the disease, and succumbed, within the relatively short time of 2 months. They became emaciated and often developed opacity of the cornea.

4) *Goats.* — The inoculated animals did not die. Trypanosomes were very rarely to be found. In the blood of some goats which were inoculated experimentally, trypasonomes were seen 107 days after inoculation.

5) *Sheep.* — All the inoculated sheep died. Trypanosomes could seldom be discovered, nevertheless the blood was infective. The animals gradually lost flesh and finally succumbed. As centres of infection, goats

and sheep are not so dangerous as buffaloes, because they are rarely attacked by *tabanidae.*

Guinea-pigs and rabbits proved very susceptible to camel surra, and all of them died in from 17 to 180 days after having been experimentally inoculated with blood taken from infected camels.

929 – **Fowl Spirochaetosis in Doukkala, Morocco** (1).— Delanoi, P., in the *Bulletin de la Société de Pathologie Exotique*, vol. XVI, No 6 Meeting of June 8, 1921, pp 316-320 Paris June 1921

Since 1915, the author had suspected the presence of fowl spirochaetosis in Doukkala, and in 1920, he found spirochaetes in the blood of two chickens and of one young hen. In the last case, treatment with novarseno-benzol, rapidly proved the efficacy of this remedy against the disease. Experimental inoculation of 2 ducks and 2 geese in the wing-vein with 0.5 cc. of infected blood (containing a fair number of parasites) mixed with a citrated physiological solution showed that the goose and duck can contract a serious and rapidly fatal disease from an intravenous injection of infected blood.

There are two chief clinical types of the natural disease; an acute form, in which death ensues very quickly (the natives say that very frequently their fowls die suddenly while laying); and a sub-acute or chronic form with more or less complete paralysis, or rather paresis, of the lower limbs.

Very probably a benign form also exists with few or none of the external symptoms of the disease. The agent transmitting spirochaetosis is the fowl-tick (*Argus persicus* Fisher), locally known as the " black flea " The larvae are especially numerous in the summer, and made it impossible to keep fowls in hen-houses or enclosures, so that the only thing to be done is to imitate the natives and leave the birds at liberty.

Fowls are probably not the only birds that are naturally attacked by spirochaetosis, for although the author has been unable to find spirochaetes in the blood of infected ducks and geese that have not been inoculated, he thinks it is present, for a gosling 4 months old and weighing 8 to 10 kg., which had been ill for 20 days, and was suffering from complete paraplegia, was entirely cured in a few hours by the injection of 0.135 gm. of novarsenobenzol.

930 – **Nutritive Exchanges of Animals as a Function of Body Weight.** — Lapique L in *Comptes Rendus de l'Académie des Sciences*, Vol 192, No 24, pp 1526-1529 Paris. June 13, 1921.

Charles Richet, in his researches, which have rendered classic the law of proportionality between nutritive exchanges and body surface, remarked that oxen of 600 kg. in weight, and goldfinches weighing 21 gm. are not subject to this law, for they give figures that are too high as compared with those obtained in the case of animals of average weight. In previous experiments, the author · systematically · determined maintenance rations, at different temperatures, for small birds of different sizes, from pigeons to Bengal finches. The data thus obtained for the small homeotherms, together with the author's figures, are represented by logarithmic coordinates.

---

(1) The presence of fowl spirochaetosis in Morocco was recorded by H Vemu, *Bulletin de la Société de Pathologie Exotique*, vol. XI, p 261. See also *R.*, June, 1920, No 668 (*Ed.*)

The author's experiments show that the smaller the animal the greater is the variation. Further, it has been found, that in the case of several animals of different size the exchanges re-calculated per surface unit when set down on the same coordinates, intersect, the smaller animals being above the larger, when the temperature is low, and below them when it is high. All the curves tend towards a minimum corresponding to the different temperatures ; the smaller the size of the animals, the more nearly do these temperatures approach the correct one, but the height of these minima is visibly the same, irrespective of the size of the species. It is at the surrounding temperature, which varies with each species, when the loss of heat occasioned by physical conditions is equal to the heat evolved by the actual life processes, that the law of surface holds good from one end of the scale to the other. If on the other hand, a single external temperature is assumed for all species, it is clear that the law is masked by the differences in thermogenetic latitude which allows an addition to be made to the initial expenditure, in order to counterbalance the loss of heat.

It thus appears that the *law of surfaces* can no longer be explained by the need of heat; it is based upon some deeper fact of general physiology which has not yet been determined.

931 - **Correlation Between the Size and the Digestibility of a Ration.** — HONCAMP F., and KOCH, E. (Mitteilung der landw. Versuchsstation Rostock in M.), in *Die Landwirstschaftlichen Versuchstationen*, Vol. 96, Nos. 1 and 2, pp 45-120, Numerous Tables. Berlin, March, 1920.

HENNEBERG, STOHMANN and WOLFF had already doubted the existence of any important influence exerted by the size of a hay ration upon the digestibility coefficient. KELLNER, on the other hand, having fed a mixture of roughage and concentrates to oxen, observed that the digestibility of the ration decreased as the quantity increased.

Experiments carried out in America, by JORDAN and HALL on cows and sheep, gave contradictory results, whereas KATAYAMA and also SCHNEIDEWAND observed that pigs digested best the protein contained in the smallest ration.

As the results hitherto obtained were at variance, on June 1, 1914, the authors began a series of experiments on sheep, to determine the possible correlation existing between the size and digestibility of a ration, when the fodder was the same, both in the case of a ration composed wholly of bulky fodder, and in that of one containing roughage as well as concentrates.

In the 1 st series of experiments, which was divided into 4 experimental periods of 10 days separated by intervals of 8 days, 3 sheep were fed a daily ration of 600, 900, 1200, and 600 gm. respectively, of the same clover hay: the author obtained for the 2 animals and the different sized rations, average variations not exceeding the usual limit of experimental error, except in the case of crude cellulose, of which the digestibility coefficient in the largest ration was 6.6 % lower than that of the smallest.

In a 2nd series of experiments carried out under the same conditions as the preceding, but with a ration composed of clover-hay, gluten, soya-flour,potato-slices mixed with molasses and potato-flakes the digestibility coefficient of the largest' ration differed from that of the smalllest in the following degrees:— 2.7 % total organic matter; 2.2 % protein ; 1.7 % nitrogen-free extract; 6.5 % pentosan; 7.6 % crude fibre; and + 8.6 % ether extract (crude fats), the only positive difference.

In another series of experiments with 2 young sheep, the rations fed consisted of clover hay, dry potatoes, rice and gluten, and only differed from the preceding ration in containing a larger proportion of carbohydrates, especially of the soluble varieties. With this ration, the reduction of digestibility was greater than in the 2nd series of experiments.

The authors do not think that the variations in the digestibility of the albumen can depend upon the differences in the intensity of intestinal decomposition, seeing that, in the experiment, the difference between ingested and evacuated matter was allowed for. Nevertheless, they have carefully observed the organic exchanges of nitrogen and sulphur under their various forms, taking as a basis the view of ABDERHALDEN. According to the latter, it would seem probable that under normal conditions all the esters combined with the sulphuric acid of the urine (phenol, indoxyl, skatoxyl) are derived from intestinal putrefaction, an opinion that is not shared by EMDEN, GLAESSNER and FOLIN.

The author conclude by stating that: 1) In the main, their researches on the secretion and decomposition of the sulphur compounds present in the urine of herbivora have not given the desired and expected results; 2) the results of these researches in no wise warrant the assumption that there is any correlation between the small depression of the albumen resulting from the increase in the ration, and a diminution of the decomposition of albuminoids in the intestine; 3) if the quantity of sulphuric esters in the urine were alone taken into consideration, an increase, rather then a decrease, in the decomposition would be observed as a result of the larger ration.

In fact, the increase in the ration produces a decrease in the solubility and digestibility of the crude fibre in the intestine, partly on account of the short time the unit weight of the food mass remains in the intestine (which also has the greatest effect when the ration consists exclusively of roughage), and partly because, if a ration is composed of a mixture with a high content of easily-soluble carbo-hydrates, the latter are first attacked by the bacteria of the intestine, and are rendered soluble and digestible, whereas the fibre is not touched; this depresses the digestibility of the crude cellulose forming the cell wall and hence of that of the albumen of the carbohydrate substances, etc. present within the wall.

In other experiments made upon 4 young sheep fed with a mixture of ordinary fodder in proportions varying in such a manner as to give rations differing as regards the amount of KELLNER's starch equivalents, the protein alone showed any practical difference in digestibility in the ration containing least starch equivalent.

The authors conclude that although it is true that an increase in a ration reduces its digestibility, yet it does so to such a slight extent as to be negligible in comparison with the larger errors made in calculating rations based on the mean value of the composition and digestibility of the fodders given (1).

932 - **Sunflower Silage Digestion Experiment with Cattle and Sheep** (2) — NEIDIG R. E., SNYDER, R. S, and HICKMAN, C. W., in *Journal of Agricultural Research*, vol. XX, No. 11, pp. 881-888, tables 6. Washington D. C., March 1, 1921.

Report of experiments carried out at the Idaho Agricultural Experiment Station in the United States with 3 Shorthorn cows, 3, 5 and 10 years old respectively, and with 3 yearling wethers, all pure-bred Shropshires; the silage used was made from sunflowers gathered when about 50 % were in bloom but when only a few seeds were in the dough stage.

The daily ration given was 50 lb., to cows and 2 lb. to sheep. During the 7 days digestion period, following on the preliminary feeding period lasting 10 days, daily records were secured of the amounts of silage fed, silage rejected and feces voided together with the daily weights of the animals. Chemical analyses were made of all composite samples.

Taking into account all the data recorded in the 5 tables the following coefficients of digestibility for cows and sheep were determined:

Coefficients of digestibility for cows and sheep.

	Dry substance	Crude protein	Crude fibre	Ether extract	Nitrogen free extract	Ash
	%	%	%	%	%	%
Cows (Average of 3)	51.7	47.8	37.4	73.7	56.3	26.6
Sheep (Average of 3)	58.8	54.4	46.7	77.4	69.8	38.5

These experiments show that the digestible nutrients contained in sunflowers compare favorably with those in mature and immature maize. The nutritive ratio is somewhat narrower in sunflower silage than in mature and immature maize silage. Sheep utilised slightly more nutrients in sunflower silage than cows under the same conditions.

Where both maize and sunflowers are grown under favorable conditions, the selection of a silage crop should depend upon comparative tonnage per acre and cost of harvesting.

---

(1) In any case, this conclusion confirms the laws of the reduction in the digestibility and utilisation of fodders upon which Prof. JOVINO bases his calculation of the most economical ration See *R.*, May 1921, No. 551. (*Ed.*)

933 - **Studies on the Hereditary Transmission of Trotting Capacity in French Trotters**(1) — VAN MELDERT, L', in the *Annales de Gembloux*, Year XXVII, Part 6, pp 135 155 Brussels, June, 1921

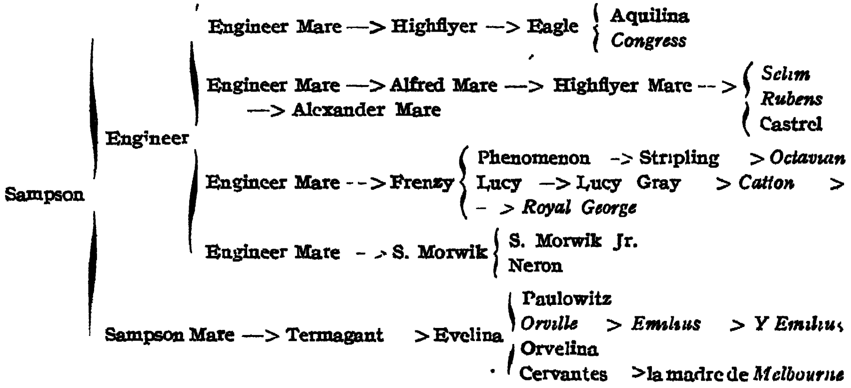
Report presented by VAN MELDERT at the last meeting of the Texas Horse Breeders' Association.

Struck by the fact that all the families of trotters had gradually disappeared in the United States in the great competition for speed, having retired from the field in favour of the progeny of "Sampson", the author began to study the history of the trotting-horse in France, and gives an account of the life of every stallion that has contributed to the improvement of the breed. His investigations show certain breeding theories to be entirely erroneous, that an exact knowledge of the pedigrees of the animals is an absolute necessity for progressive breeders, and that the registration of an animal in a Stud-Book is not sufficient guarantee of its performance as a sire.

The following is a summary of the report, which suggests new ideas concerning heredity and the results that can be attained in improving stock.

All the families of trotters in the United States have been submerged by the progeny of Hambletonian 10, in the great struggle for speed supremacy. The pedigree of Hambletonian 10 shows that this horse is descended five times from Messenger, the great-grandson of Sampson.

As a result of searching ont the descendants of "Sampson" amongst the ancestors of the trotters of France, the following lines have been discovered :



Sampson
Engineer
Engineer Mare —> Highflyer —> Eagle
Aquilina
Congress
Engineer Mare —> Alfred Mare —> Highflyer Mare -- >
—> Alexander Mare
Selim
Rubens
Castrel
Engineer Mare - - > Frenzy
Phenomenon -> Stripling > *Octavian*
Lucy —> Lucy Gray > *Catton* >
- > *Royal George*
Engineer Mare - > S. Morwik
S. Morwik Jr.
Neron
Sampson Mare —> Termagant > Evelina
Paulowitz
Orville > *Emilius* > *Y Emilius*
Orvelina
Cervantes >la madre de *Melbourne*

The great French trotters are the direct lineal descendants of *Selim*, *Rubens*, *Catton*, and *Orville*, which are the decendants of Sampson through their dams.

Sampson, although entered on the pure-blood stud-Book, was not pure-bred. His sire was apparently a draught horse. But as characters are transmitted equally well in the female and male line it is a mistake to class families solely according to the sire.

---

(1) See *R*, May, 1921, No. 529. (*Ed.*)

Speed in trotting is a hereditary character. Only certain characters are transmitted which, according to MENDEL, may be either dominant or recessive. Inbreeding intensifies some hereditary characters.

It is erroneous to regard as axiomatic that:—

(a) *Like produces like*, for absolute likeness in shape and capacity is impossible, unless the parents are very nearly related.

(b) *Crossing is a means of improving the breed.* Crossing, on the contrary, destroys the results of improvement. The hybrids of different races never attain the acquired excellence of any race.

(c) *The product represents the sum of the qualities and defects of its ancestors.* Heredity can only affect certain characters, and these are either pure or mixed. The hybrid dominants are eliminated as selection progresses.

(d) *The product takes one half from its dam. and the other half from its sire.* This is a great mistake, for the offspring may inherit more from its dam than from its sire, or *vice versa*. There are thus no ½ blood, ¼ blood, or $^{1}/_{8}$ blood horses, nor horses of any fraction of blood.

Some pure-bred horses, very nearly related to Selim, Rubens, Orville and Catton, have turned out good trotters; of these we may mention:—

Ministère	9	times	descended	from Sampson
Plutus	7	»	»	from Sampson
Dollar	6	»	»	from Sampson
The Heir of Linne	5	»	»	from Sampson
Pace	5	»	»	from Sampson
Pédagogue	4	»	»	from Sampson
Fitz Pantaloon	4	»	»	from Sampson
Monarque	4	»	»	from Sampson

Apparently it has been possible to create a race of pure-bred trotters by breeding together the thorough-bred products closely related to Sampson, and showing an aptitude for trotting.

After a century of breeding, the French trotting horse (stallion) manifests a Sampson-heredity coefficient, that is to say, that each of the trotting-stallions are descended from Sampson the number of times given by his coefficient:

1900	Azur (Lillonet)	34
1901	Beaumanoir	62
1901	Bémécourt	56
1906	Grand maitre	96
1907	Helder	83
1908	Intermède	102
1910	Kalmouck	131
1915	Pro Patria	133
1915	Phenomenon	110
1917	Romanoff	141

The higher the Sampson heredity coefficient, the greater the value of the horse.

The trotters of France have 3 different origins :— (1) Most of the present trotters are descended from Sampson, and it may be predicted that, in a few years' time, the French trotter will be a pure Sampson ; (2) the Marshland Shale family ; (3) the Fucaway family.

The paternity of Sampson can be traced through all the generations of which he is the ancestor and the influence of Marshland Shales can be followed in French breeding stock.

As son as the Marshland Shales coefficient is higher than that of Sampson, the stallion ceases to be useful in the improving of the trotters.

	Coeficient of heredity		
	Sampson	Marshland Shales	Fucaway
1848 Ouvrier	—	1	2
1876 Lavater	5	2	—
1869 Noville	3	3	4
Noirmont	2	2	2
1873 Reynolds	5	1	—
Rollon	1	5	—
1874 Serpolet Rouan	4	2	3
Sobriquet	5	7	4
1876 Un	1	3	3

This offers an explanation of the question why certain fine stallions, such as Noville, Noirmont, Rollon, Serpolet Rouan, Sobriquet and Un were not successful at the Stud Station whereas Lavater and Reynolds from whose pedigree Fucaway 201 was absent, were excellent sires.

In France, horses with much of the blood of Fucaway 201 are as a rule roans; they are somewhat exclusive, and do not mate well with the descendants of Sampson. They consist of the progeny of Serpolet Rouan César, Glaneur, Hardy, Harpon, Ouvrier, Bayard, Sarcus, Corlay, Begonia, Nougat, etc.

Conclusion. — In France, as in the United States, the trotter capable of resisting the constant increase in the trotting-pace will be the result of many intercrosses of the Sampson blood, and the race can only be improved in this manner.

934 - **New General Purpose Breed of Fowl Developed by Blending Characters of Three Established Breeds** — See No. 942 of this *Review*.

935 - **The Sardinian Horse** (1).— MORESCHI, B (formerly Director General of Agriculture), in *L'industria lattiera e zootecnica* Vol. XIX, No. 2., pp. 15-16 ; No. 3, pp. 27 28 ; figs. 2 No. 40 pp. 39-40, figs. 2 ; No. 5: p. 51. Reggio Emilia, Feb.-May, 1921.

Italian authorities on horses have long maintained that it would be very advantageous to breed Arab horses in Sardinia and as long ago as 1874 the oriental stallion, Osmanié, was sent to the State Stud at Ozieri. This animal was at work until 1893, and survived 582 mares, which produced no less than 300 foals. It is not always possible to import Bedouin Arab stallions, which alone can by regarded as belonging to the original stock: since the establishment of the Kingdom of Italy (1870) 7 or 8 have been introduced, the last being brought over in 1906 and 1907. Pure-bred Eastern horses have been purchased in Hungary, France, and even in Russia (in 1894, "Dsingiskhan", a $^3/_4$ blood Arab, was bought from the Government Stud et Baholma, this horse served a thousand mares in Sardinia and was the sire of 500 handsome foals in 25 years.

---

(1) See *R.* Feb. 1919, No. 224 ; *R.* March, 1921, No. 316, 3 (*Ed.*)

In France, an Arab stallion is always chosen as the sire for the horses and used by the light cavalery. Not long ago, the French studs boasted of a certain number of Arab stallions 50 of which had been bought in the East. The best French horses fo Arab blood are to by found in the districts of Tarbes, Pau, and Pompadour.

There are two State horse-breeding establishments in Sardinia, the Ozieri Stud, and the Bonorva, or more correctly, the Burgos, rearing dépot. The latter takes the foals bought in the island by the ministry of war, at the age of 2 or 3 years, for the cavalry, and keeps them till they are 4 ½ before sending them to the regiments. This is done, in order to prevent the breeders ruining the animals, which they cannot sell, by working them too early or hobbling them.

The author suggests the formation, by an Association of Agriculturists subsidised by the State, of grazing grounds for foals and provided with sheds to give shelter during the winter. This would reduce to a minimum the time spent by the animals at the Government Dépôts, and thus effect a considerable saving in expense.

All the horse-breeders of Sardinia are now agreed as to the advantage of the introduction of Arab blood. In the last 20 years, the Ozieri Stud has increased rapidly; in 1899, there were 48 stallions distributed among 35 Stations; in 1920 the Stud boasted of as many as 131 which, in the spring, were kept at 68 centres. Of these horses, 90 were born and bred in the island, and 41 had come from elsewhere.

In 1915, the Stations for selected mares began work in the island. There are, at the present moment, as many as 16, each with 40 of the best mares the country has to offer.

The owner, in addition to the free service of the stallion receives 150 *lire* or even 200 *lire*, if the foal is born alive and healthy. He has to pledge himself not to sell the mares, to bring them to be served by the chosen stallion, and to take every care of the mares and foals. When 2 or 3 years of age, the entire colts may be bought by the Ministry of Agriculture for the Government Dêpôts at a price not below 4000 *lire*. The mares can become brood-mares and obtain the premium above-mentioned. A large number of brood-mares have been given to the Stations for selected mares by Bedouin Arab stallions introduced into Sardinia; for instance Asciar has 9 fillies there, Sabasciar 16, Etnen Escrin » 11, Tisa 12, Talata 5, Sitta Arbain 4, Saba 12, and Talata Escrin 23.

In January 1919, the Government were able to acquire in the island, 12 entire colts, bred in the Stations for selected mares, at prices varying from 4000 *lire* to 8000 *lire*; 14 other stallions were also bought there for the Ozieri dépôt for from 4500 to 9000 *lire*.

The Sardinian horses supplied to the army proved most satisfactory, even as far back as 1893. One Sardinian mare carrying a rider, covered the distance from Bergamo to Naples in 10 days.

Breeding-studs with many brood-mares are rare in the island; some, however, exist in the Bosa district; as a rule, the Sardinian only keeps the number of mares to actually needs, and these he has served annually, in order to provide him with foals. The author gives some information regarding certain small breeding establishments which are worthy of mention, if not for their size at least for the quality of their products. There are several in the province of Sassari.

In Sardinia, there are 131 State stallions, and as many licensed by the Government. If the unlicensed animals are also taken into account we may say that there are 300 stallions which serve no less than 12 000 mares annually, and the foals born every year are 6000, or even more. Before the war. the State bought 1000, and the rest were bought and sold privately; in 1918, 4800 horses were exported from the island.

936 – **Exsperiments Made in the United States on the Value of Cottonseed Meal as a Partial Substitute for Grain in a Ration for Horses.** — BELL, G. A., and WILLIAMS J. O., (Animal Husbandry Division) in *United States Department of Agriculture, Bulletin* No. 929, pp. 1-10. Washington D. C., Dec 17, 1920.

The objects of the experiment were to determine the value of cottonseed meal as a partial substitute for grain in a ration and also to determine the amount of cottonseed meal which can be fed with safety to work horses.

TABLE I.

Horse	Ration				
	Maize	Oats	Oat hay	Wheat bran	Cottonseed meal
	lb.	lb.	lb.	lb.	lb.
Stanley	—	18	16	—	2
Virginia	—	12	8	3	—
Maude	10	—	10	—	1¼
Myrtle	—	12	8	3	—
Nell	—	6	8	2	—
Queen	—	12	8	3	—
Fauna	—	15	10	3	—
Pet	10	—	8	—	3
June	—	16	16	—	1½
May	—	18	16	3	—
Castanette	—	12	8	—	3
Gladstone	—	10	10	2	—
Georgia	—	8	10	2	—
Brown Bess	—	10	10	—	2
Evarts	—	12	10	2	—

TABLE II.

Horse	Weight at beginning of experiment	Final weight	Gain (+) or loss (—) in weight	Meal fed at beginning of experiment	Meal fed at end of experiment	Effects observed
	lb.	lb	lb.	lb.	lb	
Stanley . . .	1510	1425	— 85	0.25	2	Intermittent colic attacks when fed on large amounts of cottonseed meal.
Virginia . . .	1500	1570	+ 70	—	—	
Maude . . .	1520	1670	+ 150	0.25	1.25	Refused ration containing over 1 lb. of cottonseed meal.
Myrtle . . .	1475	1475	—	—	—	
Nell	1443	1485	+ 42	0.25	1.25	Died Sept 25 from colic Post mortem examination showed malformation of small intestine. Death not attributed directly to feeding cottonseed meal
Queen . . .	1295	1410	+ 115	—	—	
Bertina . . .	1520	—	—	0.25	—	
Fauna . . .	1770	1780	+ 10	—	—	Died Sept. 8, stomach and intestines highly inflamed from excessive feeding of cottonseed meal.
Pet	1325	1480	+ 155	0.25	3	
June	1250	1375	+ 125	0.25	1.50	No ill effects observed, although the mare refused to eat large quantities of meal.
May	1315	1390	+ 75	—	—	
Castanette . .	1260	1440	+ 180	0.25	3	No ill effects observed.
Gladstone . .	965	950	— 15	0.25	—	Feeding cottonseed meal discontinued june 16. The animal constantly refused to eat a ration containing it.
Georgia . . .	965	960	— 5	—	—	
Brown Bess .	970	940	— 30	0.25	2	No ill effects observed.
Evarts . . .	995	940	— 55	—	—	

Sixteen horses (4 pure-bred Morgans and 12 pure-bred and grade Percherons) were used and 7 were used for control purposes. One mare died from an attack of pneumonia. All the horses were in splendid condition at the beginning of the experiment except one. Owing to the apparent dislike to the taste and odour of cottonseed meal it was mixed with wheat bran.

Only fresh, finely ground cottonseed meal was used and whole oats was used as the principal grain ration : the roughage fed was good quality timothy hay used *ad lib.*

The rations varied with the appetites of the animals. At the beginning of the experiment (October 1, 1917), the daily rations were as follows oats 8 to 27 lb., timothy hay 12 to 20 lb., wheat bran 3 lb., cottonseed meal 0,5 lb., For horses who ate satisfactorily or showed no signs of illness, the cottonseed meal was increased gradually from 0.5 lb., to 0.75 lb., 1 lb., 1.25 lb., 1.60 lb., 1 75 lb., and from 2 lb.. so that during the last period of experiment the daily rations were as shown in Table I:

The summary of experimental feeding is given in Table II.

Mares fed on cottonseed meal during the period of pregnancy did not show any ill effects nor did the colts when foaled.

23 rations are suggested, the amount of cottonseed never in any case exceeding 1 lb. per 1000 pound horse. Although some animals will consume more it is not advisable to exceed this limit. The mares in this experiment thrived better and consumed their ration containing cottonseed meal more satisfactorily after they were turned out on pasture.

In any case, horses should be taught to eat cottonseed meal by giving them a very small quantity at first (about 0.25 lb., per day), and increasing it slowly so that they gradually become accustomed to the taste and odour of the meal.

937 – **Notes on Some Characteristics of Icelandic Milch Cows** — PALL ZÓPHÓNIASSON in *Bunadarrit* 34 *Aaeg Reulkiavik* 1920. Summarised in *Nordisk Jordbrugsforskning*, Part 4, pp. 147-148, and p. 150. Copenhagen, 1920.

These studies deal with 2739 cows coming from all the different districts of the island, except Östland, and are based on colour data taken from the cow-testing registers.

The author describes 11 different colours and 19 shades, which can be divided into 7 groupes as follows: —

1) Red (Raudar): red is entirely predominant, or slightly intermixed with white.

2) Black (Svartor): completely black, or with a little white introduced.

3) Kolóttar: spotted red and black.

4) Striped (Bröndottar): with stripes and bands of red and black.

5) Black-brown (Mösvartar); tinged with black.

6) White (Hirtar).

7) Grey (Gráar): chiefly white with a red or black markings.

Red	37.9 %	Spotted	5.6 %
Black	33.9	White	1.7
Striped	10.4	Black-brown	0.5
Grey	10.0		

According to this grouping, the 2729 cows may be divided as follows.

The author considers the striped animals to be of Jersey origin, probably the descendants of cows imported by the Irish monks who were already settled in Iceland when the Normans landed there. This type of cow is to be found chiefly in the places where the monks had their monasteries, and they give milk with a high fat content.

As regards yield and composition of the milk the author quotes the following data taken from the registers of the Iceland cow-testing associations for Nord and Vestlandet: —

The maximum fat milk yield obtained was 4235 kg. with 3.42 % butter fat (average of 3 years) : the maximum fat content was 4.53 % from 3643 kg. of milk (in 1 year). One cow during 10 years gave en average of 3555 kg. of milk with 4 % butter fat per annum.

938 - **Lattolo I. C. A. as a Calf Feed.** — MANVILLI, V, in the *Rivista di Agricoltura*, Vol. XXVI, No. 23, pp. 327-330, figs. 2 ; No 24, pp 340-344, 2 diag figs. 1 Parma, June 10 and 17, 1921.

The author has made a trial of the new lacteal flour, known as «Lattolo I. C. A. », manufactured by the firm of Ing, FINZI, Dr. EMPRIN and Co. at Candiolo (Turin). The tests were carried out on the cow-sheds of the Bonafous de Lucento Agricultural Institute at Turin.

The product is a fine homogeneous flour of a greyish colour, with a subtle aromatic odour, and a sweet flavour. When mixed with water in the proportion of 100 gm. per litre, it yields a liquid which, according to the makers, is equal in nutritive value to one litre of milk, and only costs 25 *centesimi* per litre, a price corresponding to 2 50 *lire* per kg., of the powder.

The author tested « lattolo »with young calves and heifers of the Schwytz breed, that had previously been fed with a ZAPPA-PIROCCHI bottle, and later hand-fed from a pail.

A young heifer that had been suckled by its dam until the 25th day, was given "Lattolo I. C. A." as a partial substitute for natural milk in the proportion of 1/3 for the first 25 days, 1/2 the following 25 days, and 2/3 for the subsequent 20 days; in all, for 40 days, aften which the heifer was weaned, and fed on grass, hay, and groundnut cake (300 gm.) At the end of the experiment, when the heifer was 135 days old it had consumed 58.75 kg. of " Lattolo powder " and its weight was 144 kg.

A young calf reared in the same manner weighed 134.50 kg. on the 120th day, and consumed 50.2 kg. of " Lattolo " powder.

Although it is true that the increase in weight obtained with " Lattolo " is slightly below the theoretical figure of 950 gm. per head per day, for calves reared on natural milk nevertheless this leaves a sufficient margin of profit on districts like those where the experiments made, as the breeder can sell his milk direct in the town.

" Lattolo I. C. A. " is relished by animals ; calves bronght up on it always enjoy perfect health. The product can also by added to skim milk. From the 10th. day a calf can be reared exclusively on skim milk to which " lattolo " has been added ; the amount given being 1 litre per 6 kg. of live-weight. In order to replace the substances removed, 50 gm. of " Lattolo I C. A. " per 1 litre of skim milk is sufficient.

939 - **Pig Breeding in Latium** (1) — BIANCHINI, B, in the *Rivista Agricola romana*, Vol. XLVII, No. 6, pp 140-145. Rome, June, 1921.

In Latium, where pig-breeding is far from being as important as it might easily be, the Roman breed known also as the maremmana (marsh) or macchiarola (maquis) pig is kept. This animal is hardy, black, well-adapted for grazing, and has much bristly hair on its back. Its flesh is fine in flavour, but deficient in fat In the north of the province, pig-breeding is carried out in some places in a systematic manner, selected animals from Umbria and Tuscany being used for the purpose. In the south, the Teano breed (or pelatelli casertani) is found. This was the original of the stock of the English Yorkshire and Berkshire breeds.

Two systems of breeding are practised, in the one case, a few pigs are kept by peasants, agricultural workers, etc. the animals bring fed on skim-milk, kitchen scraps, or market refuse ; in the other, large herds of swine are reared in the woods of Turkey oaks or ordinary oaks, where they roam in the wide clearings traversed by never-failing streams, and are collected together in the evening by the sound of the « vorgna » a kind of bagpipe

The chief aim, of the first method is to provide meat and fat for the, family or for private trading ; the object of the second is to increase the number of pigs.

For Latium the author advises an intensified and improved method of pig-breeding based on improved sties ; the use, by breeders in the neighbourhood of Rome, of kitchen and table scraps, which could be obtainned and collected at small cost in the town ; commercial crossing, that is to say, of one generation, with Yorkshires, or Large Blacks. (In 1897, red Tamworths were introduced to improve the local race at Fogliano, on the estates of Prince CAETANI, Duke of Sermoneta ; the experiments appear to have given excellent results, and would be well worth repeating) In conclusion, the author advocates the selection of the native breed, the late development and small size of the animals being to a large extent compensated for by the flavour of the meat, and their unusual hardiness.

940 - **Notes on the Poultry Stock in Belgium** — RASQUIN, M in *Journal de la Société Nationale des Agriculteurs de Belgique*, Year III, No 23, pp 160. Brussels June 4, 1921.

The statistics drawn up at the time of the Armistice gave the number of poultry in Belgium as about 5 million , before the war there were as many as 12 million head. For the last 2 years, poultry-rearing has been carried on with the greatest energy and broods of chicks are to be seen everywhere this year. Large poultry-breeders have become very numerous so that it may be predicted that by the end of 1921, the poultry will have risen to 10 million.

In this reconstruction of the industry, the question of laying, non-sitting breeds has been more considered, and some very distinct races are seen in the different villages.

In the Walloon distruct, the Leghorn is widely kept, while in Flanders, the Brackel shows signs of being once more the favourite.

Foreign breeds, consisting for the most part of table varieties are less numerous than formerly, as egg production is the chief object at present. Every encouragement is given to the rearing of Belgian breeds, which in future should be the basis of the poultry industry. On the other hand, a practical school for small poultry-farmers is to be started at Mariemont (Province of Hainault) where the question of breed is to be the first consideration. The attention of breeders ought chiefly be directed to la Campinoise, la Brackel, la Brabançonne, la Herve, and l'Ardennaise as laying races, and to Concou de Malines as a table variety.

941 - **The Sicilian Breed of Fowl.** — TUCCI, F., in *Allevamenti* Year II, No. 7, pp. 209-211 2 coloured figs. Palermo, July 1, 1921.

In Sicily, poultry-keeping is practically limited to the small villages where the agriculturist sleeps, and his family lives, and is little practised on the large farms where there are no peasant dwellings. From having been reared in these villages, the Sicilian fowl has developed an aptitude for living in a confined space. There are however poultry farms of some size in the province of Messina, the ancient country of Modica (province of Syracuse), and at Paceco, and Marausa (province of Trapani). The Marsala fowl even enjoys a merited reputation.

The Sicilian fowl has some characters in common with the Italian breed, but is distinguished by its smaller size, and the superior egg-laying qualities of the vigorous young hens. The Marausa fowl is the result of selection carried out by the author at the Palermo zoological Institute. It is characterised by the special shape of its crest, which is like a cup with a dentate rim, and by its grey-green shanks. Its plumage varies in colour.

The Marsala fowl was accidentally introduced into North America. It was one of a number of birds shut up in a coop, but was spared by the crew because, throughout the whole voyage, it continued to lay eggs of a large size Its progeny was carefully selected, and gave rise to the " Sicilian buttercup breed, which stands confinement well.

The Sicilian Marsala fowl, which has been selected by the author since 1913, has the following characters :—

COCK — Head of right size, a little elongated, wide at base. *Beak* sufficiently long, with strong base, and tip a little recurved. *Cheek* reddish. *Crest* large, double, on form of cup with dentate edgl. *Wattles* well-developed and long. *Eyes* black, encircled with yellowish red. *Earlobes* white above, pink in the middle, and red below ; surface smooth.

Neck of right length, slightly curved.

Back nearly straight, sloping slightly backwards.

Shoulders wide.

Chest of right width, flat and slightly rounded.

Legs strong ; shanks clean, grey-green, 4 toes.

Tail well-developed, erect, with large, strong-rectrices (tail quills).

Feathering golden.

Size average ; only exceptionally do the birds weigh 2-5 kg or a little over.

HEN. — Except as regards secondary sexual characters, has the same characters as the cock. The comb is less developed, the edges tending to fall over on one side.

The *pullets* begin to lay at 6-7 months old, and in the case of birds hatched in March-April from Oct. 1-Sept. 30, producing 60-70 eggs the first year, the maximum of 160 being laid the second year, and only 140 the third year. These figures refer to lots of 10-12 kept in small runs ; larger flocks always kept in pens lay somewhat fewer eggs This fowl is not a *good sitter,* it is very *hardy.*

The Sicilian fowl does well when allowed to range at will, but it does not lose its good qualities in confinement.

942 - **Lamona** (1) **A New American Breed of Poultry.** — LAMON, H. M. (Bureau of Animal Industry U. S. Department of Agriculture,, in *The Journal of Heredity*, Vol. XII, No. 1, pp. 3-29, Plates 27. Washington, January, 1921.

A new general purpose breed of fowl developed by blending the egg-producing and meat-producing characters of 3 established breeds.

The object of crossing the latter was to obtain a new breed of general purpose fowls of the type, size, and commercial qualities of the Dorking, with white plumage, yellow skin, 4 toes, yellow legs, and red ear-lobes, which would lay large white eggs. The present general purpose breeds lay a brown-shelled egg, whereas eggs with white shells are preferred on the market.

The breeds used for crossing were the Dorking, White Plymouth Rock, and the single Comb White Leghorn. The crosses were made as follows :

Year	Pen No	Mating
1912	Original mating	White Plymouth Rock ♂ × Silver Gray Dorking ♀ .
1913	22	S C. White Leghorn ♂ × hybrid females from 1912 mating.
	18	S. C. White Leghorn ♂ × Silver Gray Dorking ♀ .
1914	9	Male hybrid out of pen 22 × hybrid females out of pen 18.
	7	Male hybrid out of pen 22 × females hybrid out of pen 18.
	17	Male hybrid out of pen 22 × females hybrids out of pen 22.

In the following years, the breeding operations consisted of constant selection, as no new crosses were made, nor was any other pure-bred individual of the three original varieties employed.

In the successive generations (1913-1920) the plumage, colour, number of toes, leg colour, and ear-lobe colour were distributed as follows:

1913 : *Plumage colour :* White 3 ; other colours 28.

Number of toes : Of 107 chicks, 50 had 4 toes on each foot, 42 had 5 toes on each foot ; 13 had 4 on one foot and 5 on the other ; 1 had 5 on one foot and 6 on the other ; 1 had 60 toes on each foot.

Leg colour : 20 had white legs, 2 yellow ; 4 white of a yellowish tint, 1 yellow with whitish cast. Total 27.

---

(1) The official designation of the new breed. (*Ed.*)

Lobe colour : 19 white ; 3 nearly white ; 1 one-half red and one-half white ; 1 nearly red ; 24 in all.

1914 : *Plumage colour :* White 68 : other colours 95.

Number of toes : of 188 chicks, 137 had 4 toes on each foot ; 39 had 5 toes on each foot ; 12 had 4 toes on one foot and 5 on the other.

Leg colour : yellow 69, white 81 ; the rest (out of a total of 136) had legs of the following colours; yellowish, yellowish white, greenish yellow, blackish yellow, white with a few spots, willow, and black.

Lobe colour : Red 7, the rest of the birds had lobes varying from white to red. Total number 163.

1915 : *Plumage colour :* White 25 ; other colours 64.

Number of toes : Out of 395 birds, 308 had 4 toes on each foot, 68 had 5 on each foot, 14 had 4 on one foot and 5 on the other, 5 had 5 on one foot and 6 on the other.

Leg colour : yellow 42, white 39, the other birds had legs of all shades from white to yellow. Total number 90.

Lobe colour : Red 15 ; nearly red 19 ; 23 one-half red ; 13 white, the rest being white and red. Total 90 birds.

1916 : *Plumage colour.* White 46 ; other colours 132.

Number of toes : Out of 337, 268 had 4 toes on each foot ; 39 had 5 on each foot ; 12 had 4 on one foot and 5 on the other.

Leg colour : yellow 97, white 64 ; the rest were of all shades from yellow to white. Total number 170.

Lobe colour : Red 47, nearly red 39, white 10. Total 160. 2 fowls with red ear-lobes laid white-shelled eggs.

1917 : *Plumage colour :* White 208 : other colours 311 ; total 519.

Number of toes : Out of 805 birds, 712 had 4 toes on each foot ; 68, had 5 on each foot ; 1 had 6 toes on each foot, 20 had 4 on one foot and 5 on the other, 4 had 5 on one foot and 6 on the other.

Leg colour : yellow 392 : total 520 birds.

Lobe colour : Out of 520 birds, 140 had red ear lobes ; 15 hens with red ear-lobes laid white-shelled eggs.

1918 : *Plumage colour :* White 296. Total 479 birds.

Number of toes : 470 out of 516 had 4 toes on each foot.

Leg colour : yellow legs 445 ; total number of birds 500.

Lobe colour : Out of 479 birds, 119 had red ear lobes ; only 3 of the hens with red ear-lobes laid white-shelled eggs.

1919 : *Plumage colour :* White 390 : total number of birds 436.

Number of toes : Out of 437 birds, 428 had 4 toes on each foot and 9 had 5 toes on each foot.

Leg colour : with yellow legs 397 ; total number of birds 435.

Lobe colour : Out of 433 birds, 150 had red ear-lobes, and of these, 13 laid white-shelled eggs.

1920 : The total number of hens with red lobes that laid white-shelled eggs was 45. As to the number of toes, 664 had 4 toes on each foot, 16 had 5 toes on each foot, 2 had 4 toes on one foot and 5 on the

Lobe colour: 19 white; 3 nearly white; 1 one-half red and one-half white; 1 nearly red; 24 in all.

1914: *Plumage colour:* White 68: other colours 95.

Number of toes: of 188 chicks, 137 had 4 toes on each foot; 39 had 5 toes on each foot; 12 had 4 toes on one foot and 5 on the other.

Leg colour: yellow 69, white 81; the rest (out of a total of 136) had legs of the following colours; yellowish, yellowish white, greenish yellow, blackish yellow, white with a few spots, willow, and black.

Lobe colour: Red 7, the rest of the birds had lobes varying from white to red. Total number 163.

1915: *Plumage colour:* White 25; other colours 64.

Number of toes: Out of 395 birds, 308 had 4 toes on each foot, 68 had 5 on each foot, 14 had 4 on one foot and 5 on the other, 5 had 5 on one foot and 6 on the other.

Leg colour: yellow 42, white 39, the other birds had legs of all shades from white to yellow. Total number 90.

Lobe colour: Red 15; nearly red 19; 23 one-half red; 13 white, the rest being white and red. Total 90 birds.

1916: *Plumage colour.* White 46; other colours 132.

Number of toes: Out of 337, 268 had 4 toes on each foot; 39 had 5 on each foot; 12 had 4 on one foot and 5 on the other.

Leg colour: yellow 97, white 64; the rest were of all shades from yellow to white. Total number 170.

Lobe colour: Red 47, nearly red 39, white 10. Total 160. 2 fowls with red ear-lobes laid white-shelled eggs.

1917: *Plumage colour:* White 208: other colours 311; total 519.

Number of toes: Out of 805 birds, 712 had 4 toes on each foot; 68, had 5 on each foot; 1 had 6 toes on each foot, 20 had 4 on one foot and 5 on the other, 4 had 5 on one foot and 6 on the other.

Leg colour: yellow 392: total 520 birds.

Lobe colour: Out of 520 birds, 140 had red ear lobes; 15 hens with red ear-lobes laid white-shelled eggs.

1918: *Plumage colour:* White 296. Total 479 birds.

Number of toes: 470 out of 516 had 4 toes on each foot.

Leg colour: yellow legs 445; total number of birds 500.

Lobe colour: Out of 479 birds, 119 had red ear lobes; only 3 of the hens with red ear-lobes laid white-shelled eggs.

1919: *Plumage colour:* White 390: total number of birds 436.

Number of toes: Out of 437 birds, 428 had 4 toes on each foot and 9 had 5 toes on each foot.

Leg colour: with yellow legs 397; total number of birds 435.

Lobe colour: Out of 433 birds, 150 had red ear-lobes, and of these, 13 laid white-shelled eggs.

1920: The total number of hens with red lobes that laid white-shelled eggs was 45. As to the number of toes, 664 had 4 toes on each foot, 16 had 5 toes on each foot, 2 had 4 toes on one foot and 5 on the other, and 2 had 5 toes on one foot and 6 on the other. Total number of birds 684.

Of the 464 cross-bred chicks 155 had red lobes, 64 had nearly red lobes, 64 had three-fourths red lobes, 80 had one-half red lobes, 28 had one quarter red lobes, 51 nearly white lobes and 23 white lobes. Of the 472 chicks, 470 had yellow legs and beak and 2 had white legs and beak. Of 433 cross-bred chicks hatched from the white matings, 401 had white plumage, though a few males showed some brass on the back.

30 birds had Red Pyle markings varying from very heavy, with buff, running into other sections, to very light, with only a touch of buff on head, or buff, or red, on shoulders of males.

3 birds were white with black splashing, or ticking, or both. Out of 35 cross-bred chicks hatched from the buff-breasted matings, 24 showed Red Pyle markings in some degree, 1 poor Dominique markings, 1 poor Brown Leghorn markings, 3 poor, or light, Dominique markings with splashings of buff or white, 4 white splashed with grey, buff, red, or black, or a combination of these colours; 1 white with a little buff on the surface, 1 brownish-black stippled and shafted with buff, buff lacing on hackle, and white lacing, or spangling, and salmon on breast.

The live-weight of 208 pullets hatched in 1920 averaged 4.28 lbs. while the cockerels weighed on the average 6.25 lbs.

About January 1, 1921 the weights of birds of different ages were as follows:

	Cross-Bred Cocks average weight
Hatched in 1918	6 666 lbs.
» » 1919	7.15 »

	Cross-Bred Hens average weight
Hatched in 1916	6.3 lbs.
» » 1917	5.6 »
» » 1918	5.38 »
» » 1919	5.87 »

One cockerel whose age was unknown, as it had lost its leg-band, weighed 8.1 lbs.

The colour of the plumage may be said at the present time to be quite fixed; the colour of the ear-lobe, however, still varies much, although a considerable number of the fowls have the red ear-lobe that is required. The proportion of five-toed birds with white legs is very small, so that 4 toes and yellow legs may be regarded as fixed characters.

In body type, there has been wide variation but a long body has now been obtained though it is not always carried in a horizontal position.

The colour of the eggs has been the most difficult character to fix, but the fact that numerous individuals have been obtained possessing red lobes and laying white eggs, encourages the belief that the fixation of this combination of characters is merely a matter of continued breeding and infinite pains in selection.

943 - **Contribution to Our Knowledge of Sex Formation in Bees** (1). — JEGEN, G. in the *Schweizerische Bienen-Zeitung*, Year XLIV, No. 6, pp. 217-221. Aarau, June, 1921.

The generally-accepted theory ot the present day is that false-drones come from unfertilised eggs, and that the males from the eggs of unfertilised queen-bees, queen-bees that are too old, or male-bearing workers are capable of fertilising.

Recently, however, the author has tried to follow, with the help of cytological researches, the maturation of the sperm-cell of males produced by the eggs of working-bees. He subsequently carried out experiments in the open, in order to discover whether abnormal false drones actually possess the power of fertilising.

On examining the phenomenon of arrenotokia due to the absence or infertility of the queen-bee, and taking into account what happens in a normal colony, we unavoidably come to the conclusion that the function of arrenotokic workers in its present form can only be a secondary kind of reproduction, which was once natural, but has been modified in the course of time, on account of altered life conditions. We may even ask whether it is not an atavic return to the capacity of laying normal eggs, and consequently whether the males now coming from such arrenotokic eggs are not degenerate products.

The examination of males produced by arrenotokic workers has revealed that at the time of the maturation of the sperm-cell, there is hardly any mitosis properly so-called, and further, that the spermatozoa undergo premature degeneration in the spermiducts.

The karyokinetic division giving rise to the two polar bodies is very indistinct, and sometimes entirely wanting, which alone is enough to show that we have here to do with the abnormal maturation of a reproductive cell on the point of degeneration. Further, it is noticeable, that the production of active spermatozoa does not take place in most of the false-drone nymphs in the more advanced larval condition. In fact, mating these abnormal males with normal females has given negative results; in no case did the female lay normally.

Males produced by arrenotokic workers are thus incapable of fertilising. From what has already been said, the question that now presents itself is, whether virile males produced by normally fertilised females really come from unfertilised eggs. In this connection, the author draws attention to the fact that the observations made during the maturation of the sperm-cell render it probable, that there are two kinds of spermatozoa, one with 8 chromosomes coming from the spermatid, and another with 9 chromosomes derived from the second polar body, in which case, this third element would seem to represent a specific sexual chromosome determining the male sex.

Allowing that both kinds of spermatozoa are active, it appears very possible that, owing to food and temperature, the spermatozoon determining the male sex may be active in the body of the queen-bee, and at the time only such spermatozoa leave the spermatheca fertilising the ova as they pass into the oviduct, but that when the action of the stimulating factors ceases, the specific spermatozoon loses its power.

---

(1) See *R.*, Feb., 1920, No. 240 and March., 1920, No. 351. (*Ed.*)

The data so far obtained do not permit of any definite conclusion being reached, and in order to prove which theory is correct, it will be necessary to collect and examine the results of further observation and of other careful experiments.

FARM ENGINEERING

944 - **The Spring International Exhibition of Motorculture, Paris Febrauary 10-20, 1921** (*1). — I. Bonnamaux, H, in *La vie aux champs*, Ser. 3, No. 11, pp. 6-9, figs 7, Paris, Jan. 25, 1921. — II. *Bulletin de la Chambre Syndicale de Moto-culture de France*, No. 8, pp. 4-5. Paris, Jan.-March 1921.— III. Diffloth P., in *La vie agricole et rurale*, Year 10, Vol. XVIII, No. 15, pp. 229-234, figs 3, Paris, Apr. 9, 1921.

The exhibition of motorculture, which opened on February 10 on the race course of Vincennes, was organised by the "Chambres syndicales de la Motoculture française et des fabricants d'appareils agricoles".

II. — The following firms exhibited :—

Machinery.

Agricultural, 25, route de Flandre, Aubervilliers :— "Holt," "La Crosse," "Samson" tractors.

L'Agro (limber tractor), 116-bis, rue de Tocqueville, Paris :— "Agro" tractors.

Allied Machinery Company of France, 19, rue de Rocroy, Paris :— "Cletrac" tractor.

Amiot, H. (Societé Anonyme la *Charrue Automobile*), 8, rue de la Victoire, Paris :— "Gerbe d'or" motor plough.

Ara (appareils routiers agricoles), 2, rue de Vienne, Paris (8e): — "Ara" tractor.

Ateliers de Construction de Chatou, 37, boulevard de la République :— Chatou tractors-haulers.

E. Bauche & Cie, Le Chesnay près Versailles :— Bauche motor-hoe.

Beauvais et Robin, 31, rue de Maine, Angers :— "Amanco" tractors.

Blum & Cie, 8, quai Gallieni, Suresnes :— Tourand-Latil tractor.

Bocquentin, 15, boulevard des Italiens, Paris : "Praga" motorplough.

Borel (Etablissements), 64, quai National, Puteaux :— "Rumely-Oil-Pull" tractor.

Bouzinac, 33, rue Rousselle, Puteaux :— Supplementary cultural implement.

---

* Most of the models exhibited are well known and have been described in the *Review of Agricultural Intelligence and Plant Diseases*, June, 1919 No. 768; Oct.-Dec. 1919, No. 1222; March, 1920, No. 354; June, 1920, No. 686; thus, among *windlass traction apparatus* :— the De Dion-Bouton apparatus for power cultivation (2); Albert Douilhet windlass (4); Filtz-Grivolas hauler (4); Agro limber tractor (3) among the *motorploughs* :— Gerbe d'Or (3); Tourand Latil (1), Excelsior (3), Piaga (3), Moline (2), Rip (2), Chapron (1); and among the *direct traction apparatus* :— the Fiat (3), Scémia V., Nilson (3), Austin (2). Ford (2), Rumely (3), Sanduski (3), Renault (3), Neverslip (3), Oncle Sam (5) etc. tractors. New comers and those which have been more or less modified or previously described in this Bulletin with less detail, are described in the Article.

(1) See *R.*, June, 1919, No. 768. — (2) See *R.*, Oct.-Dec., 1919, No. 1222. — (3) See *R.*. (March, 1920, No. 354. — (4) See *R.*, June, 1920, No. 686. — (5)See *R.*, June, 1921, No. 664. *Ed.*)

Case de France (Compagnie), 251-253, faubourg Saint-Martin, Paris :— Case tractor.
Chapron B., 45, rue de la République, Puteaux :— Chapron motor plough and tractor.
C. I. M. A., 155, avenue du Général-Bizot, Paris :— "Titan," "Mogul" and International tractors.
Dens & Cie, 5, cité Trévise, Paris :— Sandusky tractor.
De Dion Bouton, quai National, Puteaux :— De Dion ploughing windless.
Doriot, Flandrin et Parant, 105, boulevard Saint-Denis, Courbevoie :— "César," D. F. P. vineyard tractor.
Douilhet, 9, rue Marcellin-Jourdan, Caudéian :— Douilhet ploughing windlass.
Dubois, R., 130, avenue de Neuilly, Neuilly :— R. D. Tractor.
Dupuy, G., 31, rue Poussin, Paris :— Midwest Utilitor " tractor.
Egret, J., 48, boulevard du Temple, Paris ·— Supplementary cultural implement
Ch. Faul et Fils, 47, rue Servan, Paris :— John-Deere tractor.
Fiat, 115, avenue des Champs-Elysées Paris :— " Fiat " tractor
Ford (Automobiles), 33-37. boulevard Albert 1er, Bordeaux :— "Fordson ' tractors.
General Motors export Company, 63, avenue des Champs-Elysées, Paris :— "Samson" tractors.
Globe, 28, rue Saint-Lazare, Paris :— "Globe" tractor
The Johnston Harvester Company, 148, boulevard de la Villette, Paris: — Supplementary cultural implement.
Lacour & Fabre (de), 60, rue de la Chaussée-d'Antin, Paris :— "Le Gaulois" tractor.
Lambert-Rivière (Société Commerciale), 45, avenue de la Motte-Piquet, Paris :— "Holt, International" "Mistral" tractores.
Mahieu et C.ie, 55, rue de Prony, Paris :— "Oncle Sam" tractor.
Massey Harris, 138, avenue Jean-Jaurès, Paris :— Supplementary cultural implement.
Matériel Agricole Messidor, 208, boulevard Felix-Faure, Aubervilliers :— T. P. Vine cultivators and cultivators.
Moline Plow Company, 159-bis, quai de Valmy, Paris :— Moline tractor.
Nemours Trading Corporation, 63, boulevard de Picpus, Paris :— Emerson tractor.
Oliver Chilled Plow Works, 75, boulevard de Picpus, Paris : — Supplementary cultura implement.
Perrier, H., 102-106, avenue Philippe-Auguste, Paris :— Supplementary cultural implement
Pilter, Th., 24, rue Alibert, Paris :— Austin-Avery tractors.
Ravaud, A., 1, rue des Italiens, Paris :— "Excelsior" motor-plough.
Renault, L., at Billancourt: — Renault agricultural and forest tractors.
Rip (Machines Agricoles), 12, rue Boissy-d'Anglas, Paris :— "Rip" tractors.
S. C. E. M. I. A., 9, rue Trouchet, Paris :— "U. 20 Scemia" tractor.
Société Agricole, Industrielle et Commerciale du Sud-Ouest. 65, allées Jean-Jaurès, Toulouse :— "Twin-City" tractor.
Société Auxiliaire Agricole, 47-49, rue Cambon, Paris :— "Agrophile-Pavesi" tractor.
S. O. M. U. A., 19, avenue de la Gare, Saint-Ouen :— "Somua" motor cultivators.
La Traction et le Matériel Agraires, 18, rue de Mogador, Paris :— "Nilson," "Agro," R. "Beemann" tractors.
R. Wallut & Cie, 168-170, boulevard de la Villette, Paris : — Mac Cormick tractors.

LUBRICANTS.

Société andré Fils, 8, rue de la Tour-des-Dames, Paris.
Vacuum Oil Company, 34, rue du Louvre, Paris.
Société d'Exportation Industrielle, 1 rue Blanche, Paris.

TRACTORS FOR POWER FARMING.

III. — (1) The Mistral tractor of the CULTURE FRANÇAISE — It has the fewest possible parts. The parts can be taken out separately and are easily accessible. The triangular suspension, the selection of raw material as well as the very high coefficient of safety of the parts, make it a very strong apparatus.

The maximum out-turn is obtained thanks to:—

(1) The choice of the motor and radiator.
(2) The minimum of intermediate transmission parts and perfect suspension.
(3) The rational use of ball bearings.
(4) The entire adhesion to the ground without useless extra weight (the apparatus weighs only 1775 kg.) by means of its special strakes.
(5) The absence of a differential and the arrangement for disengaging the driving wheels. This prevents noise: the apparatus never gets stuck and clears obstacles easily.

The system of disengaging one driving wheel, right or left, enables the *Mistral* tractor to turn in a radius of 1.20 m. The headlands are thus reduced to a minimum.

The shape of the wheels in front ensures good steering of the apparatus. Its centre of gravity being very low, the *Mistral* tractor can be very much inclined for work in hilly ground.

Simplicity, strength and power ensure to the *Mistral* tractor the rapid amortisation of its purchase price and a low consumption of oil and fuel (petrol or paraffin at the choice of the purchaser).

(2) Samson Tractor has the following characteristics:— Vertical motor; 4 cylinders; 102 mm. bore; 140 mm. stroke; developing 20 H. P.; 10 H. P. at the bar. Fuel petrol or paraffin. Speed:— 2 forwards, 3 km. and 4.5 km.; 1 backwards, 2 km. Weight, 1400 kg Radius of turning 3.50 m. capacity of tanks:— petrol 12 litres, paraffin 75 litres.

(3) Amanco-Hart-Parr paraffin Tractor 30 HP. — It is characterised by the following essential points:— A simple, solid construction, result of 20 years of experiment; an economical output of work which can attain 40.79 (Bourges competition, August 1920) and even 54 ares per hour (Thorenbais-les-Béguines, Belgium, September 1920).

The consumption of ordinary paraffin used was 27 litres (Bourges competition, 1920) and 24 litres (Belgium competitions, 1920) per hectare.

I. — (4) Delieuvin Tractor. — Progresses on wheels. Previously entered only at the Chartres demonstrations (Autumn, 1920). It is characterised by an ingenious auxiliary gripping arrangement formed of 2 very light wheels placed behind the back axle and moved by the latter by means of a chain. These wheels furnished with stakes are normally raised by a spring, but are pressed strongly on the ground as soon as the resistance of the plough to forward movement becomes too great. This enables the tractor to exert an adhesion which is a function of the tractive effort and increases with it.

VINEYARD AND HORTICULTURAL APPARATUS.

(5) CHAPRON Tractors of 13-18 H. P. and 15-20 H. P. (1) and motor ploughs of the same maker of 10-15 H. P. and 15-20 H. P. — In the last-named apparatus the working parts are collected immediately behind the driving wheels to facilitate very sharp turning.

Each tractor has 2 means of steering, one acting on the driving wheels, the other on the small hack wheel placed under the seat of the driver, enabling the plough to be guided easily on steep slopes and the apparatus to be turned round almost on its own axis between the rows of vines. The driver, having in front of him all the steering apparatus, can control his work and regulate exactly the depth of work of the shares. The motor, which is very flexible, can run at from 300 to 1200 revolutions a minute. All the parts are made of hard nickel-chrome steel.

III — (6) The R. D. tractors are suitable for farming on a small scale and vineyards. Its small dimensions (total width, 0.95 cm.; base, 1.50 m.) enables it to move about freely in the thickest vineyards without fear of injuring the growth or uprooting the vines: it is easily capable of ploughing to a depth of 13 cm., and deeper in light soils; all cultivating implements — ploughs, harrows, rollers, cultivators, etc. — can be attached to it. Transmission is insured by 2 speed gears always in action, with optional disengagement of one or the other; the speed per hour is about 2 km. on the first and 5 km. on the second speed gear, the first including the reverse movement: the back wheels are driven by chains enclosed in sheet steel cases; a special mechanism allows of the automatic disengagement of one of the wheels when turning: in that case the whole motive power can be brought to bear on a single wheel, right or left; this arrangement enables very sharp turns to be made (about 3 metres diameter) and the deepest ruts to be got out of without difficulty.

The motor has two speeds: one of 500 revolutions a minute developing, stationary, 8 H. P. on the shaft; automatic regulation for the control of threshing machines, root-cutters, straw-choppers, etc.; the other of 800 revolutions developing a tractive force of 12 H. P.; working with petrol or paraffin as desired.

Being easy to drive, this apparatus is specially suitable for maimed persons. Model A is arranged so that it can be used as a locomotive on rails with 0.60 and m. 0.70 m. tracks.

I. — (7) The BREMANN hoer (2), used for market-garden cultivation. Its single cylinder 6 H. P. motor takes the place of a strong horse and allows of ploughing with a single plough or drawing a hoe, a sprayer, a harrow. It is chiefly used for cultivating in vineyards, where it draws a vine-dressing hoe and ploughs for earthing up and uncovering. It consumes about 3 4 to 5 litres of petrol.

---

(1) See *R.* Mar. 1920, No 351 (*Ed.*)

(2) See *R*, March, 1920, No. 354 (*Ed*)

(8) The small 6 H. P. SOMUA apparatus, which works by means of a rotary tiller consisting of flexible teeth that cut the soil, is well suited for cultivating gardens.

(9) The PETARD and PREJEAN rotary cultivator (1).

III. — (10). The Midwest Utilitor. — This small tractor advantageously replaces a horse, for it does double the work at half the cost. It passes through vineyards and can till the smallest plot of ground. It is easily driven with a simple pressure of the fingers on the handles The machine itself supports its heavy parts which have not therefore to be held up as with an ordinary plough. The motor has an effective force of 4 H. P. and consumes little; it is therefore a quiet horse which is never tired. In fact, when it has finished work in the fields, by placing a belt on the pulley, it can be made to work any machine such as a churn, skimmer, threshing machines, pump, saw, etc. and most of the mechanical apparatus used on a farm.

The *T. P. Rotary Cultivator and Vine cultivator* is a mixed motor-cultural apparatus (weight 550 kg.) which can be drawn by a horse, an ox, a mule or even by an ass. It does not compress the ground and it does away headlands.

Its use enables implements (hoeing, rotary harrowing and all tillage operations up to 15 cm. in depth by 90 cm. in width) to be run rapidly over the ground. Its track is 80 cm. wide.

The driver has not to use force in his work, and as a seat is provided he can put in a long day's work.

The apparatus, working at the speed of a horse walking, can work up to 3 or 4 hectares in 10 hours. The motor only serves to rotate the implements; the fuel consumption is only 15 to 22 litres a day according to the depth of the work done. In vineyards and among plants in lines the nominal area worked is estimated at 6 ha. per day (depending on the spacing of the plants).

The T. P. Rotary Cultivator and Vine Cultivator ingeniously combines animal traction and mechanical working for vine cultivation, cultivation in lines in market gardens and in the Colonies.

PLOUGHS.

Among new ploughs, M. DIFFLOTH notes: — The reversible MESSIDOR ploughs for flat ground, which can be coupled behind any tractor. The MESSIDOR plough consists essentially of a supporting frame attached behind the tractor and supporting the mechanism for regulating the depth of ploughing. This frame is carried on two wheels in front, one of which, on the ploughing side, keeps the machine straight, and on a pivoting back axle mounted on two articulated wheels which automatically straddle the side of the last furrow.

On the supporting frame the body of the plough itself is jointed moving up and down round a strong longitudinal axle enabling one or other of the two series of mould-boards, coulters and cutters, arranged at right-angles on the structure, to be put into position for ploughing. This moving up and down is operated by means of a flywheel situated near the driver and working a simple mechanism requiring only a very small effort to be set in motion. Projections which can be regulated limit the up and down movement and oblige the driver to put his plough always in the desired position for ploughing. It is impossible for the driver to make the plough work in any position except that fixed by the projections, which ensures perfect regularity of the work.

---

(1) See *R.*, Oct-Dec, 1919, No. 1222. (*Ed.*)

With the Messidor plough a high yield of power and great economy in working can be obtained from the tractor to which it is attached.

The tractor moves entirely on the unploughed land, thus using the minimum power for moving; there is much less wear of its parts and its wear and tear is reduced by a half.

With this apparatus any tractor can move backwards without unhitching the plough, so that it is possible to plough plots which cannot be ploughed with motors working with ordinary ploughs.

The regularity of the ploughing is the outcome of the simplicity of its regulation, of the symmetry and the automatic working of the arrangements for coupling, control and of handling. The moving up or down of the plough, turning, transport, are effected without touching any of the regulators affecting the ploughing.

The point of traction can be regulated and the coupling arrangement gives automatically the desired inclination to the plough, according to the side towards which the band of soil is turned. As the plough is entirely supported on its own wheels, ploughing is not effected by the movements which the tractor may make in crossing hollows or lumps in the fallow. It is automatically guided by the " bordayage " of its wheels, which ensures that the furrows are parellel.

The supports, the coulters and the cutter stems can be regulated in slope and spacing at the will of the operator. The coupling is arranged so as to have no effect on the adhesion or the steering of the tractor. The tractor, moving entirely on the fallow, does not crush the ploughed soil, does not compress the bottom of the furrow and the headlands, reduced to a minimum, are never trampled down, as the tractor never repasses over the same places.

The most usual type of Messidor plough is the three gang type which can plough to all depths down to 28 cm. and take a band 90 cm. wide. This model can be transformed in to a double plough by rapidly dismounting the two hind ploughs. This apparatus can be turned into a light double plough for certain tractors and into gang plough types with great ploughing width for special requirements.

The double Brabant plough is a fairly heavy implement, large and difficult to handle at the ends of the farrows. The application of the new limber with movable axle under the frame has entirely modified the working conditions of this plough.

A new double Brabant plough:— Victoire, is shown by the firms of Filtz and Grivolas. This arrangement constitutes an interesting experiment made in modernising our old agricultural implements; it is applicable both to light double ploughs drawn by animals and to heavier implements that can be coupled to agricultural tractors and can plough to depths of 20 to 25 cm.

This latter class of plough is therefore recommended to owners wishing to use tractors for cultivating level ground.

The axle is movable, and is fixed to the lower ends of two uprights acting as supports to the implement and jointed about their upper third round two gudgeons situated on the same axis and placed on the frame of the plough on the right and left of it. These two uprights can therefore turn round that articulation and their upper parts, slightly bent, form arms which can occupy all positions on a sector; the free ends of these arms are pulled forward by the action of two strong spiral springs which at the same time draw the axle backwards. That axle, is, when starting, drawn forward by the coupling itself by means of a rod and by the hauling chain, this latter first exerting its force on that axle, and afterwards mainly on the head of the plough itself. During this time the uprights turning round their axis take up a more or less inclined position determined by the extreme position of the arms coming against pins whose position on the sectors can itself be modified.

A depression of the whole plough results, which, coinciding with the starting of the plough produces gradual embedding in the soil, the springs acting as shock absorbers for both the plough and the tractor. That depression being capable of limitation at will, according to the position in which the pins are placed, it is evident that the moving of the said pins forms a very practical means of regulating the depth of ploughing.

As soon as traction ceases, the chain being no longer stretched, the action of the springs alone is effective, and the supports leave their inclined position and take up a vertical position, at the same time bringing back the axle of the plough to its back position or position at rest.

This change in the inclination of the supports has the effect of raising the frame of the plough causing automatically a partial unearthing of the ploughs. The bringing back of the axle, and consequently of the wheels, to an extreme backward position, brings back the line of support of the plough under a point near to its centre of gravity. It results that a large part of its weight passes in front of that line and that it becomes lighter behind and consequently easier to turn.

In conclusion the Desprez dynamometer may be noted, a simple and strong apparatus with which it can be ascertained when the tractor is about to furnish its normal force and avoid overworking it.

AGRICULTURAL INDUSTRIES

945 – **Wine Makng in the Province of Mendoza, Argentina.** — See No. 923 of this *Review*.

946 - **The Use of "Wood" Wool for Filtering Wines.** — MARESCALCHI, A., in *L'Italia vinicola e agraria*, Vol. XI, No. 10, pp. 148-149. Casale Monferrato, March 6 1921.

The "wood wool" generally used in packing is made from very thin, fine shavings of soft wood (poplar or willow).

For the last 5 years, owing to the law prohibiting the use of pomace for filtering wine beyond the limits fixed by the prefects, the use of these shavings as a filtering material has become very common in Italy. The method of preparing it, which has been improved by M. Angelo Pansera, is as follows:— The thin shavings are well beaten to free them from dust, and then soaked in water for at least 2 days, the water being renewed daily: the water is alloved to drain off, and the shavings pressed. Then they are are put to soak for 2 days in water to which 500 gm. of tartaric acid per hectolitre have been added. Finally, the shavings are pressed, and afterwards they are ready for use. They are placed in the vat and pressed down in such a way as to come only a little above half its height (5 or 6 kg. are required per hectolitre of the capacity of the vat), planks being placed on the top to keep them under pressure. The filter thus prepared is used just as if it was pomace. It lasts for years, as after washing, it can be employed again, for it does not ferment in the summer, become sour, or alter in any way. Its use imparts absolute clarity to the wine. This filter can also be adopted for musts and vinegar, or for the first filtering process during the usual time the pomace is kept. It is advisable to make two filters, one for wines with a good deal of sediment, and the other for ordinary wines in general use.

947 - **Results of Experiments Carried Out in Italy at the University Scientific Laboratories on Specimens submitted to Them by the National Scientific and Technical Committee for the Growth and Development of Italian Industry.** — I. PERATONER A. (Direttore del Laboratorio di Chimica farmaceutica della R. Università di Roma). — II. PELLINI, G. (Direttore del Laboratorio di Chimica farmaceutica della R. Università di Palermo). — III. PIUTTI, A. (Direttore del Laboratorio di chimica farmaceutica della R. Università di Napoli), in *Bollettino scientifico-tecnico, Periodico bimestrale per gli Atti del Comitato nazionale scientifico-tecnico per lo sviluppo e l'incremento dell'industria italiana*, Year III, No. 2, pp. 72-73., Milan, March-April, 1921.

I. STUDIES OF THE PRINCIPLES CONTAINED IN PLANTS WITH MEDICINAL OILS IN SOUTH ITALY AND THE COLONIES. EXPERIMENTS ON THE CASTOR OIL PLANT. — In 1918-1919, the seeds of 40 varieties of *Ricinus* cultivated in the Royal Botanic Gardens of Naples were studied. In the first place, their oil content was determined, not only by means of extraction with ethyl ether, by also by pressure with, and without, heat. The following varieties yielded the largest proportion of oil:—

	Per cent.
Ricinus sanguineus (from Legnago)	56.085
» » local	56.47
» » from Vilmorin	55.45
» *Scafati* pale	54.475
» » red	53.795
» *Borboniensis*	52.605

In spite of their large oil yield, the following varieties are not to be recommended: —

Ricinus zanzibariensis dwarf	55.215
» » red	53.83
» » blood-red	52.245
» *Gibsoni* blood-red	55.05
» *viridis* (from India) pale	51.575

R. zanzibariensis, on account of its small production of seeds; *Gibsoni* because its capsules are dehiscent, and the seeds get lost, *viridis* as being a plant of inferior development and hence of low yield.

On the other hand, the *sanguineus* varieties and those cultivated at Scafati (both the red and pale kind) are strongly to be recommended. The *Borboniensis* variety, although apparently productive, is subject to fungoid disease, and should therefore be excluded.

In order to determine the purity of commercial castor oils, a method was then devised by which it was possible to estimate very easily and rapidly the amount of ricinolein they contain. On allowing phosgene (carbonyl chloride), to bubble gently through oil heated at 100°C., it reacts quantitively and gives a trichlor derivative of ricinolein, insoluble in alcohol, differing in this respect from castor oil, and heavier than water. This chlor-derivative is easily separated from the dissolved phosgene, if heated to 50-60°C., and the absorbed chlorine is then determined by the PIRIA-VOLHARD method. If castor oil were entirely composed of ricinolein, the theoretical amount of chlorine (chlorine index) would be 9.49 %; in practice it varies in oils taken from different varieties of *Ricinus* between 8.9 % and 9.2 %. Other oils (those from olives, almonds, cotton, sesame, groundnuts, etc.) fix amounts of chlorine varying between 0.08 % (almonds), and 0.19 % (groundnuts), therefore their addition to castor oil decreases the chloride index proportionally. The method has been tried with good results on artificial mixtures of different oils and castor oil.

Oil from thorn-apple seed (*Datura Stramonium*). — This is obtained by extraction with carbon disulphide and ether; in both cases, the yield varies round about 25 %, but the oil especially when extracted with ether, contains a certain amount of daturin (atropin) which renders it very active biologically. It is being used experimentally at the present time in several clinics for diseases of the eye and in one medical clinic.

Otto of Roses. — Some varieties of rose were grown for their essential oil by Prof. CAVARA at the Royal Botanic Gardens of Naples. Excellent results were obtained from the flowers of *Rosa Hayi* and *Rosa Brünner* by extraction with petroleum ether. An oil with very strong scent was procured by first freeing it from the wax by means of absolute alcohol and evaporating the latter in a vacuum. Anticaïn can also be easily extracted from *Rosa Hayi* which can be well substituted for the sunflower in laboratories.

Other essential oils. — These have been obtained from the seeds of fennel (*Foeniculum* sp.), the leaves of balm (*Melissa officinalis*) and the leaves of bay (*Laurus nobilis*) ; a large number of other plants are being studied such as foxglove (*Digitalis* sp.), marjoram (*Origanum* sp.), lavender (*Lavandula* sp.).

II. STUDIES ON THE PRINCIPLES THAT CAN BE EXTRACTED FROM THE MEDICINAL AND PERFUME PLANTS OF SICILY. — The experiments began by distilling the essential oils obtained. The following plants have been studied :— *Origanum siculum* (var *Bentham*) ; *Ruta bractosa ; Myrta communis ; Eucalyptus Globulus ; Mentha Pulegium* (var. *hirsuta Gussonei*) ; *Calamintha Nepeta ; Santolina Chamaecyparissus ; Chenopodium multifidum ; Rosmarinus officinalis.*

One fact worthy of mention is that the essential oil of the Sicilian marjoram which grows wild in many parts of the island is largely used there as a condiment. The variety examined contained 49.5 % of phenol (entirely consisting of thymol except for traces of a phenol which was not identified). About 98 % of the essential oil of *Ruta* consists of methylheptylketone and methylnonylketone, the former predominating (it makes up about $^2/_3$ of the whole).

III. — STUDIES ON THE JUICE OF CITRUS FRUITS AND ITS MORE SYSTEMATIC COMMERCIAL UTILISATION. — The object of these researches was to study the best means of keeping the fresh juice (to be used as a food or beverage) in a condition suitable for export and to devise a suitable method of collecting and purifying it.

In order to preserve the juice of lemons none of the usual chemical anti-ferments must be employed as the Italian Health Regulations prohibit their use. The only anti-ferment allowed, sulphurous acid, imports an unpleasant acidity to the juice. Sterilisation by heat in an autoclave and pasteurisation give the juice a boiled taste that prevents its use as a beveragé. An attempt is to be made to by hydrogen peroxide and ozone.

Satisfactory results are apparently obtained by concentrating it in a vacuum at temperatures not above 50°C.-60°C., a concentrated extract representing from $^1/_8$ to $^1/_{10}$ of the juice being produced. It is a dense, yellowish liquid of the consistency of honey, which whep poured into moulds, sets in a gelatinous mass

If some grammes are dissolved in a glass of water the solution has the pleasant flavour of fresh juice.

The sterilisation of lemon juice by means of ultraviolet rays has also been attempted.

In the commercial preparation of this juice, the present methods of pressing the fruit must be abandoned. For this reason the author has been led to study a new treatment of the fruit, with a view to removing by mechanical means the superficial coloured external portion of the fruit alone. This contains the oil-bearing glands and the essential oil. The white part of the cortex is left untouched as far as possible.

Microtome sections of the outer cortex have been made and the thickness of the oil-bearing layer thus determined.

The fruit after this thin, external layer is removed, is cut in the direction of its short axis into two equal halves. The knives used for the operation are of silver, or heavily-plated metal, bronze, phosphorised aluminium, or of horn.

The juice is not extracted by a press, but with a special mechanical apparatus consisting of rotating glass lemon squeezers. The remains of the lemons are put into an ordinary press to extract the remaining juice. The lemon juice is then filtered, in a stone-ware centrifugal filter, not a filter-press. A knitted cloth, not a woven cloth, is used for filtering. The receptacles containing the juice must be of stone-ware, and the tubes must either be of stone-ware, glass, or commercial fused quartz.

If a concentrated extract is needed, the copper bowl should be heavily plated with silver, not tinned.

948 - **Paper Pulp Supplies from India. I. Chemical-Enquiry. II. Preparation of Bamboo Prior to Digestion.** — RAITT, W., (Cellulose Expert to the Government of India, attached to the Forest Research Institute, Dehra Dun, India), in *Journal of the Royal Society of Arts*, Vol. LXIX, No. 3579, pp. 509-517. London, June 24, 1921.

The Indian Forest Research Institute has made a careful study of the paper pulp question and amongst all the various plants suggested as utilisable for paper manufacture, has found so far that only 2 small groups, both belonging to the Gramineae are economically sound as regards the quantity and quality of their cellulose and the manufacturing conditions under which they can be exploited. These are bamboos and Savannah grasses. The author estimates that taking everything into consideration, Burma, Bengal and South-West India could produce 10 million tons of pulp per annum, and Assam 3 million (from Savannah grasses). The possibilities and present state of affairs as regards bamboo cultivation has been described by PEARSON in *The Indian Forester*, Volume XLVI, Nos. 11 and 12 (1). The author in the present paper confines his statements chiefly to the chemical side of the question, and the problem which interests the paper manufacturer, namely, the getting into solution of the non-cellulose constituents of his raw material.

The preparation of bamboo prior to digestion has given rise to some difference of opinion, and the author draws attention to the physical and constructional features associated with bamboo and the consequent effect of crushing or chipping, the two preparatory treatments now in vogue. The fibre brindles of bamboo lie perfectly parallel to each other with no cross graining and interlacing; they split cleanly and crush perfectly without reducing to dust. Groups of sap canals are abundant, which run parallel thoughout the whole length of the stem. In the dry material these are filled with air, which being in a state of capillarity is extremely difficult to dislodge, and in the case of chips, offers a powerful resistance to the penetration of liquor, besides adding to the buoyancy of the mass and tending to float a portion of it above the liquor. The splitting which is the first effect of crushing, runs along these canals which are thus laid open to attack by liquor on their interior surfaces and the capillary air is eliminated : wood presents no such feature.

---

(1) See *R.* May, 1921, No. 498. (*Ed.*)

Throughout the entire length of stem, bamboo is of homogeneous, one-aged one season growth and therefore must not contain differences in density and quality. In wood there must be a proportion of indigested chips in wood pulp digestion, but there is no need for this in the case of bamboo. The nodes, contrary to general belief, are not denser than the internodes. Their specific gravity is about 5 % less, but they contain more pectose and lignin and their colloidal resistance to liquor penetration is, therefore, greater. The antidote to this is by opening up their tissues completely. By crushing, this can be done so thoroughly that they can scarcely be distinguished in the general mass. As chips they must result in a considerable proportion of undigested specks and blemishes in the pulps.

The author draws attention to one peculiar feature of bamboo relative to which a warning should be issued, viz. the extraordinary phenomenon it exhibits of cyclical gregarious seeding and death. A factory planted in a district without some inquiry having been made as to the seeding cycle, might find itself suddenly bereft of supplies for a prolonged period. There are 2 methods recommended : first, the next seeding period may be known to be at such a date that supplies can be depended upon for a period long enough to secure an ample return in capital invested in the undertaking, and second, the presence in the area of an alternative species which, as is invariably the case, does not flower at the same period.

949 - **Manufacture of Tobacco Shade Cloth.** — Cox, J. W. in *The Textile World*, Vol. LIX- No 21, pp 41-42, figs. 4. New York, May 21, 1921

It has been recognised for some time past that a suitable shade should be provided to protect wrapper leaf from the sun. Many things have been tried and found unpractical for various reasons, and cotton cheese cloth, netting and osnaburg were used on experimental patches. These, however, did only fairly well, and eventually certain cotton manufacturers evolved the present tobacco shade cloth, which is cheap and is found far more advantageous than anything previously suggested. This article explains in general its uses and manufacture.

950 — **The Far-Eastern Lac Industry in France** (1). — Verneuil, P , in the *Bulletin de la Société d'Encouragement pour l'Industrie Nationale*, Year CXX, Vol 133, No 2, pp 179-192, figs 8. Paris, February, 1921.

The lacs of the Far-East, which are not connected in any way with the varnishes known as " laques " in France, or with "gum lac " (or " stick lac "), an animal product derived from the secretions of coccids, are of purely plant origin, being latexes obtained by tapping from various trees cultivated in China, Japan, and Tonkin. Although these trees are now less grown in Japan and China, they are increasingly cultivated in Tonkin, which has for a long time been the only country in the world that exports lacs, some 2500 tons of this product being exported each year.

---

(1) See Lac-Yielding Trees of Indo-china and their Products, *R.*, Feb , 1919, No. 207. (*Ed.*)

Lac is increasingly employed in modern industry, being largely used in aviation (as a protective cover for propellers, etc.), and also in electricity (being unequalled for its insulating properties).

The author studies in succession, the lac-tree of Tonkin (*Rhus succedanea*); the tapping of the latex and preparation of the lac; the native processes connected with its application, which are long, tedious, but very well executed; the physical and chemical characters especially the question of its hardening when exposed to cold and to heat); and its use in modern industries.

Lac has wonderful qualities which render it of paramount importance to industry, but the archaic operations connected with its use, hand-mixing, laying on with a brush, and the endless rubbing down and polishing, are bound to be superseded. They are ridiculously slow and tedious, even in the Far-East, where, at all events in appearance, labour is cheap, and would be an impossible anachronism in France. Such processes absolutely prevent the commercial use of lac.

If this substance is ever to be of any practical utility in industry, it will have to be prepared mechanically. Fortunately, mechanical kneaders have been devised that will answer their purpose very well, and an aerograph system of applying the varnish has been invented. The instrument is a substitute for from 10 to 20 experienced varnishers, according to the extent of surface to be treated. It has finally been announced that rubbing down machines can be had to reduce the endless work of rubbing down propellers and furniture. The author is testing a method for varnishing barrels and all other receptacles with small orifices, which will certainly give excellent results.

951 - **Present Position of the Camphor Industry throughout the World and Notes on Methods of Cultivation Employed** (1). — I. Present Position of the Camphor Industry. *Bulletin of the Imperial Institute*, Vol. XVIII, No. 4, pp. 524-536. London, Oct.-Dec. 1920. — II. Camphor Production and Exports in Japan. *Board of Trade Journal*, Vol. XIV, New Series. No. 1216, p. 400. London, March 18, 1920.

I. The effect of the Japanese monopoly has been to encourage the production of natural camphor in various countries, and has stimulated the efforts to solve the problem of the profitable manufacture of synthetic camphor. Hitherto it has not been found profitable to produce the latter on a commercial scale in competition with the natural product, but the American camphor refiners are seriously considering the desirability of developing the manufacture of synthetic camphor (true synthetic camphor may be made by preparing borneol or isoborneol from pinene hydrochloride or hydrobromide, and subsequently oxidisingit.)

---

(1) See *R.* May 1920, No. 528 and *R.* March 1921, No. 294. (*Ed.*)

The camphor difficulty is, however, not merely a question of the high price of Japanese camphor, but the almost complete absence of the product from the free markets of the world. The production of camphor from leaves (1) in Florida will alleviate the position to some extent so far as the American manufacturer is concerned, but strenuous efforts should be made to obtain supplies by the cultivation of the camphor tree in all countries suitable to its growth, and the home manufacture of synthetic camphor is distinctly advisable whenever possible.

The author gives details of the past and present sources of supply in Japan, Formosa and China, and the future possibilities both in these countries and methods of cultivation now in progress elsewhere in the United States, the British Empire, etc.

JAPAN. — The Japanese Monopoly Board are stated to have planted 3 000 000 trees between 1900 and 1906, and 11 000 000 in the 3 following years, and to have resolved from 1913 onwards to plant 3000 acres with camphor annually for 12 years. About 1270 trees are planted per acre. After 5 years experimental work, it was stated that leaf distillation was to be begun on a practical scale, and it was estimated that 6 500 000 lb. of camphor would be produced annually from these plantations. Although the average yield since then has varied, the yield anticipated for 1921 is from 6 615 000 to 7 938 000 lb. Whilst it is obvious that this yield, if realised, will not meet the world's demand for camphor, the restrictions upon exports imposed by the Japanese Government will permit only a very small proportion of the supply to enter foreign commerce.

II. According to the report issued in the *Board of Trade Journal*, which quotes the figures published in the *Yokohama Chamber of Commerce Journal*, the production of crude camphor and camphor oil respectively for the 7 years from 1912-1918 inclusive is given as follows: in thousand *kin* (1 *kin* = 1.323 lb.):—

1912: 5115 and 7073; 1913: 5576 and 7395; 1914: 5865 and 8388; 1915: 6220 and 9882; 1916. 6517 and 11 010; 1917: 4168 and 7857; 1918: 2740 and 5591.

The export of Japanese camphor to England, France and Germany before the war exceeded 1 million *kin* each, and to the United States was about 2 ½ million *kin*. The total quantity exported abroad about equalled the quantity consumed in Japan in celluloid and other manufacturing industries.

According to the figures, there is a gradual decrease in camphor export, especially to the United States and the quantity of camphor consumed in Japan has also decreased considerably since 1916 before which there had been a gradual increase. This may be explained by the shortage of supply and does not signify any decrease in the demand.

I. FORMOSA. — This is now rapidly becoming a manufacturing area rather than a region of production and export of the raw material, a trend which has been accentuated since the war started. In May 1920 all export of crude camphor was prohibited, a limited amount of refined camphor being allowed to foreign refiners at a discount of 3 % below the market price.

---

(1) For percentage of camphor furnished by leaves and branches in various countries, see *R.* June, 1920, No. 646. (*Ed*)

ÇHINA. — The threatened monopoly not only of the camphor refining but also of the celluloid industry by Japan has naturally stimulated the search for other sources of supply of camphor or for substitutes for the manufacture of celluloid. American buyers are looking to China for an immediate addition to the supply. In the Shan States of southwest Yunnan there are stated to be an immense number of camphor trees only awaiting transport facilities for their exploitation.

The recommendation offered is that an American Syndicate should start operations in South Hunan and South Kiangsi, establishing distilleries on modern lines, cutting in a conservative manner, and encouraging planting by demonstration plantations, lectures, pamphlets, and free distribution of seed and seedlings; and should afterwards extend their action into Kweichow, Kwangtung, and Kwangsi. Experimental production from wild and planted trees is being carried out in the island of Hainan, and the native camphor oil which in China usually contains 60 % camphor is being bought up.

UNITED STATES. — The Celluloid Company have now planted 3000 acres at Satsuma, and the Arlington Company 12 000 acres at Waller (since 1914); and planting has also been carried out in Texas and in the San Joaquin Valley. California. The trees are doing well in poor sandy soil being sown thickly at first, and transplanted when a year old into rows 15-16 ft. apart and 3 ½-4 ft. apart in the rows. The leaves are cut 4 years after transplanting, new growth rapidly replacing the portion pruned, so that two prunings become possible within the year. The rows are ultimately trimmed into V-shaped hedges 7-8 ft. high; the yield of flush, is now estimated at 5 tons per acre per annum yielding from 125 to 150 lb. of camphor. A special station for the study of camphor has been established at Orange City (Iowa) and a trimming machine has been designed which prunes 6 acres per day (1). It has been found that young leaves contain more camphor than the 1 or 2 year old wood, so that no severe pruning is desirable; but, if the leaves are cut once or twice a year, it seems improbable that, as seems to be expected in Florida, the mature wood in later years can contain much camphor. Fallen leaves give a good percentage of oil and camphor, and it appears economical to air-dry the leaves before distillation, but rain or direct sun on the flush reduces the camphor content. For successful camphor cultivation a temperature not falling below 20° F and a rainfall of not less than 50 inches are two points worthy of notice.

There being every prospect of successful cultivation in the Philippinnes, the Government, has granted the control of a large area of suitable land there to an American Company.

---

(1) See *R.* March 1921, No. 294. (*Ed*)

BRITISH EMPIRE :— a) *Burma :* — Plantations up to altitudes of 3000 ft. have proved successful, but at 4000 and 6000 ft. have failed.

However, the tree does well at Ootacamund in the Nilgiris at an altitude of 7300 ft. ; and has also grown well at Dehra Dun.

b) *Federated Malay States* — Experimental planting began in Selangor in 1904, and during the early years the growth equalled that in Japan.

The tree was however, found to be liable to attacks of termites *Attacus atlas*, *Fomes*, *Rosellinia bothrina* etc. It was possible, nevertheless, to begin pruning in the 3rd year, an acre of trees yielding about 5 tons of flush 3 times a year and the leaves, when air-dried, giving from 1.1 to 2.6 % of crude camphor. Assuming a yield of 1 %, 10 000 lb. of flush are required for 100 lb. of crude camphor, as against 15 400 lb. with a yield of 0.55 % from prunings of trees under 3 years of age. The cost of collection, distillation and shipping is estimated at 63s. per 100 lb

c) *Ceylon* — Being nearer the Equator than the natural range of the species, camphor did well between 3000 and 5000 ft. but not below 2000 ft. Lime and potash, were found to be necessary in the soil. The trees were coppiced to a height of 4 or 5 ft., and were found to yield 14 lb. of flush per annum each giving from 27 to 34 % of camphor oil and 0.75 to 1 % of camphor, which, with the trees 4 ft. apart in rows 8 ft. apart *i. e.* 1360 to the acre, should give 143-190 lb. of camphor per acre. Successful results have been obtained on a sandy loam where the rainfall is not less than 90 in., where the trees have been planted in hedges running across the direction of the prevailing wind.

Seed does not keep well in Ceylon, but may be stored in moist charcoal until May or June and is soaked for a day or two before being sown.

d) *Mauritius.* — A *Cinnamomum* sp. has grown well, but yields an oil very different from tree camphor oil, containing cineole, but no safrole and a little camphor.

e) *South Africa.* — Experiments suggest that camphor might be profitably cultivated in some of the warmer and moister parts of the Union territory.

f) *West Indies.* — There are two distinct unproductive forms of *Cinnamomum* and yet another form which gives a normal yield of 1% or more of camphor in Jamaica, Trinidad and Dominica. Obviously the inferior varieties should not be allowed to hybridise with the true variety and should as far as possible be eliminated.

g) *Australia.* — *C. Camphora* is commonly grown in Queensland, and a native species *C. Olivieri* is stated to contain camphor, but requires further examination ; and in the Young district of New South Wales, a 15 year old tree gave 1.02 % camphor from its fresh leaves, a result comparing favourably with those obtained in Florida and elsewhere. It is suggested that the leaves might advantageously be distilled for the crude products on the bush with a similar apparatus to that employed for the Eucalypts.

Giving a return after 3 or 4 years the crop is far less speculative in character than if planted for wood distillation after the lapse of from 15 to 60 years.

OTHER COUNTRIES — Reference is made to the cultivation in the Straits Settlements, Madagascar, the Canaries, Buenos Aires, Algeria and also in Italy (1) where on the shores of Lago Maggiore, a tree has reached 90 ft. in height and 1 ft. in diameter within 8 years from the time of sowing, a height rarely reached in a century, and a diameter usually requiring 25 years growth.

It is therefore clear that the camphor tree can be successfully grown in many countries and if care be taken to secure the true form, a small but constant yield can be obtained by the distillation of leaves, etc. which at prices considerably below those now general, will be amply remunerative, and there are evidently great possibilities in the future quite apart from the old recognised sources of supply in Japan and China.

952 - **Nitrogen and Other Losses During the Ensiling of Maize.**— SHAW, R. H., WRIGHT P. A., and DEYSHER E. F., in *United States Department of Agriculture Bulletin No.* 953 pp. 1-16, bibliogr. of 19 works. Washington, D. C. May 14, 1921.

For several years the Dairy Division of the United States Department of Agriculture has been studying to find out more definitely what losses incident to the ensiling of maize are necessary, and what is the proper method of handling the crop to prevent such losses. This bulletin deals with the losses of nitrogen and other elements in maize silage made under ordinary farm conditions.

A cylindrical concrete silo was employed 42 ft., high × 14 ft., inside diameter, holding approximately 150 tons, and located at the Dairy Division Experiment Farm, Beltsville, Md. The floor was 4 ft. below the lowest door and the silo up to this door was water tight. The experimental work was carried on for 2 seasons, 1914-15, 1915-16. The depth of the silage after settling was approximately 38ft.

The weight and chemical composition were recorded of: 1) the maize in each sack as it was buried; 2) the contents of the sacks as they were moved from the silo; 3) the juice. The losses or gains in each sack were estimated, based on the weights ensiled.

The results of the chemical analyses as given in the Tables, show many evidences of a down-wash of soluble material, the upper part of the silo losing and the lower part gaining. The greatest loss of dry matter in any bag in 1914-15 was only 18.64 %, while the average loss for all the bags was 8.66 %. The bags in the upper and lower halves of the silo showed respectively, 12.74 % and 4.70 % losses in dry matter. The apparent reversal of results in the following season may be attributed to the much larger outflow of juice. The average loss for all bags, however, from the 2 year's work, may be taken as nearly 10 % of the dry matter, which is probably due to a large extent to the fermentation of the carbohydrates and to the carrying away of a soluble material by the juice. The reducing and non reducing sugars almost entirely disappeared. There was a considerable loss in crude fibre and in the furfurol yielding bodies.

---

(1) See *R.* June 1920, No. 646. (*Ed.*)

The evident loss in total nitrogen may be due largely, if not entirely, to the nitrogenous compounds which escaped in the juice. The albuminoid nitrogen suffered a loss of over 50 %, while the non-albuminoid forms increased several times their own weight.

If the total nitrogen of the 2579 lb. of juice collected in the first season is expressed as pure protein, the loss was 28.89 lb. which represents the protein in about 1500 lb. of. average silage. In the second season, the results expressed in a similar way, show a loss of 150.75 lb. in the 9494.5 lb. of juice collected, representing the protein in about 7500 lb. of average silage.

There was a gain in ether extract, which is probably due to the formation of new ether-soluble bodies.

The juice which was collected the second season amounted to nearly 10 000 lb. This juice averaged 0.263 % total nitrogen, 0.0283 % albuminoid nitrogen, 317.9 parts ammonia nitrogen and 1472.9 parts amino-nitrogen per million.

953 – **Comparisons between Sun-Drying and Stack-Drying of Fruits** (1). — NFER, F. E, in *Monthly Bulletin of the Department of Agriculture, State of California*, Vol. X, No. 2. p. 71. Sacramento, Ca, Febr. 1921.

Report on experiments carried out at the University Farm, Davis, California.

Stack drying resulted in giving practically the same product obtained from evaporators. An apricot was cut in two and each part treated differently. All lots were exposed to the same amount of sulphur. At the end of 48 hours the sun-dried product was beginning to get in the condition when it should be stacked. At the end of 72 hours, the sun-dried was somewhat too brown, whereas the other was just about right. A better coloured fruit was obtained than the ordinary sun-dried product. It was not curled up at the edges and on slat trays it was turned out in less time. It seems advisable in stack drying, instead of putting the fruit directly in the stack, to expose it to the sun for a half-day, in order to get the colour produced by the sun, and then place it in the stack until dry. This saves a certain amount of moisture and gives a choicer product The sugar content seems to be practically the same but the eating quality of the stack-dried fruit is superior. Stack-drying should not be conducted with 3 × 8 ft., trays because the fruit may mildew before it is dry. It is advisable to use smaller trays whenever possible (2 × 3 or 3 × 3).

954 – **Method of Distinguishing an Egg Preserved in Lime Water from an Ordinary Egg.** — KEIS, K. and STUDINGER. J. (2) (Communication made by the Chemical Laboratory of the Canton of Bâle), in the *Annales des Falsifications et des Fraudes*, Year XIV, No. 151, pp. 148-151, Paris, May, 1921.

According to the " Manuel Suisse des denrées alimentaires, " the most certain way of distinguishing an egg which has been kept in lime-water from a fresh egg, is by determining the lime content of the ash of the albumen. The data given by the "Manuel Suisse" are based in Ivan RÖZSENYI's work entitled "On eggs preserved in lime" (*Sur les œufs à la chaux*). The authors subject this book to a critical examination, and also give the results of their own experiments.

---

(1) See *R.* Aug. 1921, No. 858 (*Ed.*).

(2) Published in La Revue Pharmaceutique suisse No. 14, Feb. 1921 (*Ed.*).

From the tests carried out with the eggs from a single hen-house they obtained the following data:

No	Duration of immersion in lime-water	Ash	CaO of ash
1	fresh	0.75 %	2.64%
2	1 months	0.80	2.04
3	3 months	0.76	1.44
4	5 months	0.78	1.43
5	6 months	0.73	1.12

As can be seen, there is no increase in the lime content, even at the end of 6 months, and the percentage of lime is variable even in the case of eggs having the same origin.

The ash of the white of lime-preserved eggs from Croatia and Denmark was found to contain from 0.71 to 4.85 % of Ca O, with the exception of one egg with a cylindrical flattened yolk, and reddish albumen; this was probably a very old preserved egg, in which the white had become mixed with the yolk before it was opened, and which contained, as in the case of the eggs in RÖZSENYI's experiment, a very high percentage of lime.

These tests show that the amount of lime present in the albumen of fresh eggs is very variable: about 0.59 to 4.25 % of the ash. The lime content does not perceptibly increase, even if the egg is left for several months in lime-water, and the weight of the egg remains unchanged. Therefore the amount of lime in the white of an egg affords no means of judging whether or not the egg has been put in lime water.

The vitelline membrane of lime-preseved eggs is easily affected, after even a relatively short time. For this reason, the authors are of opinion that, as the lime content of the yolk is much higher than that of the white, the high figures obtained by RÖZSENYI are due to a little yolk having been mixed with the white, owing to the rupture of the vitelline membrane when the egg was broken.

If this membrane is fragile, an egg can be considered as not fresh. It is well-known that the specific gravity of an egg that has been kept in the air shows whether it is fresh or not. In the case of eggs with an easily ruptured vitelline membrane, the specific gravity will not indicate whether they have been preserved in lime, but will show that they have been preserved in some liquid, or kept in the air, the specific gravity in the latter case being much lower than in the former: the specific gravity of eggs preserved in a liquid remains invariable.

PLANT DISEASES

GENERAL INFORMATION

955 - Organisation and Development of the Bureau of "Sanidad vegetal" of Cuba.

— *Communicated by* Dr. F. F. Falco, *Delegate of Cuba to the International Institute of Agriculture.*

The history of the Phyto-pathological Service of Cuba is of comparatively recent date, but it is only just to state that the Service has developed very rapidly and uninterruptedly. As soon as the Republican Government came into power, a small Phytopathological Service composed of honorary members was instituted for the purpose of studying certain questions of Phytopathology and Entomology specially connected with the export and import trade. Neither this Commission, however, nor the larger one appointed later, was capable of coping with all the problems requiring solution.

In 1916, as a result of the careful enquiry instituted, subsequent to their many scientific expeditions, by Professors John R. Johnston and Patricio Cardin (at that time chiefs of the Departments of Phytopathology and Economic Entomology of the Agricultural Experiment Station of Cuba), the urgent necessity was felt of adopting the most speedy, practical and efficacious means for the control of certain injurious insects and diseases that are so prevalent as to constitute a veritable calamity to national agriculture, and at the same time of instituting a severer and more thorough supervision of the transport of plants and plant products, not only within the boundaries of the national territory, but also when they enter and leave the country. To this end, the Ministry of Agriculture, in conjunction with the President of the Republic, appointed that same year a "Commission of Plant Health" composed of a President, Dr. John R. Johnston, a Secretary, Dr. Mario Sanchez Roig, and one member, M. Patricio Cardin.

Three inspectors, an Office staff, and workers were also appointed. This Commission commenced its work by devoting itself especially to the study of the problem which then appeared the most pressing, viz., the destruction of the "mosca prieta" (*Aleurocanthus woglumi*) (1) which was doing serious damage to the citrus and other fruit trees of great economic importance cultivated in the east province. About the same date, the Commission instituted investigations into the Panama disease (2) that attacks different varieties of bananas, especially in the region of Artemisia. Further, at Baracoa, the centre of coconut cultivation in Cuba, where a terrible disease known as coconut bud-root (1) was decimating the plantations, the first steps were taken to isolate the centres of infection and thus hinder the spread of the epidemic.

---

(1) See *R.*, Oct., 1918, No. 1186. (*Ed.*)

(2) See *R.* Jan. 1911, No 329; *R.* May 1911; No, 1549; *R.* Dec, 1912, No. 1686 (*Ed*)

The results of the first efforts of this Commission were such as speedily to convince the authorities of the country of the necessity of continuing and extending the work, which was greatly appreciated, both by the agriculturists and fruit-growers of Cuba. Therefore, the said Commission was converted into a larger institution called the " Bureau of Plant Health . " From that time, larger sums were allocated in the State budget for the use of this Bureau, its expert Staff was increased, the organisation of the Service was arranged so as to allow it to deal with the problem requiring most attention, its premises were enlarged, and it was provided with the necessary disinfecting apparatus, means of transport, and a fine laboratory.

The following datails relate to the organisation of the Bureau of Plant Health, which has continued to work in a perfectly normal manner.

THE CENTRAL BUREAU. — At the head of the entire organisation has been placed a Bureau with its headquarters at Havana. In order that the general work may progress faster, and be better distributed, the management has been entrusted to two persons, one being Prof. JOHN R. JOHNSTON, Chief of the Bureau of Plant Health, who orders and directs all operations of a scientific nature and devotes himself generally to all questions of technique, and the other, M. FELIPE DE LA CRUZ, chief of section and Staff, who attends to the administration, and matters connected with the Staff.

In addition to the various staffs employed in book-keeping, registration, statistical work, and the archives, the Bureau has technical experts employed in the following sections:—

PORTS, RAILWAYS, AND POSTAL SERVICE. — To this section is entrusted the supervision of all plants or plant products introduced into the country. It also supervises the despatch of plants and fruit to markets from places where quarantine regulations have been, or are about to come, in force, as regards the said plants and fruit. At the same time, it enforces the regulations and quarantine measures decreed by the Government of Cuba respecting certain foreign plant products.

GARDENS AND NURSERIES. — With a view to keeping all commercial market-gardens free from any serious diseases, the said gardens are regularly inspected, and if found in a satisfactory condition, are granted a certificate valid for certain time, and permitting plants to be despatched therefrom without further preliminaries.

This inspection of the gardens and nurseries is of great scientific importance to Cuba, for the reports drawn up give a list of all the insects and plant diseases that have been observed, and the data thus collected will serve as a basis for the general and detailed entomological and phytopathological map of the country.

---

(1) See *R.*, Dec., 1910 ; *R.*, March, 1912, No. 598 ; *R.*, Oct., 1914, No. 961 ; *R.*, Jan., 1916, No 116. (*Ed.*)

[955]

INSPECTION SERVICE. — Any person wishing to transport plants or portions of plants, from one place to another must obtain a certificate of good condition from the Bureau of Phytopathology, granted after due inspection. This service exercises constant supervision over all exported fruit packed before despatch, in order to prevent any leaf, or branch, leaving the country which is infected with pests, or diseases, that might entail quarantine measures being enforced against Cuban products.

ENTOMOLOGY, PHYTOPATHOLOGY, LABORATORY, AND MUSEUM. — A phytopathological laboratory is attached to the services of the Department, where, all the parasites collected during expeditions, or on special or general missions of enquiry, are classified and those sent by agriculturists when applying for advice. There is also a small museum containing specicimens of the insects and diseases collected by the scientific staff in the course of their excutsions and inspections. This museum which adds to its collection every day, is a very useful auxiliary in the work of determining and identifying insects, diseases, fungi, etc.

EXCHANGE. PUBLICATIONS AND LIBRARY. — The " Bureau of Plant Health " exchanges its publications with the scientific societies and Institutions of nearly all the countries in the world. Thanks to its Department, a movement for popularising and disseminating useful knowledge regarding plant diseases has been started throughout the country by means of bulletins and circulars in the form of books and pamphlets, or by the agency of newspapers and reviews.

The principal works published by the Bureau are as follows:—

Bulletin No. 1 (book) — La Comisión de Sanidad vegetal y su labor (The Commission of Plant Health and its work).

Bulletin No. 2 (book) — Algunas plagas de nuestros cultivos por Rodolfo ARANGO (Some of our Crop Pests).

Circular No. 1 (pamphlet) — La mosca prieta y medios para combatirla (The Black Fly and means for its control).

Circular No. 2 (pamphlet) — La enfermedad del cocotero (The Disease of the Coco Palm).

Circular No. 3 (pamphlet) — La enfermedad del plátano. (The Disease of the Banana).

Circular No. 4 (pamphlet) — La Plaga " salivita " en la yerba " Paraná " (The " salivita " Pest on the Paraná Plant).

Circular No. 5 (pamphlet) — Disposiciones vigentes sobre el servicio de Sanidad vegetal (Measures in Force Regarding the Plant Health Service).

Circular No. 6 (pamphlet) — La enfermedad " mosaico " de la caña de azúcar por John R. JOHNSTON (Mosaic Disease of the Sugar-Cane.

These publications are supplied gratuitously to subscribers, and in general, to all applicants.

ZONES OF WORK. — In order to be able better to carry out all the practical work within its sphere of action, which consists in the extirpation of pests, plant surgery, etc., the Bureau of Plant Health has mapped out zones of work. It has separate Stations in the districts where the worst disease centres are situated, and the duty of the various Staffs is to take all the prophylactic measures recommended by the Directors of the Bureau of Plant Health in special cases.

PROVINCIAL INSPECTORS. — In each Province, the Bureau is represented by an Inspector, whose work includes supervising plant-transport, and settling all matters connected with the affairs of the Bureau.

CHIEF PROBLEMS. — One the principal questions that has occupied the attention of the Bureau of Plant Health since its institution, is the extirpation of an insect popularly known as " mosca prieta " (the black fly, *Aleurocanthus woglumi*), a parasite that is very injurious to various fruit-trees, especially the citrus trees, etc., that constitute one of the country's most important sources of revenue, and the mango, which ranks next in economic importance.

A disease that for many years, has greatly reduced the coconut production of the island and of several regions of the American continent — " pudrición del cogollo del cocotero " (coconut bud-rot) — is also a problem to which the Department has devoted much attention. Gangs of workers are kept to disinfect the zones where the coconut palm is most intensively cultivated, and they have succeeded in checking the progress of this much-dreaded epidemic.

From the centre to the west of Cuba, the majority of the varieties of banana are very subject to what is known as the Panama disease, produced by a fungus of the genus *Fusarium*. This disease makes it very difficult to grow dessert bananas such as Johnson and Manzana.

The Bureau carries out special prophylactic measures suitable to this case, and exercises supervision on the transport of banana cuttings from one place to another, so as to prevent the spread of the malady. In this manner, it has been possible to confine it to one part of the island, leaving the eastern portion, quite immune. This has just been officially confirmed during a tour of inspection carried out by one of the members of the Agricultural Experiment Station of Cuba.

A sugar-cane disease called " mosaico, " " rayas amarillas " and " matizado " found in Java and Hawaii, has also been recorded at Porto Rico (1), where it causes great damage. A little later, its presence was observed in the sugar-cane zone of the United States, whence it was doubtless introduced into Cuba, where it has been reported from various places a long distance apart.

The Bureau of Plant Health, threatened by an outbreak of this disease, which would have been disastrous to the sugar crop, the most important source of the wealth of the island, and being well aware of the danger of the spread of the disease, exercised the most rigorous supervision, with the hope of entirely eliminating it. To this end, it keeps in contact with a large number of the sugar growers of the Republic with whom it exchanges observations, and is thus informed of all details which can serve as a basis for the serious and practical study of " matizado ".

---

(1) See *R.*, May, 1919, No. 655; *R.*, June, 1919, No. 785; *R.*, 1920 No. 698. (*Ed.*)

One matter of recent date, and of great importance to the agricultural interests of Cuba, is at present occupying the attention of the Bureau of Plant Health, namely the means of preventing quarantine being imposed by the United States upon plant products imported from the island. As these measures are directed against the possibility of infection being conveyed by a diseased leaf, or portions of leaves, owing to the want of cleanliness of the ferry-boats, the Bureau of Plant Health has pledged itself to the Agricultural Department of Washington to guarantee the immunity from black fly of all plants liable to the attack of this parasite and growing on a radius of 200 feet on either side of railway traversed by the trucks engaged in the ferry-boat service.

956 - **Entomological Branch, Department of Agriculture, Canada.** — See No. 822 of this *Review*.

DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS.

957 - **Diseases of Cultivated Plants in the Cape Province, South Africa.** — PUTTERILL, V. A., in *Union of South Africa, Journal of the Department of Agriculture*, Vol. II. No. 6, pp. 525-532, figs. 6. Pretoria, June 1921.

Observations relative to diseases which attack certain plants in the Cape of Good Hope Province.

1) " Chlorosis," observed at Wellington in October 1920 on numerous plum trees (var. Kelsey), 12 years old; apricots in the same orchard were also attacked but less severely than the plums. The disease appeared in this case to be due mainly to the general lack of nutrition for the plants and of organic matter in humus form and possibly also to lack of iron.

2) " Lithiase " of pears: according to reports in May 1920, the fruits of about 200 pear trees 20 years old (var. " Bon Chrétien ") were attacked at Somerset West during the last two or three years. In 1919-1920 the attack was especially severe; about 15 % of the fruits of the above mentioned trees were injured. The soil had not been well drained up to last winter and in addition to this, last year it was particularly dry which explains to a large extent the spread of the disease.

3) *Rhizopus nigricans.* This caused the very serious rotting of peaches (var. Sea Eagle) packed for exportation ready for shipment to Stellenbosch. The same fungous was also found with *Penicillium italicum* on plums and peaches stored for some time. As regards control measures, it is recommended that the fruits be handled with the greatest care and damage round the peduncle should be avoided at picking time. On no account should fallen fruits be allowed to rot under the trees and

if impossible to utilise, they should be collected and burnt. It is probable that insects play an important part in the propagation of the parasite.

4) Chrysanthemum rust (*Puccinia Chrysanthemi*), fairly common in 1921 on chrysanthemums at Sea Point. This disease can be checked when the plants are only slightly injured, by picking off and burning the diseased leaves; plants very severely attacked should be burnt; Bordeaux mixture may be used with advantage as a spray for unaffected plants in order to prevent the spread of this disease.

958 - **Treatment for Rejuvenating, Olive-Trees, Vines, and Fruit Trees in General.** — LOTRIONTE, G., in *La Nuova Agricoltura del Lazio*, Year IX, No. 190, pp 28-29. Rome, April 1, 1921.

This treatment for restoring the vigour of trees and shrubs (olives, vines and fruit-trees) is especially efficacious in the case of individuals weakened by age, lack of cultural care, the action of cold or frost, and the attacks of plant or insect enemies

It can, however, be applied with equally good results to young or middle-aged trees and shrubs, for it increases their vigour and productivity to a remarkable extent, and is indispensable for trees which not only show clear signs of organic weakness, but also have their trunks covered with mosses and lichens, that cause direct injury to their host, and at the same time, harbour pathogenetic microorganisms.

A complete treatment calculated to induce rejuvenation naturally includes a series of operations ranging from systematic pruning to suitable manuring, and the usual cultural works which must be executed with the greatest care.

In order to complete and increase the effect of the last-mentioned practices, the author advises a method he has used successfully for 20 years, viz., covering, or spraying, the plants, according to whether they are of low or high growth, with a mixture composed of sulphate of iron (5 kg.), slaked lime (5 kg.) and water (1 hectolitre).

This lime-iron wash is very adhesive, not removed by the rain, and prepared in precisely the same way as Bordeaux mixture.

In the case of trees in a very weak state and especially in that of old olives suffering from root-rot, it is most advisable to extend the treatment to the large roots. For peach-trees, lime-iron spraying is an excellent addition to the usual winter treatment (spraying with 3 % Bordeaux mixture), as it controls leaf-curl (*Exoascus deformans*), and other causes of want of productivity.

The best time for using the lime-iron mixture is at the end of winter, from the middle of February to the end of March, or the first few days in April, in any case, not before the leaves begin to bud. One application, repeated every two years is sufficient.

959 – ***Fusarium roseum*** **a Hyphomycete Injurious to Wheat in the Rice Growing Regions of Italy.** — NOVELLI, N., in *Il Giornale di Risicoltura*, Vol. XI, No. 7, pp. 103-105. Vercelli, July 31, 1921.

In 1921, many fields of wheat situated in the rice-growing regions of Italy were attacked by *Fusarium roseum* Link, which is regarded as being the conidial form of the ascomycete *Gibberella Saubinetii* (Mont) Sacc.

This disease (wheat scab or blight), was also very common in other parts of Italy during the same year, and caused losses in some fields estimated at 20 % or more.

Awnless varieties are most attacked; though " Gentil Rosso, " " Carlotta Strampelli, " " Cologna, " " Varesotto, " etc., also suffered severely.

As protective measures, the careful drying of the wheat before thrashing is recommended; the grain should also be sieved, in order to eliminate all infected, stunted seeds. The seed-corn should be changed, and the seeds carefully disinfected with a solution of copper sulphate.

960 – **Ergot (*Claviceps* sp.) Ascomycete Observed on Many Grasses in Australia.** — BIRMINGHAM, W. A., in *The Agricultural Gazette of New South Wales*, Vol. XXXII, Pt. 6, pp. 410-412, figs. 8. Sydney. June 2, 1921.

In February, 1921, the Manager of Bathurst Experiment Farm submitted specimens of Blue Grass (*Andropogon intermedius*) to the Biological Branch for examination. A sticky secretion was found associated with the panicles due to the presence of the sphacelial stage of *Claviceps* sp.

In March 1921, the Manager of Glen Innes Experiment Farm observed the following specimens attacked by *Claviceps* sp., the ergot stage being present in each case; wheat, rye, Hungarian or Awnless Brome (*Bromus inermis*), a Canary grass (*Phalaris minor*), Loietta rye grass (*Lolium multiflorum* var.), fescue, Tall (*Festuca elatior*), Giant (*F. arundicanea*), Hooker's (*F. Hookeriana*). All the later crops and late growth of grasses had been seriously infected whilst the early varieties and early growths of grasses were practically free.

Specimens of *Pollinia fulvum* and *Panicum bulbosum* attacked by ergot have recently been submitted to the Biological Branch by the Principal of Hawkesbury Agricultural College.

This fungus appears to be more prevalent in warm moist seasons. Some previous records of this fungus in Australia are: Hooker's fescue (Glen Innes Experiment Farm, 1914) and wheat and rye (Glen Innes, 1914). MC. ALPINE records it on Perennial rye grass (*Lolium perenne*) and DARNEL (*L. temulentum*) in Victoria, 1895.

961 – **Diseases and Pests of Coconut Palm in Porto Rico.** — See No. 912 of this *Review*.

962 – **Diseases and Pests of the Camphor in the Federated Malay States.** — See No 951 of this *Reviw*.

WEEDS AND PARASITIC FLOWERING PLANTS

963 - **Copper Sulphate in the Control of the Field Poppy in Wheat Fields.** — VILCOQ, in *Comptes rendus des séances de l'Académie d'Agriculture de France*, Vol. VII, No. 29, pp. 640-642. Paris, Juln, 27, 1921.

The results of experiments carried out for the purpose of determining whether copper sulphate had a strong toxic action upon the field poppy (*Papaver Rhoeas*), and if so, the strength of the copper solution required to destroy it.

Some plots of ground belonging to the Agricultural College of Chesnoy (Loire), in which the wheat succeeding mangels was infested with field poppy, were sprayed with increasingly concentrated solutions of copper sulphate (3, 4, 5, and 6 %).

By this means, it was found, that 3 % and 4 % solution had hardly any effect, but that *Papaver Rholas* is not insensible to 5 and 6 % solution ; the latter is the highest concentration that can be used for fear of damaging the wheat. A 6 % solution blackens and destroys the lower leaves of the poppy ; the plant, however, continues to grow, though less vigorously, and its development is but slightly hindered.

INJURIOUS INSECTS AND OTHER LOWER AMIMALS

964 - **Biological Studies on *Aphis rumicis*.**— DAVIDSON F, in *Bulletin of Entomological Research*, Vol. XII, Part. I, pp. 81-89, 6 figg. London, June, 1921.

The specific name of *Aphis rumicis* Linn. is applied by the author to the black aphis found in spring upon the spindlewood-tree (*Euonymus europaeus*), and later in the season, upon beans, poppies and numerous other plants. This insect has many synonyms owing to its polyphagous habits, but the name given it, in 1746, by Linnaeus has the right of priority. The chief synonyms are: *A. papaveris*, Fabr., *A. euonymi* Fabr. and *A. fabae* Scop.

As scientific literature contains no complete description of *A. rumicis*, the author though it well to give in his paper a detailed account, illustrated by figures, of all the different forms of this species.

The morphological description is followed by a sketch of the life-history of the pest based on many rearing experiments, and upon observations made in the open.

These experiments were carried on during 1913, and the first half of 1914 ; when they were interrupted by the outbreak of Great War, and not resumed until 1920. The author reserves to himself the right of publishing his results by degrees. He is of opinion, that a through investigation of the life-history of the species in question would throw much light upon the very difficult biological problems connected with the family of the *Aphididae*.

[963-964]

965 - ***Chalcis euthryrrhini* sp., Hymenopteron Parasitic. on *Euthyrrhinus meditabundus* a Beetle Injurious to the Mango, in North Queensland.** — DODD, A. P, in *Bulletin of Entomological Research*, Vol. XII, Part 1, pp. 67-68. London, June, 1921.

A morphological description of a new species of Hymenopteron, *Chalcis euthyrrhini*, of which some specimens were obtained in the neighbourhood of Cairns and Townsville (North Queensland), by breeding the curculionid beetle *Euthyrrhinus meditabundus* Fabr., which is injurious to the mango. Other individuals were reared on the dead wood of the latter tree, or captured on the dead, or dying, wood infested by the coleopteron.

966 - ***Dicrurus macrocerus.* Useful Indian Bird.** — FLETCHER, T. B., and INGLIS, C. M., in *The Agricultural Journal of India*, Vol. XVI, Pt. 4, pp. 359-364. 1 col. pl. Calcutta, July, 1921.

Dicrurus macrocerus Vieill. (" Black Drongo " or "King Crow ") is one of the most common and familiar birds occurring in all cultivated areas. This bird is found near dwellings; it accompanies cattle often perching on their backs, and also follows the plough all with a view to the capture of insects. The food consists almost exclusively of insects, and largely of injurious insects such as crickets, grasshoppers, moths, bugs and insect larvae

The nest is usually placed in a tree between April and August (usually in May in Bihar).

The Drongo is protected by law throughout the whole year in Delhi, in the United Provinces, Bengal, Assam and Burma. As it a most useful bird it deserves every protection and encouragement. The latter can be attained in the case of cultivated areas, by the provision of suitable perches for the birds to rest on.

967 - **Means of Preventing the Officinal Cantharides *Lytta vesicatoria* from Injuring Fruit Trees.** — LOTRIONTE, G., in *La Nuova Agricoltura di Lazio*, Year IX, No. 204, p. 77. Rome, July 10, 1921.

In certain provinces of central and south Italy, the officinal cantharides or " Spanish Fly " (*Lytta vesicatoria* L.) often causes perceptible injury to olive and many other fruit-trees by rapidly devouring the leaves and tender shoots.

The only means of defence hitherto employed has consisted in shaking the trees attacked very early in the morning, when the coleoptera, numbed by the cold of the night, fall to the ground, where they can easily be collected to be sold to the chemists.

By the advice of the author, this treatment has been superseded in Latium for some years past, especially in the case of olive trees, by applying a spray with an acid Bordeaux mixture base (1.5 kg. of copper sulphate and 1 kg. of slaked lime in 1 hectolitre of water), to which has been added lead arsenate (1.0 to 1.5 kg.). A single application made at the beginning of the invasion has always sufficed completely to free the trees, after some hours, from the insects.

By the time the olives are gathered, the slight traces of lead arsenate will have already disappeared from the surface of the fruits, so there is no fear of any toxic effects.

968 - ***Pulvinaria ornata* n. sp. Coccid on Citrus Trees in New South Wales.** — FROGGATT, W. W., in *The Agricultural Gazette of New South Wales*, Vol. XXXII, Pt. 6, pp. 427-428, pl. 1, Sydney. June, 2, 1921.

Description of *Pulvinaria ornata*, n. sp., found in abundance in 1920 in all stages of development, on the foliage of a lemon tree near Sydney.

P. psidii and *P. tecta* are two allied species and *P. cellulosa* is even more closely related to the species in question.

An examination of plants in the vicinity of the lemon tree resulted in the discovery of foliage of *Pittosporum undulatum* thickly infested with these mealy bugs. It would appear, therefore, that *P. undulatum* is the original or natural host of this bug, from which it had migrated to the lemon tree.

969 - ***Oryctes rhinoceros* a Coleopteron Injurious to the Coconut Palm, in Goa, Portuguese India.** — DOS REMEDIOS FURTADO C. X., in *Govêrno Geral do Estado da India, Direcão dos Serviços Agricolas e Florestais, Boletim de Agricultura*, Year II, Nos. 1-4 pp. 82-85. Nova Goa, 1920.

The coconut palm is one of the principal sources of revenue in the Colony of Goa. Among the enemies of this tree, the coleopteron, *Oryctes rhinoceros* L. (1) occupies a very important place, although the serious damage done by this insect is, it appears, little known to the greater number of the coconut growers, being frequently attributed to another beetle *Rynchophorus ferrugineus* Fab. (2), which continues the destructive work of the first, frequently causing the rapid death of the tree attacked.

O. rhinoceros has a predilection for the tenderest parts of the coconut palm, and selects the terminal bud. If the tree is severely attacked, it soon appears sickly, and very quickly succumbs, the terminal bud perishing first.

The galleries excavated by *O. rhinoceros* in the interior of the tree help *R. ferrugineus* to effect an entrance, and this beetle is even more injurious, and dangerous, than its predecessor.

The natural enemies of *O. rhinoceros* assist in controlling it, but there are other means of destroying the insect, or of preventing its appearance, which are most efficacious when applied collectively by all the owners of palms, attacked by this pest. The dead trees must be felled without delay, and removed from the plantations. They should be cut open lengthwise, and the fibrous portion removed and burnt.

As the beetle is greatly attracted by light, it has been suggested that large fires should be kindled at night; practical experience has, however, shown the author that no satisfactory results can thus be obtained.

It is best, at the beginning of the winter, to dig trenches with a capacity of 8 " mãos cubicos " and to place upright in them 4 pieces of coconut stem. When the stems begin to decay, the adult female beetles are attracted out in August, and the larvae must be carefully destroyed. They make a good chicken food.

---

(1) See *R.* Dec. 1915, No. 1367 *(Ed.)*.

(2) See *R.* July 1917, No. 696. *(Ed.)*

The author states that having once put into a vessel containing water, a few small fish and other refuse, with the idea of using them when decomposed as a manure for certain plants in his garden, he found after some days, that the vessel was full of beetles which had been attracted by the smell emitted by the decomposing matter.

In order to prevent the coleoptera taking refuge in large heaps of plant refuse, some kitchen salt, which has a repellent effect upon the insects should be mixed with the rubbish. It is a good plan to turn over the heaps to the sun in September and October, in this way, some of the larvae sheltering there will fall a prey to the poultry, and the rest should be destroyed by the farmer. All the other organic matter intended for use as a fertiliser in the plantations, ought to be treated in the same manner, for salt not only repels the beetles, but has a fertilising action upon the coconut palm. Some persons advise spraying the terminal bud of the palm with salt water, but this can only be done with the help of mechanical sprayers, otherwise the operation is both costly and difficult.

The larvae hiding in the galleries can be extracted with a piece of wire having a hook at the end; when the grubs are removed, a small quantity ($^1/_{10}$ litre of oil of turpentine or tar is poured into the galleries, and the entrance is closed with clay.

One general rule that ought never to be neglected is to keep the plantation extremely clean; this is in fact an excellent means of preventing, or minimising, the attacks of *Orycetes rhinoceros*, and of other enemies of the coconut palm.

970 – ***Euthyrrhinus meditabundus* a Beetle Injurious to the Mango in Australia.** — HILL G. F., in *Bulletin of Entomological Research*, Vol. XII, Part 1, pp. 63-66, figs 1. London June 1921.

Adult specimens of the Curculionid *Euthyrrhinus meditabundus* Fabr. used formerly often to be met with in the woody district to the south of Darwin (Northern Territory), and have frequently been obtained from the branches of two indigenous trees, and of *Anona* and *Poinciana*, as well as from those of two undetermined, ornamental, foreign trees growing in the Botanic Garden at Darwin. As a rule, there trees were not much injured, although the specimens of *Poinciana* sometimes suffered considerably. Mango-trees, although seriously attacked and sometimes destroyed by termites (*Mastotermes darwiniensis*), seemed to be avoided by *E. meditabudus*, even when growing in the immediate neighbourhood of infected trees belonging to other species.

Since 1919, however, the author has had the opportunity of studying, at Townsville (North Queensland), the life-history and habits of this beetle, and has found, that it is a formidable enemy of the mango, a tree which although it is not much cultivated from the commercial standpoint, is nevertheless a frequent denizen of many gardens in North Queensland, where it is greatly prized, not only for its beauty, and the shade it affords, but also for the fine crops of fruit it produces.

The first symptom that shows the tree to have been attacked is the withering of the terminal branches; this is followed by partial defoliation, the growth of groups of leaf-bearing adventitious shoots along the primary and upper branches, and the death of the secondary, and subsequently, of the primary branches. The cause of these alterations is only revealed when the adult beetles begin to emerge from the dead, or dying, branches, or even though this is of rare occurrence, from the branches in which the sap continues to flow.

The young larvae, which hatch out from the eggs deposited by the females in shallow cavities, excavate galleries in the cortex, and afterwards in the sap-wood. These galleries first run, either obliquely, or horizontally, but sooner, or later, assume an entirely horizontal course. The damage usually done by the larvae is so great, that the branch is destroyed before the first adult insects emerge.

The cortex of a badly attacked branch is covered with holes of different sizes; those up to 2 mm. in diameter are made by the adult forms of the parasitic hymenoptera, which when in the larval stage, destroyed the larvae of *E. meditabundus*, whereas the largest (which may be as much as 7 mm. in diameter), are the work of the adult beetles.

E. meditabundus is not exempt from the attack of parasites of which the following have been identified: *Chalchis euthyrrhini* Dodd n. sp. (1), *Thaumasura curculionis* Girault, and *Th. pavo* Girault. None of these parasites have, however, proved themselves of much practical utility.

No experiments have yet been made in the artificial control of *E. meditabundus*. In the meantime, it seems reasonable to suppose, that the infested area could be restricted by cutting down the trees which are much attacked (and therefore useless) and burning them before the adult insects emerge.

971 - *Chermes cooleyi* Aphis on the Douglas Fir *Pseudotsuga Douglasii* in England and Scotland.— CUNLIFFE, N., in *Quarterly Journal of Forestry*, Vol. XV, No. 3, pp. 157-159. London, July, 1921.

Chermes cooleyi Gill has been introduced into England from North America within the last few years, almost certainly on imported trees. Apparently it was first noticed about 1904, but it was not recognised specifically until 1907, when it was discovered at East Liss in Hampshire. Since then it has been noted in many localities in England and Scotland, most probably having been distributed with nursery plants, but it has not, as far as is known at present, spread into Wales and Ireland.

The life cycle of *Ch. cooleyi* has only been partly elucidated in Great Britain, its habits from June onwards being unknown. It is well known, however, that it winters on the needles in the larval stage. These larvae are clearly visible to the naked eye, appearing as minute black specks on the wax of the under-side of the needle. In the majority of cases these larval forms are concentrated on the more shaded branches that is, the infection is most apparent near the stem. It is this form which produces the white wool so noticeable on the trees in early spring. When these larvae mature, they deposit numbers of brown coloured eggs on the old needles, beneath the protective coat of wool. About the middle of May the individuals hatched from these eggs, migrate along the branches to the newly formed shoots and settle there on the under sides of the needles. In June, two types of individuals appear from these migrants, namely, *a*) wingless forms which produce white wool and deposit their eggs on the same host plant, and *b*) winged forms. At this point the knowledge of the life-cycle fails. Probably the wingless forms maintain the infection on the original host, producing either larvae which rest until the following spring or a series of generations, each similar to the previous one, the last of which in autumn will give rise to the hibernating larvae on the needles. The winged forms leave the Douglas fir needles almost immediately, to seek new hosts of the same or another species.

---

(1) See No. 965 of this *Review*. (*Ed.*)

It is not possible to say in the present state of knowledge, whether *Ch. cooleyi* will become a dangerous pest. It is incapable of ravages comparable with those of defoliators or bark pests and yet it must necessarily reduce the vigour of the host. No doubt, when attacks are recurrent, there is considerable loss in increment, particularly when young stock is in question.

The old needles, attacked by the early spring form, show some yellow discoloration on the upper surfaces. The succeeding generation which attacks the young shoots, causes mottling on the upper surface of the needles, a certain amount of deformation or " elbowing " and when the pest is numerous the whole shoot wilts under the attack.

It is not likely that the fir will be killed by *Ch. cooleyi* unless the trees are severely attacked for a number of consecutive years.

The prominence of the pest in 1921 is probably due to the climatic conditions of the winter and spring seasons, the mild winter favouring the hibernation of the larvae on the needles, and the warm, dry spring aiding and accelerating the maturation and multiplication of these individuals.

The inseet can be controlled readily in the nursery by the use of a nicotine soap wash, or even a strong soap wash alone if the remedy is applied in the autumn, when the insect is in the larval stage, unprotected by any woolly covering. In any case, nursery plants, infested, or even liable to infestation, should be cleaned in some such manner before despatched to another locality, because no economic measure for the eradication of the pest once established in the plantation can be advocated.

A High School of Rural Household Economy in Belgium

by JEANNE DE VUYST

From the first, the instruction in Rural Household Economy which owes its origin to Director General PROOST has been deservedly successful with the inhabitants of the country districts of Belgium and is developing rapidly. For a long time past, however, the Inspectorate has indicated the need for giving a more scientific training to the teaching staff of the Intermediate Rural Education Services and of the Peripatetic Schools. Moreover, it appeared to be of the highest importance to have some form of Higher Professional Education for the daughters of the large land owners and farmers, and for women who intend to live in the colonies. At several important conferences it was urged that the scheme of Agricultural Instruction should include an "École Normale supérieure" During their travels the women Inspectors of Household Economy had come across instances of schools of this class in other countries and were of opinion that Belgium should not be allowed to lag behind its neighbours.

Hence the Council for the Improvement of Agricultural Education decided that it was necessary to establish one of these higher schools for girls. Thanks to Baron RUZETTE, Minister of Agriculture, a High School of Rural Household Economy was founded at Heysel (Laeken, Brussels) in October 1920, with the object of turning out specially trained women competent to direct field work or to act as leaders of groups of farmers' wives, familiar with modern methods, or as themselves the wives of landed proprietors in sympathy with country life.

The new Institution has also the equally important object of serving as a Training College for Mistresses able to popularise and disseminate Technical Instruction.

The Higher Training College "Institut Normal supérieur" of Rural Household Economy is situated at Heysel, near the Royal Palace of Laeken in the fine estate of Hosseghem, which is within 30 minutes journey of the Gare du Nord, at Brussels. The estate comprises 24 acres of cultivated land and a magnificent park, 36 acres in extent. For practical work, a farm, kitchen garden, orchards and ornamental grounds are provided as well as land intended for various crops.

The organisation of the domestic life is particularly interesting. Each student has her own room and all the rooms are differently arranged so that the students can become acquainted with the most suitable types of furniture. To save space some very interesting combination furniture has been designed. There is nothing of the forbidding aspect of a school about the place; as far as possible the students enjoy a family life.

⁂

The school is directed by a Principal who possesses a Ph. D. degree, and is assisted by a staff of qualified Mistresses. Theoretical and Practical courses are given bv University trained professors. Each week, experts, either native or foreign, give lectures on questions of the day.

The methods of instruction adopted at the School are specially designed to develop initiative and common sense. Thus the students are expected to prepare their next lesson themselves, the subject only being given, and for this purpose they have access to reviews and books in the Library. Very little use is made of mere memory work.

Regular periods are devoted to practical work; every day a section is busy in the kitchen and another on the farm, and time is also set aside for work in the garden. This would appear to be the best method, for theory without practice is of little value and practical experience deepens the impression of the lesson. By these methods the Students learn to make the best use of their time and to organise their own work.

⁂

The Institute has been at work since October, 1920, and the examinations in July 1921, proved very satisfactory. The work and studies of the year are taken into account and rank equally with the examination results. The total of marks gained decided the rank and grade for entry into the second year; the marks obtained for the year's work count as one half and the examination marks as the other half. Memory plays quite a secondary part in the Examinations which lay for greater stress on what the students know how to do on their own account with skill and intelligence. Thus they have to prepare answers to a limited number of questions dealing with each of the courses taken, the questions being given to them at least three weeks before the examination. Each student has different questions to answer which are chosen by lot, and to help them to answer, they can have recourse to all the documents that have been collected during the year as well as to the books in the library.

Previous notice is also given of the practical tests which are also assigned to the students by lot. As evidence of initiative they are encouraged to submit new forms of apparatus not mentioned in the lectures and to demonstrate their value to an examining board. The highest marks are given to those who submit the most ingenious and practical devices which are most in accord with the general aim of the school and are designed to improve the amenities of rural homelife. The examinations are thus not of the ordinary character but are all the more a preparation for practical life.

⁂

In a short time a new building, facing the present College, will be ready to receive the students, twenty in number, who have been admitted to the second year course Here too, each student will have her own room with its distinctive furniture. All the arrangements will be of the practical order but simple and in good taste and avoiding any scholastic severity. A baby clinic is also being erected and the students will thus be initiated into their future duties as wives and mothers. In all probability they will be given the care of young children orphaned by the war and be charged with their upbringing till they reach school-age. The Director's private house will also be in the grounds.

It should be noted moreover that the College can come to an agreement with similar institutions in other countries to arrange for the temporary interchange both of members of the staff and of students. This should prove of the utmost value to both as they will able to compare methods and return from their sojourn abroad with interesting experiences, which will be all to the advantage of the progress of the Higher Training College scheme.

⁂

A large number of well-known persons both of Belgian and of other nationalities have visited the College and can testify to the fact that thsi new Institution is a busy hive of intensive and intelligent work. The students, both Flemish and Walloon, meet together in the lecture rooms and in the practical work; throughout the work proceeds cheerfully and with zest just as in home surroundings. They are allowed a wide measure of liberty and are not constantly annoyed by paltry and useless regulations; it is intended that they should themselves establish the good tone of the College and feel then own personal responsability for it. They are aware that the College can be a "higher" Institution in any true sense only if they themselves attain to the higher level both moral and intellectual. This elementary truth, on which every constitution should be founded. is well understood by the students, and it is a genuine pleasure to see how cheerily they work even at the humblest tasks.

⁂

This quite summary description gives but a very incomplete idea of the importance of the Institution. The reader would be well advised to supplement his knowledge by applying to the Administration for a copy of the illustrated prospectus, and, best of all, he should himself pay a visit to the College where he will be sure of a warm welcome.

Motorculture in Spain

by

M. MIGUEL BENLLOCH

Agricultural Engineer

The special geological structure of the Spanish Peninsula and the very varied nature of its topography account for the existence of very diverse climatic and agrogeological conditions. It would therefore be very difficult to establish any specific characteristic for Spanish Agriculture ; its types are so complex that it would almost be correct to say that all systems are included. There is therefore no necessity to inquire whether motor-culture has its place in Spanish agriculture.

The factors which brought into being the problem of motorculture in other countries had their exact parallels in Spain and on the widest possible scale. In consequence of the European war the problem has been greatly intensified for the belligerent countries, and great developments have taken place but, unfortunately, rather in the domain of material than of economic solutions. There has been some repercussion of the crisis in Spain also, though naturally its characteristics have been far less serious, seeing that the principal cause, the labour shortage, is not felt there. It was, however, sufficiently strong to stimulate a remarkable amount of interest among Spanish agriculturist, which has continued to increase up to the present time and is evidenced by a growing demand for tractors.

As no machines were made in the country it was necessary to buy in the foreign market. It was inevitable that the North-American machines had a great advantage, principally because the United States were most favourably situated for providing this class of goods, and might almost be said to be the only Nation able to give delivery.

The use of tractors in Spain began after the outbreak of war. At first it met with considerable suspicion, and was regarded merely as the beginning of an attempt to solve the problem of motorculture (in its practical aspect) and as yet only a question for technical experts. The experts had, in fact, foreseen the need and were already considering the problem.

The results have been and continue to be collected and recorded carefully by Prof. MARIANO FERNANDEZ CORTES, Director of the Royal Station for Machine testing in Madrid, the leading Spanish authority on the subject. The antipathy of the farmers to the use of tractors (machines for motor-culture) and their reluctance to envisage the terms of the problem and to devise means for arriving at a possible solution is now declining; more rapidly in the South than elsewhere. In this region in consequence of the extensive methods of cultivation employed, the question was of a more urgent nature and the use of tractors appeared to become more and more appropriate as they became better known.

One is justified in stating that the former antipathy has now been converted into sympathy, and that while the decrease of the former was by no means uniform, the latter shows to a marked degree a general tendency to increase, which may even be regarded as somewhat dangerous. For it is impossible not to recognise that it is partly due to false notions encouraged by the exaggerated propaganda carried on by manufacturers and the equally delusive ideas inspired by the motor-culture competitions, at which the spectacle of the cutting a few furrows with relative ease merely conduced to an unintelligent and ill-considered use of the tractor, leading to disastrous results.

In spite of the increasing frequency with which tractors are now employed, there are probably not more than a thousand at work in Spain at the present time. The work which the technical experts have undertaken in order to obtain a solution, or rather solutions, of the problem, for in consequence of the extreme variety of the circumstances and conditions of each case a single solution is impossible, presents itself under a double aspect.

I. — The work carried out by the Royal Station in machine-testing in Madrid. This provides an accurate description of the characteristics of the different types of tractors in use.

II. — A comparative definition of the types of work and performance of the different grades of tractors as the result of open competitions in various districts.

The first provides a form of guarantee for the farmer who desires it, the second a standard of judgment in the choice of a suitable type or method. Moreover the " Granjas agricolas " (Experimental farms) of the State also conduct trials and practical demonstrations with their own machines. They display both advantages and difficulties, so that the farmer can draw his own conclusions for each particular case.

Below is a list of the types and models of the tractors which have been introduced into Spain up to the present (1921): for the sake of clearness, they are divided into groups.

INDEPENDENT TRACTORS, WITH LAND WHEELS.

With two driving wheels: United States: " Avery " 25 HP; " Hart Parr " 30 HP; " Deering " 20 and 30 HP; " Rumely Oil Pull " 20 and 30 HP models; " Titan " 20 HP; « International " 16 HP; " Case " 18, 27 and 40 HP models; "Emerson" 20 HP; "Fordson 22 HP; "Parret" 25 HP; "Nilsson" 36 HP: — French: "Citroën" 12 HP; "Chapron" 20 HP: — English: "Happy Farmer" 25 HP; "Saunderson" 25 HP; "Austin" 25 HP: — German: "Hansa Lloyd" 25 HP; "Lanz" 25 HP. — Italian: "Fiat" 25 HP; "Romeo" 25 HP.

With a single driving wheel "Benz" 25 HP (German); "Big Bell" 25 HP (United States).

INDEPENDENT TRACTORS, WITH CHAIN TRACKS.

United States: "Cletrac" 20 HP; "Holt" 35 HP; "Steel Mule", "Yuba" 25 HP: — French: "Renault" 30 HP; "César" 12 HP (single track): — German: "W. D." 35 HP.

TRACTORS WITH THREE DRIVING WHEELS.

"Glasgow" 27 HP (English)

MOTOR CULTIVATORS OR MOTOR PLOUGHS.

German: "Komnick"; "W. D." 80 HP: — Czechoslovakia: "Excelsior" 40 HP, "Praga" 40 HP: — United States: "Moline" 18 HP; "Doct all" 9 HP; "Beeman" 6 HP: — French: "Agro" 12 HP; "Tourand-Latil" 35 HP.

OTHER MOTOR DRIVEN MACHINES.

French: " S. O. M. U. A., 4 and 25 HP. models.

To sum up spain has already had experience of 23 machines of North American manufacture, 8 French, 6 German, 4 English, 2 Italian and 2 Czechoslovakian.

To give an idea of the method of the motorculture trials some details are appended of two important tractor-trials, which took place at Seville and Saragossa (1) respectively, towns typical of two quite distinct types of Spanish agriculture.

The following were the points of mechanical detail and working power which served as the the basis of classification at the Seville trials:

---

(1) See *R.* Nov.-Dec. 1920, No. 1168. (*Ed*).

Mechanical features and conditions of the work carried out by the machines.

I — Indicated power of motor.
II — Maximum tractive effort at base (in kg.).
III — Nature of work carried out by the machine.
IV — Depth ploughed under the test conditions
  - Maximum.
  - Average.
  - Minimum
V — Working capacity under test conditions.
  - Length of trial.
  - Surface worked in trial.
  - Surface worked per hour.
  - Resulting classification.
VI — Type of fuel used.
VII — Fuel consumption.
  - Per hour.
  - Per hectare.
  - Resulting classification.
VIII — Description.
  - Of ploughing.
  - Of behaviour of the machine.
IX — Amount of soil displaced per hour.
X — Notes.

Technical coefficients for comparison carried out by the machines in uniform soil.

I — Nature of the resistance *R* of the soil worked by the machine determined by the model PARLIN plough and the SCHAFFER and BUDENBERG self registering dynamometer in kg. per sq decimetre of the furrow.
II — Section *S* worked (as executed by the machine in accordance with the terms of the test) in sq. decimetres.
III — Average working speed *V* in metres per second.
IV — Tractive effort *R. S. V.* compared with the model plough in kilogrammetres. in H. P.
V — Fuel consumption *C* per working hour in litres of gasoline.
VI — Consumption per effective H. P. compared with model plough coefficient of comparison $\frac{C}{P}$
VII — Notes.

At the Saragossa trials, the technical data were recorded similarly with such modifications as were required by the nature of the district

A special feature of this trial was the carrying out of a test or demonstration on ground with a slope not exceeding 1 in 12.5 feet. This trial is of special interest because of the hilly character of many districts in Spain, and the comparative results were of considerable importance.

It will be seen that detailed and careful observations were made on both the mechanical and the agricultural side of the tractors' work, so as to provide a comprehensive description, indicating in definite and concrete form the nature of each machine.

The abundance in certain areas of dry tracts of country with an irregular or very scanty rainfall and great summer heat, and the compact nature of certain soils put a greater draught strain on the tractors that than for which they are naturally built. The result is a sensible reduction in the work that can be expected of them which is naturally disadvantageous economically. This is the explanation of the not infrequent phenomenon that a tractor reputed to be able to draw with ease a plough with three shares, finds it very difficult to draw one with two shares only on Spanish soil.

Difficulties regarding mouldboards and inadequacy of turning space, as well as the small size of the holdings in certain districts are additional and serious obstacles to the development of motor-culture in Spain.

Hence there still remain a number of practical problems and it is to be regretted that the national trade interests still lack the energy to make a contribution to their solution. With their intimate knowledge of the special nature of the agriculture of the country, they are advantageously placed for the invention of a limited number of classes of tractor, which could fulfil the conditions of an ideal machine. Among these must be reckoned: Strength combined with lightness, i. e., the minimum of weight; small dimensions; high penetrating capacity; small consumption; solidity combined with ease in working, allowing for the fullest attention to be given to the plough and the work: equal ease of working both on the outward and the return journey.

SECOND PART

ABSTRACTS

AGRICULTURAL INTELLIGENCE

GENERAL INFORMATION.

972 - **The Danger of Using Hydrocyanic Acid for Disinfecting Flour.** — MARCHADIER (Directeur), GOUJON (Chimiste du Laboratoire Municipal du Mans), and DE LAROCHE (Directeur du Laboratoire d'epidémiologie de la 4e région), in the *Journal de Pharmacie et de Chimie*, Year 113, Series 7, Vol. XXIII, No 10, pp. 417-420. Paris, May 16, 1921.

The authors advise that the treatment of flours with hydrocyanic acid should be prohibited, for investigations made in the Mans municipal Laboratory have shown that flour can fix an appreciable amount of this acid. The sample examined, which was of pure wheat flour, contained, 82 mg. of prussic acid per kilogram. This is below the danger limit (118 mg.) fixed by the Higher Council of Public Health of France (*Conseil supérieur d'hygiène de France*).

It must, however, be remembered that flour in the form of bread is the basis of man's daily food, and that baking does not remove all the prussic acid it contains; hence the presence in flour and other foods of even smaller quantities than the amount permitted by the above Council, constitutes a danger to the consumer.

973 - **The Meat of Tuberculous Cattle from the Hygienic Standpoint.** — SPARAPONI, G. C. (Assistant Inspector of the communal Abattoir of Venice), in the *Annali d'Igiene*, Vol. XXXI, No 2, pp 125-131. Bibliography of 44 works. Rome, February 1921.

The problem of the use of meat from tuberculous cattle in the ordinary way for human food has been much discussed and studied during the last fifty years, but the results obtained have been contradictory and differently interpreted. This is due to the fact that, owing to the lack of accurate methods for determining the presence of latent tubercule bacilli in the meat or organs of tuberculous cattle, there, are no data upon which a correct judgment can be based. The author points out that the different results obtained by modern investigators as well as those of former times are attributable to the different anatomical type studied by them.

At the present day, the anatomical forms of tuberculosis which make the meat toxic are well-known, but such meat when cooked, becomes innocuous, and according to NOCARD and and LECLAINCHE, "the consumption of meat which is even raw, or but little cooked, and contains some tubercle bacilli has certainly no bad effect upon man." Further, there is no fear of toxic tubercular substances remaining in the cooked meat, since, as GALTIER and EDELMANN have shown, tuberculous beef contains only negligible quantities of such matters and these are very rapidly eliminated by the organisms of living cattle; this has been demonstrated by FIORENTINI and GARINO, who thus explain the fact that even serious tubercular lesions may exist where the state of nutrition of the affected animals is excellent.

RUMPEL, and many other authors, have shown that the nutritive value of sterilised meat of tuberculous cattle is in no wise inferior to that of the flesh of healthy animals, so that the meat may safely be used for human food, for which purpose it is now very frequently sold in secret. The author therefore advises a radical change in the regulations of the present Italian health legislation dealing with the use of the meat of tuberculous cattle (art. III of the General Health Regulations, February 3, 1901).

974 - **Experiments made in the United States Concerning the Practical Application of X-ray Radiation in the Destruction of *Trichinella spiralis* in Infested Meat.** — SCHWARTZ, B., in *Journal of Agricultural Research*, Vol. XX, No. 11, pp. 845-854. Washington, March, 1921.

Six series of experiments conducted by the Zoological Division of the Bureau of Animal Industry, United States Department of Agriculture. The trichinous meat used in these tests was obtained from hogs (Series I, II, III and V) and guinea pigs (series IV). The first were killed several months after artificial infection, the second about one month after. The trichinous meat was packed in wooden or cardboard boxes and exposed to X-rays and then fed at once to rats and mice.

The units of X-ray varied in the different experiments. For series I, II and III respectively they were: 2899, 966, 191, 81, 35 and 19; 600, 300, and 350; 674, 924, 1363, 2162, 1081 and 3094 (1).

In Series IV, the infested meat was exposed to the direct action of the rays at a distance of about 25 cm. from the focal spot of a COOLIDGE-type tube. The pressure across the tube terminals was 73 kilovolts. The meat was exposed to radiation for 42, 84, 126 and 168 minutes respectively. The current through the tube varied during the time of treatment from 4.2 milliamperes to 4.9. The boxes were so placed that the rays from other tubes in the machine had very little influence on the contents.

In series V, the dosages used were not indicated.

Results of the experiments showed that the trichinae may be seriously injured by X-ray radiation. In series I, larvae isolated from the infested meat by artificial digestion 3 days after treatment, appeared to be unaffected. These larvae were normal in colour and in reaction to heat, whilst larvae from treated meat fed to rats and mice were incapable of attaining full sexual maturity in the intestines of their hosts. Injuries from X-ray treatment are not visible in the encysted or artificially decapsuled larvae by artificial digestion (gastric juice), but becomes apparent only when the larvae find a suitable host in whose intestine they are normally capable of continuing their development.

---

(1) Purely arbitrary units 1000 of which are equivalent to a dosage received at a distance of 5 in. from the focal spot of a COOLIDGE tube with a current of 4.2 milliamperes and a pressure of 70 kilovolts across the tube terminals. Treatment continued for 42 minutes.

In certain cases, trichinae underwent granular degeneration. In others, sexual maturity was attained, but no evidence of successful copulation could be found, which indicated that the structural and functional sex maturity was non-existent and the sex cells appeared to be atrophied.

In addition, trichinae appeared to exhibit considerable variation in their susceptibility to X-rays. Certain intensities gave rise to injury in some cases and had no effect in others which may be accounted for by factors as yet not determined.

Admitting that a reliable method of destroying the vitality of the sex cells in trichinae by means of X-ray treatment of infested meat can be perfected, it is still questionable whether such a method would be acceptable as a prophylactic measure. The trichinae apart from the damage done by their migrating larvae are offensive as intestinal parasites. Consequently, unless the X-ray treatment has the effect of diminishing the injurious action of the intestinal stage of trichinae upon the host as well as destroying their powers of reproduction, it can scarcely be considered a satisfactory prophylactic measure.

The author quotes the observations made by TYZZER and HONEIY (1) who found that encysted trichinae, subjected to radium radiation, failed to develop in mice. These investigators also determined that whereas radium radiation failed to destroy sexually mature trichinae in live rats, trichinae in rats which were exposed to the rays beginning with the second day after ingestion of trichinous meat, showed retardation in development. Radiation of the larvae in rats before they had begun to develop proved fatal to them.

The experiments described do not permit the drawing of any definite conclusions as to the feasibility of using X-ray radiation as a practical means of destroying trichinae in pork.

975 - **The Transmission of Poison from *Rhus* spp. to Persons.** — MC. NAIR, J B, in *American Journal of Botany*, Vol VIII, No 5, pp 238-250, bibliogr. of 49 works. Lancaster, Pa, May 1921.

Report of investigations made by the author in connection with the transmission of *Rhus diversiloba* poison from 3 standpoints: botanical, chemical and pathological.

---

(1) TYZZER, E. E., and HONEIY, H. A., The effects of radiation on the development of *Trichinella spiralis* with respect to its application to the treatment of other parasitic diseases *Journal of Parasitology*, Vol. III, No. 2, pp 13-56, 1916 (*Author's Note*)

From the results obtained it may be concluded that the poison is non-volatile as it is not distillable normally by steam or under reduced pressure, and cannot be carried by contact with a volatile substance. This is contrary to the idea put forward that it is a non-volatile poison carried by a volatile oil.

Dermatitis occurs only on the area of skin to which the poisonous sap has been applied; a general irritation is not produced as by volatile irritants. It does not diffuse rapidly in the skin ; the period of latency is very long. Portions of the plant which do not cause dermatitis are: the pollen, trichomes, epidermis, cork cells and xylem; the poison is confined exclusively to the resinous sap. Leaves decrease in virulency by drying, owing to loss of fluid of the sap and from oxidation of the poison. Poisoning without actual contact with substances that have poisonous sap on them, such as clothing or hair of animals etc. may occur.

The author gives details of work carried out in connection with *Rhus* poisoning for very many years by various investigators but makes special mention of the work done by PFAFF on the active principle of *R. toxicodendron.* (*Journal Exp. Med.*, vol 2, pp. 181-196. 1897) who was the first to come to the conclusion that the poison must be a non-volatile skin irritant.

976 – **Ligurian Provincial Committee for Small Industries.** — *Bollettino dell'Associazione Italiana Pro Piante Medicinali, Aromatiche ed altre utili*, Vol IV, No 7, pp 110-111. Milan, July 1921

A provincial committee for small industries has just been established at Porto Maurizio. Its programme includes the following subjects:— Practical instruction in herb-growing; instruction in distillation; instruction in trading in aromatic and medicinal plants; instruction in the formation of co-operative societies of herb-collectors and distillers; lessons in cultivating the above mentioned plants; assisting and advising persons interested in this work. The institution is subsidised by the Ministry of Agriculture, and is going to lay out at least 2 experiment fields.

CROPS AND CULTIVATION

977 – **Weather Forecast and Agriculture.** — GOLD, E., in *The Scottish Journal of Agriculture*, Vol IV, No. 3, pp 251-258, 1 fig Edinburgh, July 1921

Forecasts are now made in Great Britain in the following way:— Reports are collected several times a day from different places scattered over a wide area extending from Ireland to Madeira and from Spitzbergen to Cairo ; a few reports are also received, almost daily, from some ship in the Atlantic to the West of Ireland.

The data transmitted give information respecting:— The height of the barometer; the way in which the barometer has been changing; the temperature ; the direction and speed of the wind; the clearness and humidity of the air; clouds and their height; and a brief description of the weather at the time, and in the interval since the preceding report.

By an ingenious utilisation of figures, the whole information is telegraphed in 4 groups, each consisting of 5 figures.

The information thus received is entered upon charts or maps. These maps are compared with the maps immediately preceding them and with maps for the same season in previous years, to see what changes followed when the maps had the same characteristic features as those from which the forecasts are being prepared. Data showing the temperature and the direction of winds at great heights are also obtained, one from aeroplanes, the other by the observation of small free balloons.

In forecasting the following principles are always kept in mind:—

(*a*) Weather travels, so that a region will usually experience the weather which is travelling towards it.

(*b*) Hills and mountains modify the weather by forcing the masses of air to rise to greater heights, where they may condense.

(*c*) Cold surface air tends to displace the layers of warm air beneath it, thus also producing condensation.

(*d*) Cold air moving over land or sea, where it becomes unduly warmed at the surface is set into vertical circulation, with the production of cloud and showers.

In 9 cases out of 10, it is possible to forecast with reasonable accuracy and confidence for a period 24 hours ahead.

In addition to the information supplied to the Press, special telegrams are sent to any address on payment of the cost of the telegrah and a small registration fee.

In this way regular forecasts are provided, notifications of spells of fair weather are issued, and telegrams are sent indicating the progress of meteorological events, and warning when the spell is about to break. Frosts and storms are also notified.

The author makes some remarks on the organisation of the Meteorological service abroad, especially in the United States where excellent results have been obtained, and expresses the hope that Great Britain will follow the good example set in America. He strongly advises the use of signals hoisted in some prominent position to announce the approach of frosts or of severe gales, or the setting in of fair weather.

978 - **Summer Rainfall and the Penetration of Mediterranean Vegetation into the French Pyrenees.** — GAUSSEN, H., in the *Annales de Géographie*, Year XXX, No. 166, pp. 249-256 + 1 Map. Paris, July, 1921.

The character of the basins of the Ariège and the Hers is, from the physiographical standpoint, distinctly Atlantic, for the mountain chains are so arranged as to create, in the central part of the Pyrenees, conditions favourable to the penetration of oceanic influences.

Nevertheless, in some of the regions situated on the further side of the limestone mountains of Ariège and Garonne, distinct oases of Mediterranean vegetation are to be found. This vegetation is characterised by its power of enduring prolonged drought. The author studies the special conditions of these oases from the points of view of the climate and the flora, taking as his basis 3 factors:— The drought map; (2) the limit of the olive-tree; (3) the limit of the ilex.

Drought Map. — For the eastern sector, the months of June, July, August, and September were examined, and for the western sector, July, August, September and October. The total rainfall during the four months provided the data for making the curves, and the map upon which they are drawn, this period being the driest of the year in the regions under consideration.

An examination of the map reveals a very interesting fact, *viz.*, that in the midst of the rainy mountainous district, relatively dry oases are to be found situated at the bottom of the valleys. Thus, at Tarascon, in the valley of the Ariège, the rainfall for the four months is 226 mm., whereas in the immediate neighbourhood at Prat Communal, Cabannes, and Foix, it is 439, 265 and 255 mm. respectively. In the same way, the rainfall at Suz, a dry spot, is 257 mm., whereas 306 mm. of rain fall at Gavarnie, 336 mm. at Argelès, and 359 mm. at Lourdes during the same period.

Throughout all these regions, the rainfall seems to decrease as the valleys are ascended. This is probably due to the condensing action of the great buttresses covered with forest that intercept the last water-vapour coming from the Atlantic, thus at once creating a dry zone in the upper parts of the valleys.

Limits of the Olive Tree. — The olive grows along all the valleys of the middle Pyrenees, penetrating far into the mountainous district to the average height of 875 m. at Olette in the Tet valley.

An examination of the maps showing the dry districts, and the distribution of the olive will reveal many points of resemblance between the two. Thus, the 180 mm. curve marks the limit of the maximum cultivation of this tree, and the 200 mm. curve coincides with the extreme limit of its growth.

Similarly, the patches of olive trees in the high valleys are often found on dry spots. These facts are the more remarkable, seeing that drought is a somewhat complicated factor depending, not only upon the amount of the rainfall, but equally upon the duration and intensity of the atmospheric precipitations, temperature, evaporation, agrogeological and topographical conditions, etc.

Limits of the Ilex. — As with the olive, the pluviometric curves of summer drought give interesting results for the ilex. The tree is found only in the immediate vicinity of Tarascon (being entirely absent in the surrounding district) and, as we have said above, at Tarascon, in the valley of the Ariège, there are only 226 mm. of rain in the 4 wet months, although the rainfall in the neighbourhood is higher.

From the examination of the large amount of data collected, the author has concluded that, in the eastern sector of the Pyrenees, the ilex when growing on calcareous soils, cannot stand more than 200 mm. of rain in summer, whereas in the south-eastern and south-western sectors where the ground slopes considerably, it is not harmed by as much as 250 mm.

Excessively low temperatures in winter may quite exclude all southern trees, but there are many places in the Pyrenees where they do not grow in spite of the relatively mild winters. On the other hand, the capacity of resisting low temperatures often depends upon the meteorological conditions of the preceding summer, which must be dry, to enable the tissues to mature properly.

The dominant factor determining the existence of Mediterranean oases in the French Pyrenees is, without any doubt, the dryness of the summer, as is clearly seen in comparing the rainfall charts (for the 4 dry months) and the maps of vegetation.

979 - **Weather Bureau Activities in California as Applied to the Production of Sugar Beets, Citrus Fruits, Dates and Rice.** — PALMER, H. A., in *Monthly Weather Review*, Vol. 49, No. 4, pp 219-223. Washington, April 1921.

While most climatological data obtained in California are used directly or indirectly in agriculture, certain stations are maintained primarily for this purpose with reference to the more important crops.

1) SUGAR BEET. — The Spreckels Sugar Co. has established a scientific laboratory at its headquarters which includes in its equipment all the standard meteorological instruments, and amongst them the various types of air and soil thermometers found at a first-class Weather Bureau Station. Investigations have shown that there is an intimate and complex relationship between weather and the sugar content, but the optimum weather condition has never been determined as it varies with soil, elevation, latitude and time of sowing. It has already been recognised that the optimum weather for the production of seed does not correspond with that for sugar production. As a result, however, of these conclusions, the experiment station has established a considerable number of climatological stations near the Coast of Central California and in the interior valleys. Another company, the Union Sugar Co. with headquarters at Bettervia, also maintains a meteorological service of its own but on a less extensive scale.

2) CITRUS FRUITS. — Climate determines the districts available for the successful culture of citrus fruits. The bulk of the crop is grown in southern California, and the foothills of the interior valleys of central and northern California have been found well adapted to its cultivation. The most northerly orange groves, near Oroville, produce the first mature oranges every autumn for which fancy prices are paid.

It is unnecessary to add that meteorological data form an important consideration in the successful production of citrus fruits. These relate principally to frost, heating, hot waves, fumigation, irrigation, etc., which necessitates a complete knowledge of local atmospheric conditions. Official weather data is available at the orchard meteorological Stations the chief being: Pomona, Redlands, Riverside, Porterville, Lemon Cove, Lindsay, Oroville and Yorba Linda.

3) DATE PALMS. — Successful date culture on a commercial scale requires tropical or semi-tropical weather conditions. Frosts or prolonged low temperatures cannot be endured by the date palm and the mean temperature must be relatively high. On the other hand, the water requirements are light, and the palms will flourish in what appears to be a sandy desert, provided that the temperature conditions are favourable. These peculiar conditions are found in the Coachella Valley where the United States Bureau of Plant Industry has introduced the culture of the date palm on an extensive scale. About 70 species, imported from Africa or Asia are under inspection at the India Experiment Station. Seedlings of the best adapted varieties are already available for distribution. Special mention is made of the "Delget Noor" variety which has been found to be adapted to general cultivation in the Imperial Valley. Meteorology has contributed in no small measure to the successful introduction of the date palm; meteorological instruments form an important part of the equipment of the India Experiment Station and of the Mecca substation.

4) RICE. — Less than 10 years ago, the Department of Agriculture introduced rice culture into California on a commercial scale on the flood plain of the Sacramento River. The new industry grew rapidly; the limiting factor seems to be inadequate water supply, hence the importance of controlling the factors in order to permit the highest possible use and at the same time economy of water. Of particular importance are precipitation and river-stage data in connection with irrigation. The University of California also maintains an independent evaporation Station in connection with its Rice Experiment Station, and yet another at Dodgeland in the heart of the rice growing district, maintained by the Weather Bureau and by the Dodgeland Co.

In conclusion it may be added that there is no agricultural undertaking of any kind in which meteorological problems do not stand in the forefront.

980 - **Acid Soil Studies in the United States.** — I ROBINSON, R. H., (Oregon Agricultural Experiment Station), Acid Soil Studies — I. A Study of the Basic Exchange Between Soil Separates and Salt Solutions, in *Soil Science*, Vol XI, No 5, pp 353-361, tables 8, bibliography of 6 works. Baltimore, M D, May, 1921. II. ROBINSON, R. H., and BULLIS D. E, Acid Soil Studies: Changes in Calcium Compounds Added to Acid Soils. *Ibid.* pp. 363-367, tables 4, bibliography of 5 works.

I. — Four characteristic acid soils were selected for study in Western Oregon (silt loam, gravelly loam, clay loam, medium sandy loam) and soil separates were made by mechanical analysis of the different samples. Five different salts, namely potassium nitrate, potassium chloride, potassium acetate, calcium acetate and sodium chloride were used in the study.

From the results obtained it may be concluded that the acidity of the different soil separates liberated by the action of a certain salt solution is approximately the same, although the manner in which the salts of mineral acids react with the soils studied is apparently different from the reaction with the salts of an organic acid. The so-called acidity liberated by potassium nitrate, potassium chloride and sodium chloride is due mainly to aluminium and iron rendered soluble by basis exchange. However, the acidity produced by calcium acetate and potassium acetate was due to acetic acid liberated either by replacement of the hydrogen of hydrous silicates or by selective adsorption of the basic element in the salt solution. The hydrogen-ion concentration of the different separates of the soil was constant.

Results indicate that the size of the soil particles, the presence of colloids or organic matter in the clay separates or the composition of the different separates does not have a great influence on the hydrogen-ion concentration, and consequently on their acidity.

II. — In the foregoing investigations, studies were made to ascertain the reasons why some acid soils of Oregon do not respond to lime treatment. In an effort to answer this question further experiments were carried out with the same soils by the application of calcium carbonate and calcium oxide used in amounts equivalent to the lime requirement of the different soils. The pots containing the soil thus treated were sunk into the ground and spring barley was grown in them to aid natural functioning and changes that the calcium compounds might undergo. After exposure to the weather for one year, representative samples were taken and the calcium determinations were made.

It was demonstrated that, when calcium carbonate or calcium oxide was added to several acid soils, most of the calcium was retained after exposure to weather for one year, although part had been lost by leaching by about 40 in. of rainfall; the calcium retained was combined chiefly with humus and easily decomposable silicate. Most of the calcium present in the acid soil that did not respond to lime treatment (the gravelly loam) was found combined as a silicate decomposable with difficulty. This, however, does not explain the reason why the soil does not respond to lime treatment.

In any case, after exposure to the weather for 1 year, all the soils treated as mentioned above gave an alkaline reaction.

981 - **Studies on the Rate of Formation of Soluble Substances in Several Organic Soils in the United States.** — McCool, M. M., and Wheeting, L. C. (Michigan Agricultural College), in *Soil Science*, vol. XI, No. 3, pp. 233-247, figs. 5, tables 7, bibliography of 2 works. Baltimore, M D., March, 1921.

Research concerning the rate of formation of soluble salts in a great many mineral soils have been made, but little is known of the behaviour of organic soils under similar conditions.

The results of a preliminary study of such activities in 7 organic soils are here presented concerning: —

1) The relative solubility (taken to mean the power of soil to form soluble substances) under different moisture conditions.

2) Relative solubility of different depths of the soil section under optimum moisture conditions, the freezing point method for the determination of soluble material in the soil solution being employed.

According to the results obtained, at any given moisture content, the effect of a higher temperature is to increase the rate of formation of soluble material, and conversely, lower temperatures decrease the rate of formation. For the higher temperatures, optimum moisture conditions tend to bring greater amounts of material into solution than are found under saturated water conditions; exactly the opposite effect was observed with lower temperatures. Generally moist soils upon standing, increase in concentration to a certain point, after which a decline occurs. This is probably due to the following causes: *a*) reabsorption, *b*) chemical change to less soluble compounds; *c*) biological activity. Organic soils vary at different depths in the amount of soluble substances present; different depths also vary in the rate and amount of material made soluble upon standing. Below a depth of 2 ft. the muck soils studied are very inactive; the surface layers usually produce the bulk of the soluble plant foods, and in general the ability to yield soluble materials decreases regularly from the surface to the water-table

The comparison made between the depth of weathering of organic and mineral soils is of decided interest, and investigations show that the climatic action is negligible below a depth of 2 ft. whilst the most recent mineral soils of fairly heavy texture have weathered from 3 to 6 ft. deep, and sandy soils even deeper. Apparently, therefore, there would be a larger area where the soil materials are more soluble in mineral soils, and this may have some bearing on the excessive fertiliser requirements for mineral elements in soils rich in organic material.

982 - **The Amount of Unfree Water in Soils at Different Moisture Contents.** — BOUYOUCOS, G., (Michigan Agricultural Experiment Station) in *Soil Science*, Vol. XI, No. 4, pp. 255-259, bibliography of 3 works. Baltimore, M.D. April, 1921.

A new classification of soil humidity has been demonstrated by the author: gravitational water, free water and unfree water (capillary adsorbed and combined) (1). By carrying out a series of determinations with reference to unfree water on diverse soils and with varying moisture contents, not including the hygroscopic moisture, it was evident that the amount of water which the soils are able to render unfree appears to remain constant, and does not vary with the different degrees of humidity. The dilatometer method was employed following the usual procedure, considering all the water that refused to freeze for the first time at the supercooling of —1.5° C. as unfree water, and that which did not freeze after supercooling at —4° C as combined water; and the difference obtained as capillary-adsorbed water.

The fact that the amount of water which the soils are able to render unfree does not vary with the degree of humidity, is extremely important especially in relation to the availability of moisture in soils at different moisture contents, the possible behaviour of soils towards fertilisers, the physical condition of the soil, etc. Changes in the physical condition of the soil causes a certain variation in the total amount of unfree water, and the form most susceptible is the capillary-adsorbed water whilst the combined form seems to remain constant; practically speaking, the transition from one form into the other is not absolutely sharp.

---

(1) See *R.* June 1921, No. 507. (*Ed.*)

This constancy has been contradicted by KERN (1) according to the conclusions drawn from his mathematical considerations; this may be explained by the existence of unknown factors which make it unsafe to predict conclusions mathematically.

983 - **Analysis of Soils.** — VESTERBERG, K. A., Svensk Kem. Tidskr. 1921, 33, 12-22; in *Journal of the Society of Chemical Industry*, Vol. XL, No. 11, p. 401-A. London, June 15, 1921.

The author questions statements to the effect that salts dissolved in the moisture in soils are absorbed by plants at the same ratio as the water itself; the roots do not take up the salts etc. in the proportion in which they occur in the soil.

As regards the concentration of plant foods in soil moisture, which constitutes the minimum requirement of plants, the following quantities are suggested:

Phosphorous pentoxide, 1-2 mgm. per litre; nitrogen 2-5 mgm. per litre; potassium, 10-20 mgm. per litre.

Climate would possibly have some effect on the efficiency of these amounts of foods.

984 — **Irrigation with the Couten Sprayer.** — See No. 1041 of this *Review*.

985 - **The Influence of Fertilisers Upon the Productivity of the Soil.** — JORDAN, W. H., Soil Studies, I. The Influence of Fertilisers Upon the Productiveness of Several Types of soil. — II. The Influence of Fertilisers and Plant Growth Upon Soil Solubles in *New York Agricultural Experiment Station, Bulletin* 473, 27 pp. Geneva, N. G., March 1920.

It was found, by growing barley under forcing-house conditions, on 9 different types of soil consisting for the greater part of loams, the vegetative growth was influenced very little by the application of either litter or leaf-mould. During the first year's experiments, well-composted farm manure did not produced additional growth, although the results obtained with it the second year were satisfactory, but the plants to which commercial fertilisers were applied grew much more than those receiving stable manure, the quantites of nitrogen, phosphoric acid and potash being the same in the two cases. Slaked lime applied with farm manure had a very irregular effect according to the different types of soil, in short, nitrogen appeared to be the sole fertilising substance having a marked influence upon barley.

To confirm these results, two soils were selected, one highly productive, and the other less fertile, and barley again planted. It was found that, under forcing-house conditions, the soils appeared to supply sufficient quantities of phosphorus and potassium for luxuriant vegetation.

---

(1) See *R.* 1920, No. 388. (*Ed.*)

The application to the soil of soluble compounds of nitrogen, phosphorus and potassium, materially increased the proportion of water solubles in the soil; these were used by the plants, and their amount was thus rapidly reduced before the barley had attained considerable growth. In the latter stages of its development, the quantity of the water-solubles remained constant and was much the same (with the exception of the phosphorus) as that present in the soil receiving no fertiliser.

To sum up; it would seem that from the practical standpoint, the above data show the importance of the solubility of the three essential ingredients of fertilisers, especially in the production of quickly-growing crops. Plants accumulate a large proportion of the required nitrogen and ash ingredients during the early stages of growth, for which reason, in the case of forcing-house culture, vegetable-gardening, and of such crops as cabbages, potatoes and wheat, an adequate supply of immediately available food appears to be indispensable in order to obtain good results.

986 - **Tertiary Nodular Phosphates in Italy.** — CORTESE, E., in *La miniera italiana*, Year V, No. 2, pp 49-51, 1 fig. Rome, February 28, 1921.

The author, after mentioning the nodular phosphates that have been found near Cape Santa Maria di Leuca, which he does not think worth consideration at present, owing to their low content of tricalcium phosphate (less than 30 %), passes on to describe the phosphates discovered in the Province of Syracuse (Sicily). The richest district appears to be that of Donna Lucata, where there are 2 phosphate beds of considerable thickness, and with nodules containing an average of 15 % phosphoric acid, corresponding to 30 %, or a little more, of tricalcium phosphate. A concession of some 500 hectares has been obtained in this district, from which about 1 ½ tons of nodules per square metre could be obtained; this would give a reserve of about 7 million tons.

This nodular phosphate is very rich in calcium carbonate (containing from 48.42 to 62.67 %), and barely contains half the tricalcium phosphate required for transforming it into superphosphate.

The phosphatic content of the nodules could probably be increased by means of a system which is at present on trial, or the nodules could be ground very fine, mixed with liquid manure, and used directly, like the low-grade phosphates and phosphatic marls of Belgium.

The author is of opinion, that these stores of phosphate should not be neglected, but that the example of other, even richer, countries, ought to be followed, and the poorest natural resources turned to good account, all the more seeing that as soon as the mines of Donna Lucata are opened (they are easy to work being on the surface, and situated on the seashore), a further extension of the deposit will be revealed, and it will be possible to investigate another phosphatic substance found outside the nodular layers, and called " giurgiulenaro " (1) from its granular structure. A sample which was analysed contained 18.54 % phosphoric acid (equivalent to 40.38 % tricalcium phosphate). Afterwards, a search could also be made at Cape Santa Maria di Leuca, with a view to discovering the phosphates that are certainly present in Tripolitania.

---

(1) This word is derived from *giurgiulena*, which in the Sicilian dialect means a " nougat " of almond paste, honey and sugar; it corresponds to the Italian *giugiolena* = sesame. (*Ed.*)

987 - **An Esthonian Phosphorite and Its Effect Upon Different Plants.** — WRANGELL, M., in *Die Landwirtschaftlichen Versuchs Stationen*, Vol. 96, Nos 1 and 2, pp. 1-44, 3 plates, photographs, numerous tables. Berlin, 1920.

The scarcity of fertilisers during the war, led the author to experiment with various potassic and phosphatic minerals that had previously been neglected. Her investigations were begun at the Reval Agricultural Station, and were continued at the Hohenheim Station in 1918.

According to DEHN, the soil of Esthonia contains an average of 0.28 % of phosphoric acid soluble in 10 % hydrochloric acid, but some soils with fossil brachiopods, contain up to 1.5, and even 2.5 %. This is due to the outcrop of grey, blue (or even reddish and violet) upper Cambrian stones containing *Obolus Apollinis*, and passing down into the fucoid sand-sandstones. The beds are from 5 to 20 m. thick, whereas the true phosphatic shell-bearing conglomerate is only from a few centimetres to 1 metre thick. In the former, as in some of the neighbouring Ordovician strata, nodules of phosphorite with about 11 % of phosphoric acid are often found.

The author gives the detailed chemical composition of the different beds. The phosphoric acid content of crude *Obolus* sandstone of Reval, used in plant-growing experiments at Hohenheim was 20.4 % and the residuum (which is mostly shell-bearing), when freed from the excess of mineral matter, a process very easily carried out, may contain as much as 30 % phosphoric acid soluble both in 1 % hydrochloric and 2 % citric acid.

The *Obolus*-bearing conglomerate is composed of carbonate of lime and of apatite (like the Lahn phosphorite, Staffelite, and Dohllite), which easily dissolves in dilute organic acids, and hence is assimilated without difficulty by plants. As crystalline apatites which cannot be attacked by the roots of plants are usually also free from carbonate, the author is of opinion that this carbon content constitutes a character distinguishing earthy phosphorites, that can be disintegrated, from crystalline apatite.

The plant-growing experiments were made at Hohenheim, in zinc pots, provided with air pipes, and filled with clayey-sand poor in lime. All the pots, except the control series, were given potassic, nitrogenous, or calcareous fertilisers, the special fertilisers consisting of basic slag, two qualities of ground Obolus-sandstone (in different amounts), and other mineral phosphates.

The 1st *series of experiments* was made with mustard sown on Sept. 19 and gathered while in flower, on Nov. 2. A general nitro-potassic fertiliser was applied. The 2nd *series* with spring rye and clover, sown May 9, cut July 30, 1918, with the same general fertiliser as above; special fertilisers; apatite and Lahn phosphorite for the rye, and Staffelite for the clover. The 3^{rd} *series* with buckwheat, flax, colza, and vetches mixed with oats: sown end of July, cut in the autumn: general fertiliser Hallens mixture, plus gypsum and ammonium sulphate; special fertiliser 1.2 gm. Obolus-sandstone or basic slag. The results are given in the Table.

The remarkable effect of the Obolus-sandstone upon the mustard led to the conclusion that this hardy plant, which is very common throughout Esthonia very probably owes its favoured position to its power of breaking up and assimilating the phosphoric acid of the Obolus-sandstone; in this it is much superior to the Gramineae which make little use of the insoluble phosphoric acid present in the soil.

Obolus-sandstone gave but poor results with winter rye plus a supplementary nitrogenous fertiliser. If the special fertiliser, however, contained ammonium sulphate (a physiologically acid substance) in place of nitrate, better results were obtained; a like effect was produced by using large amounts of crude phosphates, as MITSCHERLICH did with success.

Average Crop in Grammes of Air-Dried Material.

Special fertiliser per pot expressed in grammes of phosphoric acid	Mustard	Spring rye	Clover	Buck-wheat	Flax	Colza	Vetches and oats

Apatite . . . 0.6 »	—	3.5	9.5	—	—	—	—
» . . . . 1.2 »	—	4.3	10.5	—	—	—	—

The results obtained were more satisfactory with clover than with rye. No doubt, however, if the vegetative period had been longer, better use would have been made of the Obolus-sandstone and the Staffelite. In any case, although clover appears able to use the phosphoric acid of crude phosphorites, it can make no use of apatite.

When gathered (Oct. 13), the fruits of the buckwheat were partly ripe. Flax is not very susceptible to a phosphatic fertiliser and it is believed that this plant is more affected by the acid reaction of the soil than by the alkaline reaction or by lime (1). The results obtained from colza were of little importance, as the plants developed a disease of the roots. It is stated however, that from the beginning, colza is able to make good use of the phosphoric acid in both the sandstone and slag, w hereas the Graminaceae showed no signs of its effect until latter. The mixed vetches and oats used little more of the phosphoric acid of the sandstone than of the slag, but the vetches growing in pots with sandstone, suceeded better than those with slag.

Another series of experiments with maize, which will be continued, were undertaken for determining the effect of dicalcium and tricalcium phosphates, and of Obolus sandstone in a medium consisting of pure sand with the addition of a varying fertiliser having respectively a physiologically alkaline, neutral, strongly or slightly acid reaction. The best results were obtained with dicalcium phosphate, for the sandstone only gave fairly good results when the soil had a strong acid reaction ; thus practically it scarcely pays to use Obolus sandstone as a fertiliser for maize.

For this reason, the author agrees with those investigators who maintain that different plants have different powers of assimilating crude phosphates and slag, but the capability of plants of the same family is very similar in this respect. Of those examined, buckwheat manifested the greatest power of assimilating phosphoric acid, followed, in descending order, by Leguminosae (the vetch being superior to clover), Cruciferae, flax, and finally the Gramineae. These differences led the author to divide plants into two groups according to whether they *break up or consume* phosphoric acid. The inherent power of disintegrating the phosphoric acid can however be increased by supplementary fertilisers with a physiologically acid reaction. It is hoped to be able to determine by means of further experiments whether this inherent power of breaking up phosphoric acid depends upon differences in acidity of the root secretion of plants, as is held by PFEIFFER, SIMMERMACHER and SPANGENBERG, or upon some other factor (2).

988 - **A Comparative Study of the Consumption of Sodium Nitrate.** — CALICHE, Year III, No. 4, p. 3. Santiago, Chile, April 1921.

The Table reproduced on pp. 1240-1241 gives (according to the pre-War geographical conditions), the supposed future capacity for consuming sodium nitrate in the chief agricultural countries. The calculations are

---

based on the total and cultivated areas of each country, the cultivated area that may be regarded as requiring nitrogenous fertilisers, the total and unit consumption of sodium nitrate, 100 kg. per hectare being taken as the possible amount of fertilisers used. The fertilisers are calculated as nitrate of soda, reckoning one-half as nitrate consumed.

The nitrate required for industrial purposes has not been taken into account.

989 - **The Importance of Magnesium Sulphate as a Fertiliser.** — JACOB, A., in the *Chemiker Zeitung*, Year XIV, No. 56, pp. 445-447. Cöthen, May 10, 1921.

The problem of the fertilising action of magnesium sulphate is one of the chief questions confronting the agricultural chemist. It is, indeed, well-kown that " Patent kali, " the double sulphate of potassium and magnesium has long enjoyed high favour among Dutch agriculturists, especially as a fertiliser for potatoes and leguminosae, but it is probable that its reputation is due less to the absence of chloride (the fertiliser in question being preferred to potassium sulphate which also contains no chlorine), than to the stimulating effect of the magnesium. This fact has proved of additional interest on account of the almost complete failure of the potato-crops in 1916.

The data relating to the question are very scanty, if we exclude LÖW's researches and discussions on the part playd by calcium, and WILLSTAETTERS discovery that chlorophyll is an organic magnesium compound containing 30 % magnesium.

Since 1917, however, the German Potash Syndicate has been using magnesium in a vast series of manurial experiments carried out in Germany and Holland upon potatoes growing in different soils, the basal fertiliser consisting of 90 kg. nitrogen, 60 kg. phosphoric acid, and 200 quintals of potassium.

The magnesium fertiliser was applied in the form of 2.5 quintals of kieserite (monohydrated sulphate of magnesium) that is to say, in amount corresponding to the magnesium in an equivalent dose of sulphate of potassium and of magnesium. A comparison was made between nitrogen, phosphoric acid and potassium chloride on the one hand, and nitrogen, phosphoric acid, potassium chloride and magnesium sulphate on the other; as well as between nitrogen, phosphoric acid and potassium sulphate, on the one hand, and nitrogen, phosphoric acid, potassium sulphate, and magnesium sulphate on the other.

Thirteen times in the 39 experiments, the best crop of tubers was produced by plots fertilised with potassium chloride and kieserite, and 11 times by plots fertilised with sulphate of potassium and of magnesium; thus in 24 cases, the harvest crop was the result of the application of a potassic fertiliser.

The general averages of the yield were as follows: — Without potassium, 202 quintals per hectare; with chloride of potassium 244 quintals, with sulphate of potassium 250 quintals; with chloride of potassium and kieserite 253 quintals; with sulphate of potassium and of magnesium 253 quintals. In short, with the same amount of potassium, the addition of kieserite increased the crop, on an average, 5.2 quintals per hectare. This occurred so frequently, that it may be attributed in some way to the presence of the magnesium.

The starch content was also affected; thus, the average starch production per hectare calculated for 1917-1919 was:— Without potassium 37.1 quintals; with potassium chloride 40.1 quintals; with potassium sulphate 44.2 quintals; with potassium chloride and kieserite 41.5 quintals; with sulphate of potassium and of magnesium 44 quintals. Apart from the manifest superiority of the sulphate, it is noticeable that in 1917 and 1918 the favourable effect of the magnesium was more marked.

It is not suggested, that these experiments have succeeded in solving the magnesium question, which from the industrial and agricultural standpoints, still remains open. It can, however, be said that, under certain given conditions, the use of magnesium fertilisers may considerably improve the yield, and in the meantime, the question of magnesium should occupy the attention of those engaged in the potassium industry, as there is no doubt that there will be a great demand for magnesium fertilisers on the part of agriculturists, and preparations should be made in good time to meet eventual needs for magnesium sulphate. However, it still remains to be seen whether the means hitherto taken to solve this problem are the most suitable for the purpose.

Magnesium sulphate is chiefly found in the German potassic deposits but those of Alsace contain none. During the last years of peace, only 500 000 quintals were sold out of 7 million quintals of kieserite produced, whereas 2 million quintals were used for the preparation of potassium sulphate.

The double sulphate of potassium and magnesium was extracted as an intermediate product, but now the process is carried further, owing to difficulties in drying the compound and the double sulphate on the market is artificially prepared by mixing kieserite with potassium sulphate which entails a much larger consumption of kieserite.

990 - **Graft Hybrids.** — LO PRIORE, in *L'Italia agricola*, Year 58, No. 6, pp. 172-175, 1 fig. Piacenza, June 15, 1921.

The author mentions many cases of graft-hybrids recorded in Italy and other countries, and specially dealt with a medlar grafted on a hawthorn, which was described by MANARESI, (1) who gave it the name of *Crataegomespilus Manaresii*.

The author described the DANIEL method for producing graft-hybrids artificially (by removing the top of the scion), and suggests some theories as to their origin (2), which may be summarised as follows:—

Graft-hybrids are the result of a union between somatic cells belonging to the stock and the scion, and having the power of producing individuals of intermediate characters which are either fused or superimposed.

---

(1) See *R.*, Sept., 1915, No 928. (*Ed.*)

(2) For fuller information see: G. LO PRIORE, *Saggio di Genetica sperimentale*, Turin, Unione Tipografica Editrice Torinese, 1920. (*Ed.*)

A similar state of affairs is frequently met with in ordinary grafts, and is shown by the sudden appearance of ancestral characters, especially when the grafted forms are complex hybrids with innate hereditary tendencies to numerous more or less profound variations. Thus in the same scion there may be variations of different origins, which are either intermingled or superimposed.

991 - **Effect of Salt Solutions having Definite Osmotic Concentration Values upon Absorption by Seeds.** — RUDOLFS, W. (New Jersey Agricultural Experiment Station), in *Soil Science*, Vol. XI, No. 4, pp. 277-293, tables 6, figs. 2, bibliography of 6 works, Baltimore, M. D., Apr. 1921.

This series of experiments was designed to determine to what extent salt solutions tend to resist water absorption by seeds and whether this influence has a direct bearing upon germination. The author presents data dealing only with that part of the work which has to do with rates of imbibition as these are influenced by the osmotic concentrations of the different solutions employed. The seeds comprised maize, soybeans, alfalfa, white lupin, spring wheat, water melon, field peas, Japanese buckwheat and rape.

Solutions of calcium nitrate, potassium carbonate, magnesium sulphate, monopotassic phosphate, sodium chloride, potassium chloride, sodium nitrate and a complete nutrient solution for plants were used. The osmotic concentration values of these solutions ranged in value from 0.001 to 7.0 atmospheres. The percentage of solution absorbed and the relative absorption quantities were calculated for definite periods of time, the control in distilled water being used as a unit.

There was a marked difference in the absorbing power of seed of different species. Seed of the leguminous type showed higher rates of absorption than the others. The highest rates are indicated for alfalfa, the lowest for maize. The rates were progressively retarded with an increase in the osmotic concentration values of the solutions which do not react with the seed substances to modify chemically the imbibing properties of the seeds.

Average absorption rates show an approximately linear relation to the osmotic concentration values of the solutions, decreasing with an increase in concentration except in dilute solutions.

Experimental evidence points to the conclusion that retardation of absorption rates is accomplished, through osmotic resistance offered to the penetration of water into the seed. Low osmotic concentrations appear to have a stimulating influence upon the absorption rates of the seeds of some species but not upon the rates of others. The physiological significance of these accelerated absorption rates in solutions of low osmotic concentration has not yet been determined. Increasing the length of time during which the seeds are in contact with the solution has a distinct effect on absorption, increasing the differences between the quantities absorbed from solution of low and from those of high osmotic concentration values.

902 - **Character and Productivity of Stalrag, a New Kind of Rye Obtained at Svalöf by Selection from the Stjernrag.** — LJUNG W. E., in *Sveriges Utsädesförenings Tiskrift*, Year XXXI, No. 3, pp. 95-101. Malmö, 1921.

The large-scale cultivation of Stjernråg (Star rye) and the crops it yielded in 1913, show that this variety may be regarded as marking real progress in the improvement of this cereal, which is superior to all the types hitherto grown including Petkuser.

Stjernråg has, however, one defect: the straw is long and not sufficiently strong. These drawbacks have been remedied by the discovering of Stålråg (Steel rye).

In 1911, the author found, in a plot of Stjernråg, one plant differing from the others in several characters, and also in its slightly longer culm. From this plant was obtained the line 0302, put on the market under the name of Svalöfs Stålråg.

From 1915-1920, comparative cultural tests were made at Svalöf, Ultuma, Tomby and Alnarp. The same results were obtained at Tomby and Alnarp confirming the superiority of the new type of rye. Only at Ultuma did it prove inferior to Stjernråg.

Cultural experiments were also carried out in different regions, and for periods of various lengths, to determine the value of the new variety as compared with Stjern, Petkuser, and other types.

TABLE I. — *Results obtained at Svalöf.*

	Yield in grain per hectare in kg.	Relative yield as compared with Petkuser = 100
Svalöfs Stålråg	4 385	109.3
» Stjernråg	4 232	105.5
» 0280	4 116	102.4
Petkuser	4 013	100.0
Svalöfs 0451	3 926	97.8
» selected Wasa rye	3 894	97.0
Schlanstedteråg	3 784	94.3
Bretagneråg	3 737	93.1
Midsommaråg	3 529	87.9
Wasa	3 410	85.0
Prof. Heinrich	3 405	84.8
Öst Gråråg	3 161	78.8

Ostergötland. — Stålråg here took the first place with an average yield of 2990 kg. during the period 1917-1920.

Kristinestad. — Here, however, Stålråg was slightly inferior to Stjernråg, the yields being 1973 and 2030 kg., respectively, in 1917-1920.

Malmö. — Results similar to those obtained in the above province: Stålråg 3523, Stjernråg 3563.

S. Alfsborg. — Stålråg again took the first place with 1940 kg. as against the 1000 kg. of Stjern, and the 1850 kg. of Petkuser.

Skaraborgs and Varmland. — In these provinces Stjern was superior to Stål but the differences were rather small.

Orebro. — Here Stål was first (2433 kg.) followed by Stjern (2353 kg.) and Petkuser (2234 kg.)

In short, Stålråg, on an average, proved slightly superior to Stjern, in all the comparative cultural experiments, and in some districts, its superiority was indisputable and remarkable.

This applies to the grain; for the other characters, viz., straw yield, grain percentage, weight per hectolitre, weight per 100 grains, and culm resistance, see the summary given in Table II where the culm resistance is recorded according to an empiric scale of values, going from 1 (very weak) to 10 (very strong).

Stål is inferior to Stjern in straw-yield owing to its shorter stems, but for this very reason the grain percentage is higher; indeed, in this respect, Stål is superior to all the other varieties examined.

From the standpoint of the quality of the grain, Stål, and Stjern are equal, but the culms of the former are stiffer. The resistance of Petkuser, Stål and Stjern to cold is about equal. They are very suitable to South and Central Sweden though they cannot be recommended for the Norrland.

The results of these experiments taken as a whole, warrant our regarding the new type Stålråg as a distinct step forward in rye selection, for this new product is quite equal to the most approved and widely-cultivated varieties.

TABLE II. — *Summary of results.*

993 – **Experiments in Crossing Different Species of Barley in the United States.** — MALLOCH A. S, in *The American Naturalist*, Vol. LV, No 638, pp 281-286, figs. 2. Lancaster, Pa, May-June, 1921.

The results of crossing cultivated barley and the wild species *Hordeum nodosum* and *H. murianum*. The cross *H. vulgare pallidum* × *H. nodosum* was an entire failure, but 2 hybrids were obtained by crossing *H. vulgare trifurcatum typica* with *H. murianum*. The contrast in the characters of the two parents was very distinct. The low and often recumbent habit of growth of *murianum* was contrasted with the relatively tall and erect habit of *vulgare*. The spikes of the wild barley are compressed, and composed of a number of relatively short and wide spikelets, which form rather a loose head, whereas the ears of the cultivated species are formed of somewhat short and wide spikelets; in fact, there are a large number of morphological differences between the two.

The two F_2 hybrids grew slowly and died after reaching the respective heights of 4 in. and 2 in. The seedlings were remarkable from the fact, that the sheath or coleoptile had a greater circumference than the blade, thus fitting loosely around it, instead of adhering closely as in *Hordeum vulgare*

Thus the crossing was successful, but the resulting hybrids were incapable of normal development.

The author explains this circumstance by the theory of reaction systems. When an attempt is made to combine 2 distinct reaction systems (such as evidently exist in cultivated barley and the wild species), an inharmonious group is often formed, which fails to function in a normal manner, so that as soon as the food material in the seed is exhausted, the plant dies.

994 – **The Transmission of the Character "Resistance to *Heterodera schactii*" in Barley.** — NILSSON EHLE, H, in *Hereditas*, Vol I, 1920, pp. 1-34. Summarised in *Nordisk Jordbrugsforskning*, Part 3, pp 113-115. Copenhagen, 1921

The greater, or less resistance of different varieties of barley to the attacks of *Heterodera schachtii* is of considerable importance in rotations where barley is followed by oats, for as is well-known the latter is much injured by these parasites.

If the barley belongs to a resistant type, the number of the nematodes present in the soil decreases, but if, on the other hand, it happens to be of a susceptible variety, the pests increase greatly and constitute a serious danger for the oat crop which follows the barley.

Oats sown after Chevalier (resistant) produce a crop exceeding by 59 % that obtained when they are preceded by Prinsess (very susceptible).

The degree of resistance possessed by barleys is therefore of the greatest practical and economic interest.

From this point of view, they may be divided into 2 categories, viz., resistant (or nearly resistant), and susceptible. No intermediate degrees and values are found between the two extreme types, such as occur in similar cases; this would seem to show that resistance to *Heterodera*, is due to the presence and action of a single genetic factor.

In order to study this question, the author crossed Chevalier I and Chevalier II (both resistant varieties) with Prinsess (susceptible). The F_1 hybrids proved resistant, therefore this character appears to be dominant.

In the F_2, though the experiments had been carried out under somewhat unfavourable circumstances, a large preponderance of resistant plants was obtained.

Some of the lines of the F_3 were resistant, others susceptible, and others again, were composed of susceptible and resistant individuals, with a preponderance of the latter.

If, as was suggested above, resistance is determined by a single factor, F_3 must contain resistant types, composed of resistant and susceptible individuals, and susceptible types in the ratio 1 : 2 : 1. In the cross Chevalier I × Guldkorn, the proportion is 26 : 42 : 16, which very nearly corresponds to the expected ratio.

The existence of one distinct genetic factor makes it possible to increase the amount of resistance by means of suitable selection and crossing, but it must not be forgotten that yield must be combined with resistance. As a rule, the most resistant types are the least productive.

995 - **Shrunken Endosperm and the Relation of this Character to the Factors Determining the Structure and Colour of the Endosperm.** — HUTCHISON C. B., in *The Journal of Heredity*, Vol. XII, No. 2, pp. 76-83, figs 5. Washington, February 1921.

Maize with shrunken endosperm is only a variation of the ordinary type. The kernels, instead of being smooth and round, as is usual in normal, starchy kinds, present cavities and indentations recalling those found in sugar maize.

In the latter, however, the indentation is due to the contraction of the starch, whereas in the shrunken kernels, a cavity is usually found within the upper cells of the endosperm, as if the cells, in that region had not been filled with starch. When the maize arrives at maturity and the kernels begin to dry, the top or sides sink in, thus closing the cavity, and it is this that makes the characteristic indentations.

By self-crossing, hybrids were obtained with the abnormal character. When these shrunken maize plants were crossed with ordinary types, the F_1 seeds produced were absolutely normal. Evidently, shrunken endosperm is due to a single recessive mendelian character, this may be distinguished by **sh**, and the dominant allelomorph may be expressed by the symbol **Sh**.

In two F_2 progenies, there were 705 normal and 239 shrunken kernels; this is very close to the 3 : 1 ratio expected. The fact that the genetic factor **sh** (**Sh**) is linked with the determinants of aleurone colour and structure is extremely interesting. A homozygous shrunken plant with red aleurone **CC sh sh** was crossed with another with colourless aleurone and normal kernel. An F_1 individual of this cross, grown in the greenhouse during the winter of 1918-19 was selfed; and on an ear thus obtained, there were coloured and colourless non-shrunken kernels, but all the shrunken kernels were coloured. This clearly indicates that there is a linkage of characters. To establish the fact, definitely the author made a number of back crosses between F_1 plants and the double recessive **CC sh sh**. Twenty-eight of the ears thus back-crossed produced offspring, and their kernels (8326) were distributed as follows:

Coloured non-shrunken . .	136	Colourless non-shrunken	4049
Coloured shrunken	3092	Colourless shrunken	148

These data show, that the factors, **C** and **sh** (**c** and **Sh**) are linked, that is to say, they occur in one chromosome in such a manner, as to be always transmitted together. As, however, out of 8326 kernels, 284 showed the combinations coloured-non-shrunken and colourless-shrunk, the linkage is not perfect. This is due to the phenomenon known as crossing-over in which the chromosomes divide, and the products of the division unite with one another in such a way, as to produce an actual exchange of determinants.

The rupture takes place at a point in the chromosome between **C** and **sh** (and respectively between **c** and **Sh**).

The cross-over percentage is 3.4. In order to determine the linkage relation of shrunken endosperm and waxy endosperm a ***non-shrunken waxy*** plant of the constitution **Sh Sh wx wx** was crossed with a shrunken starchy one, **sh sh Wx Wx**.

Several F_1 plants were back crossed to double recessive, **sh sh wx wx**, individuals, and 12 ears thus produced, containing a total of 2105 kernels distributed as follows:

Non-shrunken-starchy . . .	229	Shrunken starchy	833
Non-shrunken waxy. . . .	813	Shrunken waxy	230

Here there is clearly linkage between the starchy and shrunken structure of the endosperm (and similarly between the waxy structure and the normal condition of the endosperm). The cross-over percentage in this case is 21.8.

The factor **I** inhibits the development of the colour of the aleurone. The cross **II Sh Sh** × **ii sh sh** was made, and colourless kernels with normal endosperm were obtained. Several F_1 plants produced by these kernels were back crossed to the double recessive, and produced 28 ears, with a total of 7294 kernels distributed as follows

Coloured non-shrunken . .	134	Colourless non-shrunken	3525
Coloured shrunken	3509	Colourless shrunken . . .	126

Here we also have evidence of linkage, with a cross-over percentage of only 3.6.

996 - **Potato Improvement by Hill Selection in U. S. A.** — STEWART G., in *Utah Agricultural College Experiment Station, Bulletin* No. 176, pp. 3-28, figs. 14. Logan, Utah, Nov. 1920.

In 1911, a number of the highest and also of the lowest yielding hills were selected and isolated from the Majestic, Bangor and Peerless varieties, then being grown at the Utah Experiment Station. In 1912 the tubers from each hill were cut into sets weighing approximately 2 or 3 oz. and containing on the average 2 eyes. The sets were planted about 15 in. apart with rows 3 ft. apart. At harvest time each hill was dug separately and the tubers isolated and later weighed etc. About half of the best hills from the best progeny-rows and a few high yielding hills from other good rows were chosen. In poor selections, the lowest-yielding hills were used as seed. This method of selection was continued from 1912 to 1919, and is being continued still further and supplemented. Except that the poor selections were discarded in 1916, and after 1914, Bangor and Peerless stocks were also discarded on account of inferiority in yield.

The experiment was so conducted as to avoid selection for somatic characters and to secure selection for gametic qualities. This was done by growing all the best strains for 2 or more years in order to get a progeny test of the power of a strain to transmit its desirable qualities to the succeeding generations.

By 1915 the high yielding strains yielded an average of 301.03 bus. per acre as compared with 179.30 bus. per acre for unselected. From 1915 to 1920 the selcted strain has outdistanced the unselected stock of the same variety by more than 100 bus. per acre, except in 1919 when there was a difference of only 29.6 bus.; (this wide fluctuation may have been due to the extremely unfavourable growing season of 1919). In 1920, however, the superiority of the selected strains manifested itself, outyielding the unselected strain by 168.6 bus.

Taking the 6-year average 1915-1920, the acre yield of the selected strain was 60.9 % greater than that of the unselected, and the average size of tuber 24.4 % greater.

The germination of the selected strain is more rapid, the stand is better. the growth thriftier, and diseases less apparent than for the unselected potatoes of the same variety. .

A degenerate strain of highly chlorotic foliage has been isolated, but this could not be traced to any diseases.

997 - **Autofertility, Autosterility and Parthenocarpy in Certain Varieties of Fruit.** — STÅLFET, M. G., in *Sveriges Pomologiska Förenings Årskrift*, Year 22, Part 2, pp. 52-55. Stockholm, 1921.

Results of a series of experiments undertaken in 1919, in order to study the phenomena connected with autofertility, autosterility, and parthenocarpy. Several varieties of apple, plum, pear and cherry trees were examined, and classified as follows: —

AUTOSTERILE. — *Apple-trees*: Belle de Boskoop, Bismark, Rossviksäpple, Cox's Pomona, Skovfogdeæble, Signe Tellisch, Arreskov, Wellington, Sävataholm. *Plum-trees*: Ottomansk Kejsarplommon, Reine Claude. *Cherry-Trees*: Ostheimer.

PARTIALLY AUTOSTERILE. — *Apple-trees*: Hampus, Lane's, Prince Albert, Åkerö, Sommarkryddäpple, Boiken.

AUTOFERTILE. — *Pear trees*: Beurré Diel. *Apple trees*: Mank's Codlin, Brunsäppel, Tompipping, Peasgoods makalösa, James Grieve. *Plum trees*: Bonne de Bry, Stormirabell fr. Metz, Althanns Reine Claude.

PARTHENOCARPIC: Lord Grosvenor.

PARTIALLY PARTHENOCARPIC: Keswick Codlin.

998 - **A Large Collection of Wheats in Italy.** — LISSONE, E. G. (Direttore della Cattedra ambulante di Agricoltura di Saluzzo), in the *Giornale di Agricoltura della Domenica*, Vol. XXI, No. 5, p. 195, 1 fig. Piacenza, June 19, 1921.

The author mentions a collection, made by Sig. VINCENZO STEVANO of 3,000 varieties of wheat coming from all the countries of Europe, Africa, and America. These wheats have been bred by Sig. STEVANO in his experiment field at Savigliano (Saluzzo); many of the varieties quickly became acclimatised, and produced very fine grain.

After some trials, the author has convinced himself that certain foreign wheats, if acclimatised, and bred in Italy, would be successful beyond all expectation. The following Table gives the results obtained from plots of about 100 square metres during the agricultural year 1918-1919, with unselected seed of the 2nd crop (1917), or of the 3rd crop (1918).

Results of growing foreign wheats, or wheats from other regions of Italy.

Origin of wheat	Year of production of seed	Yeld of grain in quint. per hectare		Date of ripening	Preceding crop
		in 1919	in 1918		
Hungary	1918	26.4	—	June 24	Two year clover
Hungary	1918	26.9	50	July 1	Two year clover
Sicily	1918	40	31	June 27	Kitchen-garden plants
Rumania.	1917	36.6	44	June 26	Maize
Rumania.	1918	38.1	36	June 28	Peas and beans
Concepción (Chile). . . .	1917	32	44.9	July 1	Potatoes
Rumania.	1917	23.9	—	June 28	Potatoes

The yield of these wheats (32 quintals per hectare on an average) was much larger than that obtained in the neighbouring fields. This shows how thoroughly the introduced varieties had become acclimatized, and suggests, that excellent results could be obtained from them by selection.

In 1919, Sig. STEVANO was awarded an honorary diploma in France with the following inscription "For the creation and cultivation of the largest collection of wheats in the world".

999 - **Observations on the Wheats of Libia.** — SCAETTA, H., in the *Giornale di Agricoltura della Domenica*, Vol. XXXI, No. 30, p 235, figs 3, Piacenza, July 24, 1921.

The indigenous varieties of Libian wheat have very excellent qualities (1) the surest means of increasing their development and yield have still to be discovered. That is to say, it is necessary to determine :— The best ways of working the land ; the most suitable date for sowing ; the amount of seed per unit area ; the sowing method ; the best subsequent cultivation. It has been stated that it is useless to plough deeply in Libia, seeing that the native, who has cultivated cereals for centuries, has always used a rudimentary plough, and never seen any necessity for altering his primitive technique. It has further been said that deep ploughing encourages straw-growth to the detriment of grain production.

The large-scale experiments made by the author at Derna have demonstrated the undoubted superiority of deep ploughing (18-20 cm.), executed with a modern implement, as compared with the rude efforts of the Libian agriculturist. The beneficial results are, however, not very noticeable in the first year, as the ground has practically to be cleared, but are most recognisable in the 3rd and 4th years. Other conditions being equal, the best time for ploughing is before the rains.

Early sowing, at the beginning of the wet season, or even before, has nearly always been successful. Broadcasting (with 35-40 kg. of seed per hectare) is to be recommended, on account of the free tillering of the best Libian wheats (Mogarbia and Misko). In a dry country strong tillering is much to be desired, especially as it is associated with greater development of the root system.

The natural inclination to tillering has been greatly encouraged by moulding up, which makes the outside culms grow almost as much as the central ones. By this operation, the food supply of the grain is increased, and a heavier crop obtained. In fact, in some of the oases in South Tunisia and Algeria, the natives both earth up and hoe their wheat.

In Libia, wheat is encouraged to tiller by the mildness of the winter, which allows it to grow uninterruptedly until the spring, when the sudden rise of the temperature, together with the prevalence of the warm south winds, induce it to shoot up rapidly. This is the critical period for the crop, and every effort must be made to keep the ground moist, and increase the absorption capacity of the plants.

When a bad season is anticipated, wheats with a short vegetative cycle, moderate tillering and average yield (such as Screisra and some Tripolitan varieties) should be chosen, but when it is difficult, or even impossible, to forecast the weather, the colonist will do well not to confine himself to one single variety, but to sow several, selecting some with a longer vegetative period and high yield, and others with a short growing period and a lower, but more certain, yield.

1000 – **Trials of Strampelli Wheats in Italy.** — JOSA, G., in *L'Italia Agricola*, Year 58, No. 6, pp. 163-171, figs. 6 Piacenza, June 15, 1921.

Strampelli wheats (1) can be divided into 3 groups:— 1) Types for intensive cultivation, suited to North and Central Italy; in this group, there is only " Carlotta Strampelli "; 2) types for dry climates; these have been created chiefly for the Apulian region ; the chief varieties are " Apulia ", " Cervaro ", " Dauno ", and " Luigia Strampelli "; 3) more recently-created varieties for which the best environment has not yet been determined ; here belong Varrone, Ardito, Riccio, Bersagliere, and Potenziani.

As " Carlotta Strampelli " had been widely tested, and always with success in North and Central Italy, the author wished to try it also at average in the Southern Apennines where the climate is not excessively dry, the soil of the plateaux or of the regularly-sloping hills is moist, and where there are artificial meadows, and agricultural operations are carefully carried out. Prof. AZIMONTI (2) has already tried this wheat with complete success in the High Valley of the Agri in Basilicata. Equally satisfactory results were obtained by the author, as is shown by the following figures giving the yields of Carlotta Strampelli and the other varieties tested.

Test at Campobasso (altitude 680 m). — Hilly ground, well-prepared; the wheat followed a manured maize crop; complete fertiliser with superphosphate and sodium nitrate in the spring:— Carlotta Strampelli, 15.40 quintals per hectare ; Noé 14.70 ; March wheat 6.90.

Test in the Commune of Boriano (altitude 500 m). — Damp, fertile plateau soil; the wheat followed manured maize: – Carlotta Strampelli, 12.5 quintals per hectare ; local Solina, 9.15 quintals.

According to the description furnished by the " Stazione di granicoltura di Rieti ", the above-mentioned wheats for dry climates had the following characters:—

Apulia comes from the cross Rieti + Awned Spelta. The ear is white, smooth, glistening, slender; the awns are thin, scarcely 5-6 cm. in length, and parallel to the axis. Fertile spikelets 19 to 23 in number, with strong, well-closed, keeled glumes provided with a short, triangular, pointed beak. The kernels number from 31 to 46 per ear, and are reddish in colour, convex, pointed, with entirely starchy fracture. Weight of 1000 grains 47.5 gm. ; weight of hectolitre 80.6 kg. This wheat is excellent for bread-making. Used in the proportion of 79.20 % (bolter No. 120). It is a variety that does not shed its seed easily

[1008]

Cervaro was obtained from a mixture of hybrids sown in 1908 in Capitanata, and chosen from plants that resisted the drought of that year. It is soft, has tall straw, abundant leaves, is awnless, white, and smooth. Kernels very large. Flour return very high. Requires rather deep soils.

Dauno comes from the same source as Cervaro. Hard, with fawn-coloured, smooth, compact ear, and strong awns 14-17 cm. long, which adhere to the ear. Glumes with pronounced keel and triangular short beak. Kernels 36-50 per ear, 18-22 fertile spikelets. Fracture wholly flinty. Weight of 1000 grains 47.6 gm. Weight of hectolitre 79.6 kg. specially suited for making alimentary pastes, etc.

Luigia Strampelli has the same origin as the two preceding wheats. It is soft, has a white, smooth, awnless ear, with some sign of very short awns on the external glumes near the tip. Glumes with prominent keel and blunt beak. From 18-22 fertile spikelets per ear; 36 to 52 kernels per ear, fracture starchy. Weight of grains: 76.8 kg. per hecto litre. It gives 82 % of excellent flour for bread-making.

According to the author, Apulia and Luigia Strampelli appear to be somewhat susceptible to rust, and have a tendency to lodging on soil that is richer than usual. Dauno is hardy and drought-resistant, as well as less exacting in its requirements than most hard wheats.

The wheats for dry climates were tested under precisely the same cultural conditions as those under which cereals are grown in Apulia, viz., they were sown after base fallow, or an annual crop of leguminosae which had received a dressing of superphosphates or ploughed in without manuring. The seed was broadcast, 130 kg. being used per hectare. The results obtained are given in the accompanying Table (page 1254).

The year these experiments were carried out (1919-1920) was particularly unfavourable to the growth and ripening of wheat, but as on an average, other years have been no better, the above results cannot be regarded as exceptional. According to them it appears that, in arid climates, the Strampelli wheats are not markedly superior to the local varieties.

Dauno can even be mistaken for one of these varieties, red Saragolla, or Saragolletta, which is cultivated in the Lower Apennine district of Capitanata (the ancient Daunia), and in the lower part of Molise.

1001 - **Topping of Wheat.** — SUCCI, A., in *L'Italia agricola*, Vol. 58, No. 7, pp. 197-204 figs. 4. Piacenza, July 15, 1921.

For some decades, the author has made observations upon the growth of wheat, and during several years in succession, he made direct experiments with a view to ascertaining the effect of topping.

In 1917-1918, he carried out his experiments on VILMORIN wheat (a variety which is resistant to lodging), at 3 different stages, in order to be able to cut back either the two basal leaves, the two central leaves, or the two apical leaves, respectively. The times selected were:—

1) When the tallest stalks, with their leaves, when extended, measured 50-55 cm.; the lowest internode being developed and the second just visible (April 17).

2) When the tallest stalks, with their extended leaves, measured 85 cm., and the two first internodes were completely developed (5 cm.

and 6 cm. from the top), as well as all the blades, except the one at the top of the plant (May 2). At this time, the wheat was cut back twice, to 30 and 40 cm. respectively above the level of the ground.

3) When the apical shealth began to grow turgescent from the formation of the ear or, as the peasants say, " takes the form of a spindle " (May 17).

In any case, only the laminae were clipped, and these were cut just above the ligule of the highest stalks. The injurious effect of topping is shown by the following Table.

Effect of topping wheat at 3 different periods.

		Topped April 17		Topped May 2			Topped May 17	
				Topped				
		Topped	Control	to 30 cm.	to 45 cm.	Control	Topped	Control
Weight of 100 grains	gm.	3.9	4.8	3.3	4.3	4.4	3.3	4.3
Number of grains per ear . .		29.0	39.0	25.0	26.0	32.0	31.0	33.0
Weight of grains per ear . . .	gm.	1.10	1.79	0.83	1.12	1.41	1.02	1.42
Length of ears	cm.	8.4	9.2	7.3	7.6	8.3	8.9	8.7
Aborted spikelets per ear . .		3.8	2.2	6.0	5.3	3.4	4.1	4.0
Length of stalk	cm.	115.4	123.6	111.6	123.5	128.4	124.0	130.0
Length of fully-developed laminae								
2 apical laminae . . .	cm.	66.7	66.8	39.8	54.6	66.5	28.7	65.1
2 central laminae . .	»	51.2	73.4	4.6	25.7	70.7	74.0	75.8
1 vasal lamina	»	9.1	26.0	12.5	24.3	28.0	27.0	28.0

These results prove that topping constantly decreased the average yield of each stool, either by reducing the number of kernels in each head, or by lessening the unit weight. Less harm was done by the second topping (May 2). The chief effect of the early topping (April 17) was to reduce the number of kernels, and the last one (May 17) chiefly caused a diminution in the weight of each kernel.

The decrease in the weight of the grain following the first topping took place at the expense of the size and not of the nutrition of the grain, whereas by the 3rd topping, it was typically the nutrition of the grain that was affected.

The decrease in the number of grains must not be attributed to a variation in the number of the axils of the stalk (which is a character differing according to the variety and is independent of growth conditions; thus the lodging resistant VILMORIN has 2), but to the number of fertile spikelets, this being one of the characters most easily affected.

It is interesting to consider the effect of topping upon lodging (1).

---

(1) See R., July-August 1920, No. 741. (*Ed.*)

The French authors agree that topping increases resistance to lodging, but SUCCI thinks that their conclusion is somewhat hasty, for this effect may be obtained by: — 1) Strengthening the base of the stalk; 2) reducing the weight of the leaves and ears. In SUCCI's experiments, topping had the second effect, but not the first. The operation of May 2 certainly increased the resistance of the wheat to lodging, but at a heavy price. It is very doubtful whether the advantage obtained counterbalanced the decrease in the yield and the inferior quality of the grain, seeing that the 1st topping reduced the yield by 38 %; the second diminished it 20 % or 41 % (according to whether the stalks were cut back to within 45 or 30 cm. of the ground), while the third, not only reduced the quantity of the yield by 28 %, but also had a bad effect upon its quality (1).

In any case, the topping, that is likely to give the best results, that is to say, to do the least certain injury and confer the maximum benefit, is the one carried out on May 2, when the laminae only were cut, and these to within 45 cm. of the ground. This agrees with what long experience has made the general practice, where it is the established custom to top wheat in order to increase its resistance to lodging.

1002 - A New Method of Determining the Increased Yield of Permanent Pastures in Germany.

— SCHUBERT, Bericht im Sonderauschluss fur Wiesen und Dauerweiden in *Mitteilungen des Deutschen Landwirtschaftsgesellschaft*, Year XXXVI, Part 22, pp 338-339. Berlin, May 28, 1921.

There are always considerable difficulties in evaluating pastures, and especially in determining the effect produced upon them by fertilisers, because the grass crop can only be estimated indirectly by the condition of the grazing stock. This is the chief cause of error, as the individual peculiarities of the animals, are seldom taken sufficiently into account.

Many methods are used for comparing areas of pasturage that have been manured and treated differently. The most usual is to divide them into plots of the same size and to make the lots of grazing animals as homogeneous as possible.

The great difficulty in such cases is the choice of the stock, for few animals are alike in their power of turning their food to best account. "Futterverwertung", or making most use of the pasture "Weideausnutzungvermögen". Further, such experiments are often interfered with by the withdrawal of some of the animals (either on account of sickness or other causes), especially if the herds happen to be small. Other factors affecting the experiments are variations in temperature, drought, etc., to which animals react differently.

The author tried another experimental method at Nesshof (Kaibsheim, Würtemberg), and used only one herd of animals, which grazed the different plots in succession. By this means, all errors due to dissimilar utilisation of the forage were eliminated, and it was only the after-effects of the latter «Futternachwirkung» on the time of passing from one lot to another that could interfere with the results of the experiment; further, these could be lessened by moving the stock from plots that had been little manured, to others which were in a good condition.

---

(1) Cutting back wheat with a sickle has a very variable effect upon its lodging, according to the date at which the operation is carried out. SUCCI found that rather early topping increases the tendency to lodge. — See: A. SUCCI, La falciatura primaverile del frumento coltivato per seme, in *L'Italia agricola*, 1912, p. 331.

The method is as follows:— The enclosed plots to be grazed in succession must be as similar as possible in physical condition, taking the state of the vegetation into account. The herd chosen ought to be accustomed to the pasture for at least 14 days before the beginning of the experiment. The grazing results are estimated in the first place by weighing the animals and measuring the milk yield. The calculation is completed by estimating FALKE's "Weidetagseinheiten" (daily grazing units), i. e., the amount of forage required to produce 100 kg. of live weight in 24 hours ; by this means, it is easy to detect any possible defects in the pasture. Supposing, for instance, that for some reason, the herd has to graze on one of the experiment plots longer than was intended, the increase in live weight and the milk yield must unfailingly diminish without the productivity of the pasture being necessarily lower. In such a case, the daily grazing units will prove that the pasture has produced more grass in proportion to the longer time the stock has been kept on it.

The conversion of the "Weidetagseinheit" into money value is unnecessary since the pecuniary return is sufficiently shown in the calculation of increase of weight and milk yield.

Site of the experiment and fertiliser per hectare	Area in hectares	Yield per hectares			Quintals of live-weight maintained for 150 days on 1 hectare	Value of increased weight, in marks	Value of milk produced at 0.20 marks per kg.	Total cost of the fertiliser, in *marks*	Increased yield, after deducting the cost of nitrogenous fertiliser, in *marks*
		"Weidetags einheiten"	Increase in weight quintals	Amount of milk, kg.

The accompanying Table gives a summary of the data obtained in 1916 in an experiment made with milch cows to determine the effect of manuring with a nitrogenous fertiliser, and demonstrating that practical results can be obtained by this method.

1003 – **A Comparative Study of the Composition of the Sunflower Maize Plants at Different Stages of Growth** (1). — SHAW, R. H., in *Journal of Agricultural Research*, Vol. XX., No. 10, pp. 786-792, Bibliography of 7 works. Washington, D. C. February 15, 1921.

The sunflower plant is gaining recognition as a silage crop in certain of the northwestern States where climatic or soil conditions are not always favorable for the maturing of maize for silage purpose. In some sections also there is a growing feeling that sunflower silage offers a more profitable feed than maize silage, because of the greater yield that may be obtained per acre.

The Dairy Division is making an investigation of sunflower silage. This paper, which is the first of a series, presents the results of a study of the chemical composition of the sunflower plant at several different and distinct stages of its growth as compared with that of maize grown under similar conditions. The purpose of the study is to assist in selecting the proper stage of maturity for ensiling.

Tables I and II give the results of the chemical work on the whole plants. The figures for total protein, albuminoid protein, reducing sugars, non-reducing sugars, and starch are based on the dry matter.

The dry matter in each increased gradually and consistently throughout the entire period of growth.

There is no great difference in the percentage of proteids in the two plants, but it is slightly in favour of the maize.

The reducing and non-reducing sugars in the sunflower declined somewhat irregularly but persistently during the growth of the plant. In the first stage there was about one and one-half times as much non-reducing sugars present as reducing sugars. This relation was quickly changed, and in the latter stages the reducing sugars exceeded the non-reducing.

The percentage of starch in the sunflower is small and rises and falls irregularly throughout the growth of the plant.

The reducing and non-reducing sugars in the maize plant rise and fall but with a marked upward trend during the growth of the plant until the stage is reached there the kernels are maturing, when a sudden drop occurs. The percentage of reducing sugars is always far in excess of the non-reducing sugars.

The starch rises and falls until the kernels are maturing, when a sudden rise occurs.

The chief difference between the two plants at the silage stage lies in the amount and character of the carbohydrates.

From the results obtained in this study it would seem that the best stage of maturity for ensiling the sunflower plant is when the rays of the flower have become dry and are falling.

1004 - **Note on Some Recent Researches on the Cotton Plant in the West Indies with Special Reference to St. Vincent.** — MASON, T. G. (Imperial Department of Agriculture), in *West Indian Bulletin, Journal of the Imperial Agricultural Department for the West Indies*, Vol. XVIII, No. 4, pp 181-197, pl. 2, Tables 3, bibliogr. of 5 works. Bridgetown, Barbados, 1921.

Report of series of investigations carried out in St. Vincent under the direction of S. C. HARLAND to ascertain the factors which limit the yield of seed cotton in the West Indies. The methods adopted were to a large extent those employed by Dr. L. BALLS in Egypt; graphical methods were extensively used, and the results subjected to statistical treatment.

I. — LIFE HISTORY. — In an attempt to secure precise knowledge of the relative importance of the factors controlling: *a*) The number of buds produced by the plant; *b*) the number of buds becoming flowers; *c*) the proportion of flowers producing bolls, HARLAND undertook to trace the life history of the cotton plant in St. Vincent. For 3 seasons (1916-19) the number of flowers and bolls opening daily in each of the manurial plots was determined and the records presented in graph form, and from them the average flowering and bolling curves for the 3 seasons were constructed.

Inspection of the flowering curves of the 3 seasons shows that they all commenced at the end of the 9th week from sowing. The date on which the first flower appeared, however, was in every case the 57th day after sowing, but the rate of flower production was not sufficiently large to be indicated in the curve till the end of the 9th week. The uniformity of this interval is most remarkable; it will be evident that it is independent of the variations which occur in the weather from season to season, and therefore it is in no way correlated with the factors determining the rate of vegetative growth of the plant.

The commencement of the bolling curve is 7 weeks later than that of the flowering curve, and a similar period separates the dates of their respective crests.

. In estimating the number of bolls from each plot, a separation had to be made between diseased and healthy bolls. The convention adopted was to count as healthy only those which were less than half diseased. The factors responsible for the fluctuations in figures during the 2 seasons are referred to later.

This phase in the investigations has produced some useful information which may be summarised as follows:— 1) If the date of sowing be known, it can be estimated with certainty when most flowers and bolls will be produced, and when the crop will be finished; 2) practically 50 % of the June-July planted crop may be lost through bud-shedding; 3) during the 51 days of the life of the boll, the period of greatest susceptibility to shedding occurs in the first 3 weeks,.

II. — MANURIAL EXPERIMENTS. — Twenty-four plots (3 series of 8 and $\frac{1}{40}$ acre each) received the same treatment year after year. The nature of the treatment, and the mean yield of seed cotton per acre is given as follows:— nitrogen as sulphate of ammonia (30 lb. per acre) 607 lb.; phosphorus as basic slag (40 lb. per acre) 607 lb., potash as sulphate of potash (30 lb. per acre) 730 lb., phosphorus (40 lb) + potash (30 lb), 856 lb.; nitrogen (30 lb.) + phosphorus (40 lb.) + potash (30 lb), 609 lb.; cotton seed meal (600 lb. per acre), 593 lb.; cottonseed meal + phosphate + potash, 733 lb.; no manure 514 lb. This shows a % gain over no manure of +18, +18, +42, +28, +30, +15, and +42 % respectively. It is pointed out that the disease known as red-leaf in St. Vincent is most prevalent on the plots receiving no potash (1) (This has been conformed in America). Manures, however, seem to have no effect whatever on the time of maturing of the crop.

III. — ENVIRONMENT. — According to BALLS, the formation of the absciss layer which precedes the shedding of both buds and bolls is most probably brought about by a water deficiency, and as a consequence, this shortage prevailed whenever the loss of water by transpiration from the leaves exceeded that absorbed by the roots. Some recent investigations on the premature dropping of young fruits of the Washington Navel orange (HODGSON R. W. *Univ. of California Publication in Agricultural Science,* Vol. III, pp. 37-54, Sept. 1917) and HARLAND's experiments indicate that the same factor is probably responsible for much of the shedding of buds and bolls in St. Vincent; practically 50 % of the June and July planted crop was lost in 1916-17 from bud shedding and also in 1918-19.

It has been clearly demonstrated that the periods of heaviest rainfall were followed by enormous shedding of both buds and bolls, but the interpretation of the relationship between the intensity of the rainfall and shedding is, however, less thoroughly established.

IV. — FUNGUS DISEASES. — As shown above, the 50% loss from shedding of buds is practically all due to physiological causes (occasional exceptions due to external boll diseases (*Bacterium malvacearum*). Of the remainder of the potential crop 50-60 % is lost annually from the effect of diseases and physiological shedding of bolls. An estimate of the relative importance of these two factors cannot yet be formed, but an examination of the condition of certain bolls, which dropped in November 1916, is of interest:— affected by internal boll disease 64 %; affected by external boll disease 21 %; healthy bolls 14.8 %. The loss, therefore, sustained from fungus diseases, cannot be considered as important a factor in reducing crop production as the physiological factors.

V. — SPACING EXPERIMENTS. — Apparently the production of flowers is decreased if the outer nodes are suppressed by close planting. — HARLAND undertook a series of experiments, in which 2 plants per hole instead of the normal 1 plant, were left in alternate rows. Results showed that though the production of flowers per plant was not sensibly altered by this spacing, yet the number of bolls per unit area was 26 % greater.

VI. — COMPARISON BETWEEN EXPERIMENTS IN ST. KITTS (2) AND ST. VINCENT. — Manurial experiments have now been in operation in St. Kitts for some 17 years, conducted by F. R. SHEPHERD, on lines very similar to those in St. Vincent. The results are, however, of an entirely different nature. It may be noted that the yield of seed cotton in St. Kitts may exceed that obtained in St. Vincent by as much as 60 % in a normal year, and unlike the latter, a second picking is frequently obtained

---

(1) See *R.*, April 1919, No. 461. (*Ed.*)

(2) See *R.*, Feb. 1919, No. 197. (*Ed.*)

Up till now the effect of fertilisers on St. Kitts' land was negligible, but they begin now to have a larger significance.

A comparison between the flowering curves for 1917-18, and 1918-19 shows a striking similarity between the form of curves for the two islands, indicating a distinct resemblance between the life history of the plants.

Precise data as to the amount of loss sustained from bud shedding is not available for St. Kitts, but, according to available information, the loss from bud and boll dropping is much less here than in St. Vincent. The most potent factor determining the loss from physiological shedding is evidently in St. Kitts environmental aridity, whereas in St. Vincent it is the reverse; it is, however, evident that the loss of the major part of the crop in both cases is through physiological shedding. The explanation of the differences in the amount of shedding in the 2 islands is not apparent. A factor which may be partially responsible is the spacing in St. Kitts where there are 5 300 plants to the acre compared with 4356 in St. Vincent. The loss from diseases is relatively small in St. Kitts.

1005 - **General Survey of Rubber Situation in 1921.** — GIRARD, M. E. (Administrateur délégué des Plantations de Suzannah et d'An-Loc; ancien Président p. i. du Syndicat des Planteurs de Caoutchouc de l'Indochine), in *Bulletin des Caoutchoucs de l'Institut Colonial de Marseille,* Year 1921, No. 2, pp. 37-48. Marseilles, 1921.

The author emphasises the fact that it is unreasonable to suppose that former rubber plantations are likely henceforth to prove worthless as a result of the present industrial crisis, and that it is improbable that the latest market sale prices at present below the cost price in the majority of the plantations will last indefinitely. In fact it is logical to imagine that probably the excessive rates will tend to limit the length of the critical period, and that a rise in market price may be counted on, certainly before the end of 1922, and perhaps sooner if the planters cooperate in the rectification of matters.

YIELD OF RUBBER. — The check to the extension of rubber plantations, due to the depreciation in sale price of rubber following directly on the appreciable reductions necessitated through the war naturally has an important bearing on future prospects. In addition to this, unlike the crude products coming from other trees and shrubs taken as a whole, the *Heveas* never give sufficient rubber to make planting a paying proposition until the trees are several years old. To rectify the present state of affairs will, therefore, take some years.

For some time yet, the area planted with *Heveas* will remain limited to the existing 3 000 000 acres (1 200 000 hectares) in the various countries suited to its cultivation; and it is hardly probable that new trees can be planted at a reasonable cost for at least another 10 years, and even then as has been noted above it would be some years later before the yields from these newly planted trees would have any effect on the market prices.

The method of daily tapping employed continuously on the same plantations has often been followed by diseased bark and finally the destruction of the trees. This accounts to some extent for the decrease in production at present, and indicates the probability of a still further decrease: doubtless this will be altered in due course, but very gradually. It may be deduced from these facts that the maximum yield has already been reached and that now the average yield taken as a whole for plantations where daily tapping is employed, will be only about 290 kilos per hectare. Exceptional plantations certainly exist, and as much as 500 to 600 kilos have been obtained but a radical change in methods of exploitation will be necessitated to make this a general rule. Considering the time taken to effect this change, the total yield expected for the next few years from 800 000 to 1 200 000 hectares is estimated at from 240 000 to 360 000 metric tons.

Excluding the probable decrease in production hitherto mentioned, the following approximate estimate has been determined referring to the total world production of rubber (in metric tons): — 1921, 320 000; 1925, 385 000; 1929, 530 000; 1932, 670 000.

CONSUMPTION OF RUBBER. — In collective data with reference to the consumption of rubber it has been estimated that taking the production in 1921, including rubber consigned on arrival, that purchase directly on important private stocks which are due to be liquidated in consuming countries and also the enormous quantities of manufactured goods used previous to and during 1921, the total consumption amounts to approximately 350 000 metric tons.

The average annual rise in consumption during the last six years was 20 %; but no more than 10 % can be counted on for some time.

Estimates based on these calculations are as follows: — (in metric tons): — 1921, 350 000; 1925, 511 000; 1929, 746 000; 1932, 992 000.

These moderate estimates with reference to the consumption for the years 1921 to 1932 do not, however, correspond with the possibilities of production under the most favourable circumstances M. GIRARD, therefore, bases his estimates for consumption, on the reduced production rate, i. e. taking 270 000 metric tons as the total production for 1921 instead of the amount indicated in the production estimated (see above).

Following this system of calculation and the average annual rise in consumption as 10 % the following estimate is obtained.

	Consumption	Production
1921	270 000	270 000
1925	495 000	390 000
1929	720 000	530 000
1932	958 000	670 000

The present crisis could certainly have been prevented if the planters had made adequate previsions before hand, and it is believed that the return to the normal state of affairs will be hastened if they adopt exploit-

[1005]

ation methods as advised and which it appears will be put forward shortly.

In order to facilitate the verification of the figures of the numerous published statistics, the following tables have been compiled to show the world production 1900 to 1920 and the area covered with rubber plantations : —

TABLE I. — *World rubber production* 1900 *to* 1921.

(Reproduced from "*Le Caoutchouc et la Gutta-Percha*", No 190, Dec. 15, 1919.)

Year	No. of plantations	Brazil	Other countries	Total	Difference %

1916	152 650	36 500	12 448	201 598	+ 27.0
1917	213 070	39 370	13 258	265 698	+ 31.1
1918	200 950 (2)	30 700	9 929	241 579	— 9.0
1919 (1)	339 000 (3)	33 000	10 000	382 000	+ 51.1
1920 (1)	350 000	30 000	10 000	390 000	+ 3.0

(1) Estimate. — (2) Amount exported. — (3) Including 55 000 tons from 1918.

Apparently the percentage rise in production for 1901 to 1911 inclusive was on the average 3.1, and from 1912 to 1920, 23.9 and for the entire 19 year period, 11 %. There was practically the same development as regards consumption, but this showed only a rise year by year. With the introduction of mechanism, electricity and increase in comforts in general it will rise in proportion to the demand.

Tracing the rise and fall as regards production, the increase from 1915 to 1920 has been regular which is worthy of special notice, but the difficulties in exportation in 1918 engendered a restricted market of goods.

Consequently, difficulties in freightage have led to the belief in an immediate absorption capacity which in reality does not exist at this moment venig to discount limitations. It is, without doubt, this erroneous estimate which has led to the idea of exaggerated stock in America and in

TABLE II. — *Area planted with rubber (in acres).*

DISTRIBUTION UP TO DATE OF THE WORLD RUBBER PRODUCTION 1915 TO 1920. — The statistics relative to the world rubber production 1915 to 1920 are here given (reproduced from *Le Caoutchouc et la Gutta-Perhac* Yr. 18, No. 204. Feb. 15, 1921):

The total production from rubber plantations does not include the production in Cochinchina, nor in the Philippines nor in other countries where rubber is grown on a limited scale, amounting to a maximum total of 800 to 1000 tons in 1915 and to about 5000 tons in 1920; the area of these plantations is not included in the Tables indicating the area utilised and the yield per acre.

TABLE IV. — *Average total yield per acre* 1915 *to* 1920.

	Total production	Total area covered	Yield per acre
	tons	acres	kg.
1915	105 800	1 122 550	94
1916	145 400	1 505 350	96
1917	200 300	1 817 350	110
1918	226 800	2 021 750	112
1919	245 800	2 181 050	112
1920	266 500	2 293 750	116
			aver. 108 kg.

In closing, the author states that the apparent low average total production per acre may be explained by the enormous differences in yield capacity of the various plantations, due largely to the age of the trees, the type of soil, cultivation, climate and general methods employed.

In some cases, areas included in the statistics have become disused before the age fixed for exploitation; others tapped on intensive lines at 3 ½ to 4 years, have not been utilised after a certain number of years, at the moment when they should have reached under normal conditions, their maximum yield.

It should not be forgotten that by adopting the daily tapping system early, after 5 or 6 years for examplé, the yield per hectare should normally vary from 50 to 600 kilos in 10 successive years, but generally the yield amounts to 20 to 240 kilos or 12 to 160 kilos per acre (30 to 300 or 400 kilos per hectare) for 7 years, prior to decrease. After 7 years and also 10 years (less frequently), as a result of the daily tappings made up till now, the rate of production decreased with much more rapidity when efforts were concentrated on maintaining the yield percentage by intensifying the area tapped as regards depth or frequence.

This variation is not only confined to rubber but to produce taken as a whole.

With due consideration of all these facts M. GIRARD considers that logically speaking these estimates of production and consumption of rubber from 1921 to 1932 correspond in all probability to possibilities.

[1005]

1006 - **Variability of the Camphor Yield in *Cinnamomum Camphora*** (1). — DUNN, S., T. in *Royal Botanic Gardens, Kew. Bulletin of Miscellaneous Information*, No 4. pp. 129-135. London, 1921.

The existence of worthless as well as valuable camphor trees has for a long time been recognised by the camphor distillers in China, Japan, Formosa, Cochin-China, and other places where *Cinnamomum Camphora* Nees, was exploited as a wild or cultivated tree. The same phenomenon began to appear however, in newly made plantations and numerous enquiries on the subject have been received at the Royal Botanic Gardens, Kew. Requests were sent to the various Colonies where aberrant trees grew, asking that experiments might be made and that specimens and full notes on their plantations might be sent to Kew.

Notes have here been made as a result of these enquiries, and also with reference to recorded experiences of former practical exploiters as to the variations in the yield of camphor trees.

Causes of variation. — The direct cause of the presence in the camphor tree of essential oils of varying constitution and quality is to be found probably in the formation within the plant of terpentinol (C_{10} H_{16}) which is gradually changed by the activity of the living cells into camphor (C_{10} H_{16}). It is not surprising therefore that the yield of camphor varies from month to month. The cause of variation in the recorded yield of a tree in the Government plantation at Curepipe in Mauritius is suggested to be the time of the year at which the leaves were clipped for distillation. If there is any other circumstance affecting the healthiness and cell activity of *C. Campora* it will on the above theory affect the yield of camphor. This supposition is supported by the microscopic examination of the specimens of wood from the experimental plantations in Mauritius, made by BOODLE at Kew.

According to reports from Formosa, the northern climatic conditions favour the production of solid camphor, and in the south, this is to a large extent replaced by the Sho and Yu-ju oils. The climate of Florida has the effect of encouraging the same species to produce solid camphor mixed with an oil differing from the Japanese oils in its low percentage of safrol (HOOD and TRUE).

The remarkable variation of camphor content in the leaves of trees growing under different conditions of shade and soil has been reported both from the United States and from Ceylon. CARMODY (formerly Director of Agriculture in Trinidad) has drawn attention to a case where transplanting caused small trees to recover and produce a normal quantity of camphor (April 10, 1920).

From these observations it is obviously important to consider in the first place the situation most suitable for the camphor tree and also to find by experiment the best time for clipping the leaves.

There is also another line of enquiry that may lead to useful results, viz. as to the existence of botanically distinct camphor yielding varieties, for example, the smell of crushed leaves is noticed to resemble that of camphor on trees yielding that substance, whereas the " oil tree " leaves a smell of turpentine or eucalyptus. The Chinese are said to differentiate between the valuable and worthless trees in Formosa by this means. Whether this is a permanent character is not quite clear.

---

(1) See *R.* May 1920, No. 528; R. March 1921, No. 194. (*Ed.*)

Slight colour variations of the leaves have also been noticed but otherwise no visible varietal characters can be found in any part of the tree to separate " camphor " from "oil" trees. " The occurrence of the so-called oil and camphor trees side by side in the same district suggests that there may be individual peculiarities which affect the chemical products of camphor trees without being accompanied by any corresponding outward characters. Such physiological characters are known to exist with other plants e. g. *Hevea brasiliensis* (*Ann. Bot.* XXXIII, p. 313) and *Acacia Catechu* Willd. (GAMBLE, *Manual of Indian Timbers* 2nd ed., p. 297 and *Revue de botanique appliquée.* No. 1, 20. (1921).

Suggested lines of improvement. — From these statements it is evident that in order to produce plantations which can be relied upon to give good quantities of solid camphor: 1) Seed should be secured from trees known to produce camphor. The author states that it is probably available in Hong-Kong (see *Report on Botanical and Forestry Dept.* Hong-Kong, 1919); 2) Suitable climate and soil are necessary; 3) Saplings must be planted so that they may be clipped conveniently. Extracts made from *Camphor Cultivation* by HOOD and TRUE (*Yearbook Dept. Agric. U. S. A.*, 1910, pp. 453-455), show that on the Department's experimental plots the trees are planted in rows 15 ft. apart and 6 ft. apart in the row, and are grown to an A-shaped hedge 8 ft. high and 8 ft. wide at the base. At 6 years from the seed the trees will form a solid hedge in each row and will be thick and bushy to the ground. The best months for clipping must be ascertained by experiment, as observations show considerable changes in the camphor content of the leaves as the growing season advances.

As regards propagation, HOOD and TRUE advocate propagation by seed in preference to cuttings, if grown for commercial purposes, and sowing on hills 3 ½ × 1 ½ ft., with 3 seeds to the hill, and covered about 2 in. deep. This method requires about 24 quarts of seed per acre, and will produce enough trees for setting out 16 acres of field planting. The percentage of germination is very low and only about one-half the seeds may be expected to grow. Cultivation should begin as soon as possible, and as soon as a full stand is obtained the plants should be thinned to 1 per hill and a good dressing of high-grade fertiliser given.

The first season the plants should make a growth of 12 to 18 in., with a very large and vigorous root system. The treatment in the 2nd year should be the same, and at 26 months from seeding the plants should be from 2 to 3 ft. high and well branched, and are ready for field setting. Deep ploughing in the early autumn and before the trees are set is advised; they are first cut back severely, the taproot cut to 12 in. and all small laterals removed.

It is recommended that small crops, such as cotton, peas, etc. be grown between the rows for 2 or 3 years, and cultivation should be thorough and frequent.

Extracts are also given with reference to information received from EATON in the Federated Malay States (*Bulletin* 15. *Dept. of Agric.*, pp. 10-11) who advocates the soaking of seed for 24 hours before sowing. The heavy seeds which sank to the bottom were sown by themselves in rows 3 in. apart each way, and ¼ in. below the surface. The light seeds were sown broadcast as only a few were expected to germinate.

1007 - **Hop-Growing Experiments in South Africa.** — BAKER, E. (Botanist, Elsenburg School of Agriculture, Mulders Vlei), in *Journal of the Department of Agriculture, Union of South Africa*, Vol. III, No. 1, pp 27 33, pl. 14. Pretoria, July 1921.

While it is evident that many efforts have been made from time to time to grow hops in South Africa, very little has been reported as to the success of these attempts, and the author here traces the progress made since 1902 up to the present time.

The hopsets obtained in 1902; and 1905-1907 from England, Germany and America failed to establish themselves; those imported in 1913-1915 are still living and even though not yet proving an economic success, improvements in cultivation methods etc., may change the present state of affairs.

The author describes the hop experiments at George in 1917-1920 with the cultural methods employed. The object in view is to demonstrate that a sufficient return of green hops per acre can be obtained to make the cultivation of the crop an economic success. A good field of dried hops is estimated at anything from 10 cwt., per acre upwards; at George the drying process accounts for 65 to 75 % of the weight of the green crop, the average showing that about 100 lb. of green hops yield 30 lb. dry weight. Thus far some of the sections in the experiments at George have given returns from 2-year old plants of from 7 to 8 cwt. per acre; these plants should be in full bearing next season, when it is hoped that improved yields and more reliable returns will be obtained. The District of George, with climate and conditions similar to those found in parts of Europe where hops are grown, gives promise of being the most suitable part of the Union of South Africa for this purpose.

The ground used for experimental purposes consists of a sour, shallow, sandy soil, which is inclined to become water logged in certain portions for short periods every year. Results showed, however, that good drainage is essential to the growth of hop plants.

In England the practice is to apply from 20 tons, or in some cases as much as 30 to 50 tons of farmyard manure per acre, but as in George it is impossible to obtain adequate supplies, it is proposed to use, instead Karroo sheep manure at the rate 2 ½ tons sheep manure per acre in plots previously receiving 5 tons farmyard manure, and at the rate of 5 tons sheep manure per acre in plots previously receiving 10 tons farmyard manure.

To make up for the deficiency in organic mater it is suggested that green barley, or green barley and vetches might be grown as winter cover crops, and ploughed in about mid August.

While it is probable that the best mixtures of artificials have not yet been found, it is proposed for the present to continue to supplement the kraal manures with the mixtures as used during the past 3 years (bone meal, superphosphate, blood meal, etc.).

The author gives details of the cultural methods employed, viz. setting out, cutting, poling, tying and training, cultivation, picking and dryings.

The practice at George has been to use sets from underground shoots (" runners " or "suckers"), as it has been found that they give more vigorous plants. The older hills are cut or pruned early in August before the new growth has commenced. The hills are opened up, and the straps (i. e. remains of previous years bines) are removed.

Up to the present the hops have been remarkably free from disease and insect pests. The only fungus apparent on living hops has been a leaf spot (*Septoria* spp.) which was found on a few plants about picking time at the end of February and early in March.

It seems from an economic point of view that the prospects of remunerative hop growing in well selected localities are worthy of consideration. There are still various points which need to be investigated and while it may now be definitely stated that hops can be grown satisfactorily in one part of South Africa at any rate, the author emphasises the fact that the fringe only of what may possibly develop into a staple industry has so far been touched.

1008 - **Vanilla Production in Mexico.** — *Journal of the Royal Society of Arts*, Vol. LXIX, No 3569, p 360. London, April 15, 1921.

Vanilla is principally cultivated in the districts of Papantla and Misantla in the State of Vera Cruz, the most productive region lying southeast of Tuxpan. At present Mexico employs over 50 000 people in the cultivation and extraction of vanilla.

According to the report by the U. S. Trade Commissioner in Mexico it appears that vanilla grows more or less in a wild state in the low hills, and is very abundant. It grows best in rich, sandy soil not drained too thoroughly. When growing wild it is usually sheltered by the forest trees, and when cultivated it is protected by trees planted for that purpose. The temperature most favourable for its production is about 85° F,; it grows best at an altitude of 1000 ft., above sea level; the character of the soil, the temperature and humidity, etc. influence the quality of the vanilla, its aroma, and its strength. The plant ripens most extensively in January and February. There is, however, so much demand foı the fruit that for many years crops have been prematurely harvested in October and November. As a result the beans weigh 1 lb. less per 1000 than they would normally. In compliance with orders from the Government, the authorities were formerly instructed to prevent the harvesting of unripe fruit, but this order has not been strictly enforced.

One of the great problems of the owners of vanilla plantations is to provide against the robbery of their crops.

For commercial purposes vanilla is divided into 4 classes:— large fine (weight 10 to 12 oz. per " mazo " (bundle) of 50 fruits, length 20 cm.); small fine (weight almost equal to large fine, length 10 to 15 cm.); zacate (heavier weight; grows more abundantly along the roadsides in the warmer regions of Mexico, where formerly its fruit was considered to be without commercial value); basura.

There are different varieties of vanilla in the vicinity of Misantla, known as Misantla beans, which have a coarse bark; also a wild bean "vanilla platano" which the Indians eat and which differs from the ordinary vanilla (*V. planifolia*) in that the plant is much smaller but has larger leaves.

Practically all of the exports go to the United States, for which reason the American dollar is the basis of price, both for buying and selling.

1009 - **Production of Cacao in Tabasco (Mexico).** — *Journal of the Royal Society of Arts.* Vol. LXIX, No. 3569, pp. 349-350 London, April 15, 1921.

The cacao of the State of Tabasco (Mexico) though one of the richest in flavour and nourishing qualities of all varieties in the world's market, is probably the least known. This is due partly to its restricted area of cultivation but chiefly to its remarkably high price in comparison with the South American and East Indian product. Villahermosa, in Tabasco, is the centre of production and the only market for the cacao beans in Mexico. The production for 1920 is estimated at 3 300 000 lb., the largest crop since 1913.

Mexican cacao, besides being of superior quality, is also far less bitter than other varieties. The U. S. Consul at Frontera states that for this reason less sugar is required in the manufacture of candies. etc. On the other hand, as Tabasco cacao is richer in fats and oils, it should be profitable for manufacturers to import it for the manufacture of cocoa and chocolate as beverages, or even as foods, since less cacao and sugar will be required per unit quality.

The native tree differs very little from other varieties. The beans are enclosed in a sort of shell, the " mazorca " which is crushed for their extraction. The fleshy pulp surrounding the seeds in the mazorca is washed out or separated from the beans, a process which entails the chief expense in the operation of harvesting the cacao. The beans are then dried in the sun, ovens not being in use. Only manual labour is employed in the cleaning process, but if a suitable machine for this work were introduced, thereby cheapening the process of extracting and drying the beans, it is possible that the export price could be reduced to the point where the product would be within the reach of foreign buyers.

1010 - **Experiments in Crossing Different Varieties of Fruit Trees of the Genus *Prunus* in Italy.** — RAGIONIERI, A., in the *Bollettino della R. Società toscana di Orticoltura*, Vol. XLVI, Nos, 5-6, pp. 36-41. Florence, May-June, 1921.

Although no results are obtained on crossing the apricot with Italian plum-trees, which are all derived from *Prunus domesticus* and *Prunus* *insititia*, the apricot can be successfully crossed with Japanese varieties of *Prunus*. It was in this way that Burbank obtained the " Plumcot " in California.

The author obtained negative results on crossing the apricot with the " Red June " American-Japanese plum-tree, or the Burbank plum-tree (a Japanese variety introduced and put on the market by Burbank, when either of these was the male parent. The results, however, were positive, if the latter variety was the female parent. The following hybrids were obtained :—

(1) Burbank Plum × Early Tuscan apricot
(2) » » × King Humbert apricot
(3) » » × Late Paviot apricot
(4) » » × White Nubian nectarine (Sprenger's)
(5) » » Violet nectarine
(6) » » × Early St. Anne peach
(7) » » × Poggio clingstone peach
(8) » » × Vetriciano clingstone peach
(9) » » × American Triumph peach

The author thinks that his experiments show that the Burbank plum-tree has very little sexual affinity with the European varieties of plum (except Reine Claude), whereas it has a strong sexual affinity with the apricots and peaches cultivated in Italy.

He concludes by giving some practical information about the technique of these crosses.

1011 - **Notes on the Cultivation of Citrus Fruits in the United States, Porto Rico, Rhodesia, India and Cyprus.** — I. Vosbury, E. D. (Office of Horticultural and Pomological Investigations), Citrus Fruit Growing in the Gulf States, in *Farmer's Bulletin No.* 1122. *United States Department of Agriculture*, pp. 3-44. Washington, D. C., Sept. 1920. — II. Kelley, W. P., and Thomas, E. E., The Effects of Alkali on Citrus Trees, *College of Agriculture, Agricultural Experiment Station, Berkeley, California, Bulletin* No. 318, pp. 305-337, tables 14. Berkeley, Ca., Jan. 1920. — III Shamel A. D., and Scott, L. B., Frost Protection in Lemon Orchards. *United States Department of Agriculture, Bulletin* No 821, pp 1-30, pl. 3, figs. 15 tables. Washington, D. C., June 4, 1920. — IV. Earle, F. S., The Cultivation of Citrus Fruits in Porto Rico, in *Government of Porto Rico, Dept. of Agriculture and Labor, Insular Experiment Station, Rio Pedras, P. R., Circular* No. 28. pp. 1-20. San Juan, P. R., Sept. 1920. — V. Turner, A. G., (Citrus Adviser), Citrus Industry (Report on Visit to California), in *The Rhodesia Agricultural Journal*, Vol. XVIII, No. 2, pp. 142-166, tables 5. Salisbury, Rhodesia, April 1921. — VI. Paranjpe, H. P., The Cultivation of Oranges and Allied Fruits in the Bombay Presidency, in *Dept. of Agriculture, Bombay. Bulletin* No. 95, pp. 1-23. Poona, 1920. — VII. Wittle, A. H., The Possibilities of Citrus Culture in India, in *The Agricultural Journal of India*. Vol. XV, Pt. IV, pp. 444-450. Calcutta, July 1920. — VIII. Citrus Trees. *The Cyprus Agricultural Journal*, Vol. XVI, Pt. I, pp. 10-12. Nicosia, Jan., 1921.

In nearly every article here referred to, apart from full cultural details, the history and present industrial situation in the various countries as regards citrus fruits is included. Certain points concerning only the selection of varieties, soils, propagation, pruning, etc. have here been selected for comparison purposes : —

I, II, III, V. — United States (1) : (*a*) *Gulf States* (especially Florida). Vosbury states that as a result of the demand for standardisation, a committee of prominent growers and nurserymen was appointed by the 1916 Citrus Seminar at Gainesville Fla., to recommend a short list of selected varieties. The orange varieties chosen as a standard were : — " The Parson " (Parson Brown) : the best known and most widely planted early variety : season early October to November. " Homosassa " : late November to February; " Pineapple " : late December to early March; " Valencia " : latest standard variety known : March to May; " Lue " (Lue Gim Goug) : late variety of recent origin.

The more recent varieties of grapefruits in Florida are largely confined to the standard named sorts, namely : " The Hall," midseason, February and March ; " Walters," midseason ; " Marsh " (Marsh Seedless), midseason ; " Duncan," late season, April to early June ; " MacCarthy," late season ; " Davis " (Davis Seedless), new variety, considered promising ; " Triumph," very early, but small and extremely seedy. Apart from Florida the " Duncan " (well adapted for colder sections), " Marsh " and " Walters " are the most popular.

The " Lisbon," " Villafranca," and " Ponderosa " are found to be the most productive lemon varieties in Florida.

As regards propagation (2), the sown orange (*Citrus vulgaris*) (stock) has been found vigorous, resistant to foot rot, and the trees produced thin skinned fine quality fruit. On light, dry-sandy soils in S. Florida, the rough lemon stock (*C. Limonum*) have given better results (except with Parson var.). The trifoliate orange (*C. trifoliata*) is the hardiest stock for citrus fruits in common use, but it is best adapted to the rich moist soils, sandy loams with clay subsoil and is unsuited to light dry soils (these have given unsatisfactory results in the Rio Grande valley, Texas, but very successful in Southern and Central Florida). As soon as the young trees are planted the tops are cut back to a bud at a height of 2 or 3 feet from the ground. Trees that are well pruned at planting and for the next few years, need very little pruning after they reach maturity.

In Florida the usual practice is to fertilise young citrus trees 3 or even 4 times annually. The first application is made in the spring when growth starts, 1 or 2 are made in summer and the last early in September. The spring and summer applications contain about 5 % of nitrogen, 6 to 8 % phosphorus and 2 or 3 % potash.

An interesting spray schedule for citrus trees (3) is given 'relative to the control of insect pests, etc. such as scab, rust mites, red spiders, thrips, white fly, scale, etc.

[1011]

(*b*) *California*. — Turner reports that practically all plantings of oranges in California are of two main varieties, Navels (1) and Valencias (2), which are at the present time fairly evenly divided in point of acreage, but there are indications that lately Valencias (2) have been planted in larger numbers than Navels. It is claimed that at least 20 acre inches of irrigation water per acre is required for all citrus trees between April and November inclusive, and any district where this amount is not available is probably over-planted. Where dry season cover crops are to be grown, this minimum requirement must be increased to nearer 30 inches. In 1920, a total of 246,000 acres was planted (oranges, bearing 133 000, non-bearing 50 000; lemons, bearing 33 000, non-bearing 17 000; grapefruit, bearing 6000, non-bearing 7000.

The greater part of the acreage covered with citrus fruits in California is still irrigated from open distributories (made of cement or granite blocks, laid in cement with miniature sluice gates at each opening), taken down the steepest grades, on a level with the gradient of the hills, and not stepped at intervals, so as to lead out the still water, as is done in some places. The methods adopted of diverting water at outlets is to let a slot into the floor of the channel which leads directly to each little opening, and by this means to get a perfectly constant stream of water flowing over the orchards; another method used is to set a batten diagonally across the floor of the channel, so that the lower point is opposite the opening; this is also perfectly effective. It is considered that this older method is as efficacious as by using the underground stand-pipe system. An interesting experiment is in progress in one district where peat beds are being turned into orchards. A layer of peat and manure about 1 foot is thrown into the pit, then about the same amount of cull oranges and lemons; on which is distributed about ½ ton of basic slag. This is continued in the same proportions until the pit is filled; about 6 months are required for this to decompose and be ready for use. When applied to orchards, 10 cub. ft. is allowed per tree, placed in deep furrows in the centre of the rows.

Kelley and Thomas present a report of the results obtained in connection with a study of a considerable number of citrus groves in different localities in California, dealing with the effect of alkali and the relationships existing between orchard practices and the accumulation of alkali in citrus groves.

Experience in various localities has shown that under certain conditions, continued irrigation with comparatively pure water tends to hasten the accumulation of injurious amounts of soluble salts in the soil. In the presence of excessive concentrations of salts, especially chlorides, complete defoliation may take place. Mottling frequently occurs (1) and sometimes chlorosis. Both the quality and quantity of the fruit are impaired. The results of recent investigations establish the fact that some of the irrigation waters in use at the present time on citrus groves have a high alkali content and it appears that the most promising source from which a supply of really good water in quantities sufficient to meet the demands of the constantly expanding citrus industry can be obtained is only through concentrated effort directed towards the control of flood waters. By the use of suitable check dams, reservoirs, reafforestation etc. which will permit storage of mountain waters, an adequate supply of suitable water can probably be obtained.

[10[illegible]]

III. — Extremely low temperatures during December 1912 and January 1913, caused serious damage and loss to unprotected lemon orchards in many sections of California, and SHAMEL, SCOTT and POMEROY (*Office of Horticultural and Pomological Investigations*) made a study of the effect of these low temperatures in the lemon district near Corona (about 5000 acres). The altitude under discussion is about 1000 ft. protected on the south and east by the Santa Anna Range of mountains (4000 ft). The objects of these investigations were: 1) the determination of the effectiveness of orchard heaters, as measured by the number, commercial quality, and value of the fruits, produced by lemon trees in orchards thus protected compared with those unprotected; 2) the determination of the length of time unprotected trees took to return to normal production; 3) the determination of the behaviour of lemon trees in heated and non-heated orchards the 2nd year after frost; 4) comparison between the frost injury in orchards of both Eureka and Lisbon lemon trees, the two most important varieties grown in California (2).

From the investigations it appears that the main effect of protecting trees during one season of low temperatures is in the saving of one crop for the current year, and that as a rule where the trees are in vigorous condition, and receive good cultural treatment, they will return to normal production at the end of one year. In unprotected orchards, under comparative conditions, a greater amount of injury was found in the Eureka than in the Lisbon variety. But this may be attributed to the fact that the latter has a denser foliage.

IV. — PORTO RICO. — Most of the older groves in Porto Rico are budded on rough lemon (*C. Limonum*) stocks (3) but the author considers that this is distinctly inadvisable except on soils very light and sandy where other stocks fail. Otherwise on old trees that are bearing heavily the quality of the fruit is normal, but it is doubtful if it ever averages as high grade as that grown on other stocks and is very liable to disease. The author considers that the wider use of the sour orange (*C. vulgaris*) is likely to give far more promising results. This last stock is best used exclusively on all heavy wet lands, but not on light, sandy soil.

---

(1) See *R.* July 1918, No. 743. (*Ed.*)

(2) See *R.* June 1917, No. 539 and, *R.* April 1919, No. 451. (*Ed.*)

(3) Selection of stocks in Citrus propagation. See *R.* Feb. 1921, No. 162. (*Ed.*)

During recent years the native grapefruit seedlings have been attracting considerable attention as a stock, and both these and the sweet orange (*C. Aurantium*) have so far done well and are fairly resistant to disease. *C. trifoliata* has never been employed, and is unsuitable in this climate, except possibly for navel oranges.

Up to the present time, grapefruit has been more largely planted in Porto Rico than any other citrus fruit. These fall under 3 well marked types: 1) large seeded Duncan type, c. q. Walters, Pernambuco, Conners, Prolific, etc. 2) seedless. e. g. Marsh Seedless, and Howel's Seedless, etc.; 3) Triumph or native Cuban, including the Pineros, but this type should not be considered for commercial plantings.

Not enough limes are grown in Porto Rico for a comfortable local supply. As they do well on shallow, limestone soils, commercial plantings will have to be on the dry southern side, since limes are seriously injured by anthracnose in a moist climate. It would probably thrive well in the coffee district. The author considers there are also distinct possibilities for the cultivation of citrons, hitherto practically unknown in this country.

Few soils in Porto Rico are so rich that they will not require heavy annual applications of fertiliser to maintain a grove in full production. Up to the present the quality of the fruit has been affected by lack of phosphoric acid or excess of nitrogen (1). The following applications are advisable and effective when it is wished to obtain early fruit. December 15 to January 10 — 15 to 25 lb. per tree of basic slag or bone meal; also 1 to 2 lb. per tree sulphate of potash (except on clay soils) and 3 to 5 lb. per tree of nitrate of soda.

March 1 to 15 — 2 to 3 lb. per tree of nitrate of soda.

May 1 to 15 — 1 to 2 lb. per tree of nitrate of soda.

(The last may be omitted on rich lands).

This will necessarily have to be modified if the object is to hold back the crop for late spring shipment.

The most important and only really serious diseases may be summarised as follows: Scab fungus (*Cladosporium citri*) on grapefruit: the removal of useless wind breaks is advocated as trees in exposed locations are usually less injured; Stem-end rot (*Diplodia natalensis*); oranges suffer more than grapefruit. To ensure the future of the citrus fruit industry in Porto Rico, the author lays emphasis on several possible and advisable methods of improvement, etc.

V. — RHODESIA. — TURNER after his visit to California (see above) proceeds to draw comparisons between the citrus industry there and the present state of affairs in Rhodesia, especially as regards commercial transport of oranges, methods of control of disease, and irrigation systems. He considers the present system of ventilated hold stowage as used for oranges from Capetown to Europe absolutely inefficient and harmful to the future of citrus export from South Africa, and that the new system of fans throughout the ship to allow free ingress and egress of air would prove far more efficient and clear out the foul stale air which is extremely detrimental to the good carrying of fruit. A comparatively new system of wrapping and packing oranges has been tried with some success in California which would prove beneficial in Rhodesia. The separator wrap, which is a sheet of pliable card board, the size of a box and which was previously only perforated with radial cuts in regular formation, has been much improved this last season by deeply cutting at the edges, making the packing nearly automatic. It does not entirely wrap the fruit, but protects and holds it in place, and shows the packer exactly where to put the fruit Shipments to eastern markets and Canada have shown this method to have practical value. The author lays emphasis on the fact that the bulge pack system is evidently an essential point in holding the pack absolutely tight in transit, which is contrary to the belief held by authorities in the Union of South Africa who claim that the bulge is detrimental to the good carrying of oranges.

---

(1) See *R.* Aug. 1918, No. 840, and *R.* Feb 1919, No. 173. (*Ed.*)

It is generally recognised that a 25 % coloured orange is fairly green, and that even 70 % is only light coloured. Although they both may have the necessary sugar content according to the law, the poor colour militates against the sale price, and in order to overcome this, a great deal of this early fruit is subjected to a gas treatment in closed chambers for a period varying from 2 to 3 days. On account of the danger from fire with the old method of gassing fruit for colour, and to comply with present insurance risks, the gassing plants should preferably be situated in separate chambers, apart from packing houses, and usually across the road. The gas is blown by motor fans through a galvanised iron tunnel or pipe into the sweating or gassing chambers in basements or on the floors of the packing houses. The gassing lasts for 24 to 72 hours, according to the matuity of the fruit, which is then ready for grading, sizing and packing.

The author considers that if it is desired to ensure the arrival of oranges in Europe in as good condition as Californian fruit arrives in its distant markets, every precaution should be used in Rhodesia known to be of value, in the picking, packing, railing and shipping operations. There is an opportunity in Rhodesia of getting very much higher net returns from orange growing than in the former, by reason of cheaper land, water, labour and transport facilities, if only the methods of organisation are well established.

VI — VII — India. — *Bombay Presidency.* — Citrus fruits are among the most paying crops in this district. Paranjpe places before the public the methods which have been found to yield the best results and give the largest profit, not only with oranges but also with other kinds of citrus fruits. The species commonly cultivated are: Grapefruit (*C.decumana*). Citrons :— *C. Medica* var. *limonum* (" Jamburi "), *C. Medica* var. *limetta* ("Sakhar limbu"), *C. Medica* var. *acida* (" Kdagi limbu ") and the orange

(*C. Aurantium*) including sub-species: 1) loose skinned Santra, Ladoo, Kawla and Reshmi Narang; 2) tight skinned "Mosambi."

The "Navel" var., "Malta Blood" var. and the Jamaica orange are occasionally found in gardens, but are not cultivated elsewhere.

The grapefruit or pomelo, thrives best in a moist climate such as that of the Konkan tract along the sea coast, and also on the western side of the Deccan. Gholvad and Chembur are two of the important centres of cultivation in the Thana District and there is considerable scope for extension of this crop along the sea coast of the Surat, Thana, Colaba, Ratnagiri and Karwar districts. *C. Medica*, and *C. Medica* var. *limonum* can be grown practically in any sub-tropical climate for ordinary purposes and *C. Medica* var. *acida* adapts itself to a great variety of climates. It grows fairly well in the black soil of Puna-Khumbharia near Surat, but prefers well drained soil. The "Santra" and "Mosambi" are not at present grown on a large enough scale, especially in the Deccan and there is plenty of field for the extension of these two crops. The first variety is largely grown in Poona District, and the second enjoys a milder climate such as found actually at Poona. The loose skinned orange varieties are more or less inferior varieties and therefore less profitable.

The propagation by seed of citrus plants except *C. Medica* var. *acida* is not found desirable in this part of the country; seedlings thereby obtained are exceedingly thorny. On the other hand successful results have been obtained with plants budded on var. *limonum*. Propagation by the "*gootie*" (marcotte) method is also practised to a large extent, at the commencement of the rainy season, and the plant is ready for removal in about 4 months. This method is employed both for grapefruit and for limes.

The author describes the manner by which orange trees are induced to flower only once a year (contrary to their natural habit of flowering twice or 3 times in February, June and October), by means of certain efficacious cultural methods.

An analysis is appended showing the percentage content of the various types of soil in this locality. An analysis of 4 waters unfit for irrigation of citrus trees is also given and it is evident from this that water containing respectively (Parts per 100,000) :— total salts 184.00, 224.00, 360.00 and 464.00; calcium carbonate 8.00, 10.00, 20.00, and 22.80; magnesium carbonate 12.17, 15.22, 36.53 and 51.59; sodium carbonate 6.24, 6.24, 10.40 and 12.48; sodium bicarbonate 11.63, 16.05 and 23.50; sodium sulphate 19.52, 20.74, 21.96 and 51.24; sodium chloride 99.33, 136.29, 231.00 and 302.94; is included in this category. On the other hand a water sample containing total salts 80.00; calcium carbonate 12.00; magnesium carbonate 6.09; sodium bicarbonate 19.55; sodium sulphate 4.88; sodium chloride 32.34 was found to be quite fit for irrigation.

Notes and control methods employed concerning the insects pests prevalent in the Bombay Presidency are given. The said pests include *Papilio demolens*, *Nyctipao hieroglyphica*, *Arbeta tetraonis*, *Aspidiotus aurantii*, *Aleurodes eugeniae*, var. *aurantii*, aphides and termites.

[1011]

WITTLE considers that the most suitable places in South India for citrus culture would be parts of the Nilgiris, Shevoroys, Kunnamalais, etc. and in fact, almost anywhere where there is good soil, ample rainfall (average 60 to 120 inches), or where irrigation is available. He surveys the present situation generally and the methods advisable to adopt to increase the produce from the commercial standpoint.

VIII. — CYPRUS. — Although Cyprus is well suited for the cultivation of citrus fruits, their culture is centred mainly in 3 localities: Famagusta, for early oranges and mandarines; Lefka, for late oranges, and Lapithos and Karavas for lemons. The first possesses a sandy soil on a subsoil of ferruginous clay, the second a mixture of sand, chalk and ferrous and copper oxides, the third and fourth mixed sand, chalk or stones. The varieties commonly grown are: *C. vulgaris* (= *C. bigardia*), "Seville" orange, *C. Aurantium* (var. *dulcissimum* (= *praecox*) vars. *aperrimum*, *melitense* (= *sanguineum*) and *oblongum* (Jaffa orange), *C. limonum* (vars. *limetta*, *cedrum*, *pucillum* and *apyremum* (= *aspermum*). *C. limetta vulgaris*, *C. nobilis* (= *deliciosa*), *C. pergamia vulgaris*, *C. medica maxima*, *C. decumana* (= pompelmos).

Sowing the seeds of *C. vulgaris* has been found satisfactory, as on the stock thus obtained, can be grafted any variety that may be desired. This stock is fairly resistant to gummosis, collar and footrot, but grows more slowly than if propagated from layers and cuttings, and although not usually such heavy bearers, the plants have been found to be healthier and live longer. Growers in Cyprus frequently use, however *C. limetta vulgaris* as stock, grown from layers or cuttings from the same species but the fruit thereby obtained, although larger and finer in appearance, has an insipid flavour.

Planting too close together (8 ft. apart instead of the advisable 15 to 25 ft) and irrigation too freely, are the two cultural operations which need rectification if a higher yield is to be espected in Cyprus.

1012 - **Vines of Trentino and the Upper Adige** (1): **Vernaccia, Lagrein, etc..** — I. DALMASSO, G., in *L'Italia Agricola*, Year 58, No. 6, p. 176, 1 plate; No. 7, pp. 204-205, — Plate. Piacenza, May 15, June 15, and July 15, 1921. — II ZANOTTI, L., in the *Bollettino del Consiglio provinciale di Agricoltura*, Year XXXIV, No. 13, pp. 262-263. Trent, July 15, 1921.

I — VERNACCIA. — This is a name given in many parts of Italy to different vines; thus the Trentino Vernaccia has nothing in common with its namesake, the variety that produces the famous dessert wine of Sardinia. In the upper Adige it is known as "Weisservernatsch," but is in no way related to the Schiave and Schiavone types, which are also called "Vernatsch" in German.

AREA OF CULTIVATION. — Vernaccia is much grown in Adige Valley, especially in the vineyards situated on the level ground.

---

(1) For information on the Teroldigo, Negrara, Rossara, and Nosiola vines see *R.*, Mar. 1921, No. 302, and *R.*, July 1921, No. 728. (*Ed.*)

AMPELOGRAPHIC DESCRIPTION. — Shoots of average size, not very long, internodes somewhat short, colour, light cinnamon, striped; nodes little prominent; eyes large.

Buds smooth, sometimes reddish. Buds late.

Leaves of average size, trilobed, little serrated, tough; lamina with irregular surface, and somewhat vesicular; upper surface dark-green, lower surface light-coloured, downy; lateral sinuses slightly defined, petiolar sinus open; dentation irregular, teeth rounded; veins pale-green, well-defined. In autumn the edges of the leaves turn red, with a few rust-coloured patches.

Petiole short, strong, slightly tinged with pink.

Bunch of average size cylindrical-conical, very compact, often bearing a small lateral bunch; peduncle average, woody on leaving the node; pedicels green, short, warty; graft-callus well-developed.

Grape average, round, or often ovoid, owing to pressure, yellowish-green in colour (later even yellow), with much bloom, skin very hard, tough, pulp very mucilaginous; simple, not strong, flavour. Pips 3 in number (more rarely 2 or 4), large, slightly tinged with violet.

Ripens at the late second period.

Practical information on the vine. — Vernaccia is a strong-growing vine especially suited to vineyards on level ground with rather damp, deep, rich soil (Riparia soil), and to damp districts for it is resistant to oidium, mildew and rot. On the other hand, it suffers much from excessive heat and drought. It buds late, and is little affected by the white frosts of the spring. It should be pruned long.

The crop of grapes is very large at the Institute of S. Michele, and the average yield for 30 years has been 112 hectolitres per hectare, with a maximum of 158 hectolitres.

This vine usually grafts well, and does excellently on Riparia.

Practical information on the wine. — This is an ordinary table wine, which is much drunk, the must is moderately sweet and, unlike that of most of the Trentino wines, has a high acidity. At the Institute of S. Michele, the average sugar content of the must for 30 years was 16.3 % and the total acidity 10.5 per 1000. When the wine is grown in suitable places, it may contain as much as 20 % sugar, and only 8 to 9 per 1000 of acidity.

Vernaccia is either drunk as a white wine, or mixed with red wines; sometimes it is re-fermented on red grape pomace.

LAGREIN is one of the most characteristic and highly prized vines of the Upper Adige. There are two varieties one with long, and the other with short pedicels.

Area of cultivation. — This vine is grown more or less throughout the Upper Adige region, and especially in the Botzen-Gries district, but its country of origin is not known.

Ampelographic description. — Shoots of average diameter, long, dark-brown, much striped and spotted, internodes of average length, nodes large.

Buds very downy, whitish, pendent. Shoots early.

Leaves average, or below the average, rounded, three or five-lobed, but little serrated, thick, wrinkled, upper surface very dark green, lower surface yellowish green, downy; leaves show very brilliant red patches at the vintage time. Sinus usually shallow; petiolar sinus generally closed. Dentation consisting of sharp irregular teeth, the terminal tooth often very long. Veins much raised. Petiole rather long, reddish. Leaf-fall average.

Bunches of average size, pyramidal, often winged, somewhat branched with long green thinnish stalk, pedicel bright red. Graft-callus of same colour, warty; brush highly coloured.

Grapes rather irregular, usually round, generally longer than the berries of Teroldigo; of average size, violet-black, much bloom; skin somewhat thin but strong; contains much pigment and tannin; pulp very succulent; pleasant flavour, sweet, and clean. Pips 3 in number (rarely 2 or 4) of average size and much pointed. Ripens at first period.

Practical information on the vine. — The Lagrein variety requires good, mellow soil and a mild climate. Long pruning suits it best, although the basal shoots, also bear fruit. At the Institute of S. Michele it has given for 30 years an average crop of 50 hectolitres per hectare, with a maximum of 157; with a better exposure, it might bear a much heavier crop.

It is somewhat susceptible to oidium, anthracnose, and *Tetranychus*. It is well suited for grafting on the chief American stocks.

Practical information on the wine. — With good exposure above Botzen, the Lagrein vine furnishes a wine with a high alcohol content (from 11.5-12 degrees as a rule; but sometimes even 13 degrees andover); acidity moderate, sometimes slight (from 4.6 to 6.5). It has much body is highly-coloured and well suited for blending with light white or red wines like Vernaccia and Rossara; the blend has a pleasant flavour. In wine-making, the grapes of the three varieties are often mixed.

Lagrein Kretzer is a peculiar type of wine obtained by fermenting the must together with the skins for a short time (1-3 days). The resulting wine is slightly coloured, often a little sweet, and has a special characteristic flavour. It is mostly consumed locally.

II. — The vines chiefly grown in the Trentino, such as Rossara, the Paduan Marzemino, Vernaccia, etc., produce a large crop of grapes, but the wines made are only common table kinds, and in order to tide over the present crisis due to a superabundance of wine, preference should be given to vines bearing grapes suitable for choice table bottling wines, e. g., Traminer and Sylvaner, which have been successfully grown for some years in the Trentino, but on too small a scale. The author advises the use of these varieties for new vineyards.

The Provincial Council of Agriculture, the Agricultural Institute of S. Michele and the Agricultural Consortia, have agreed together to try and popularise these choice varieties. All the vines they distribute to agriculturists, whether grafted on American stocks, or growing on their own roots belong to such varieties.

[1612]

1013 - **The Cabernet Vines in Italy.** — SANNINO, L. A, in the *Rivista di Ampelografia*, Vol. II, No. 2, pp. 17-20, Alba-Livorno, February 1, 1921.

The Cabernet group consists essentially of two vines, Cabernet Franc, and Cabernet Sauvignon, to which should be added Cabernelle, or Carmenere. The two kinds of Cabernet are widely cultivated in the neighbourhood of Bordeaux, and especially around Médoc (France).

These vines have also been introduced into Italy, and have done very well where the soil and climate are suitable. The author considers that they should be used more extensively for new vineyards, but does not recommend " Cabernelle," which gives a lower yield. The Cabernets do best in friable soil with a basis of quartz sand. In Italy, the most satisfactory results have been obtained by Count CORINALDI who, shortly after 1870 planted a large vineyard at Lispida with these two Bordeaux varieties in the volcanic zone of the Euganean Hills. On the limestone zone of these hills, the wine made from the grapes of the same vines is very different and not only contains more alcohol, but is more higly coloured ; it lacks the bouquet and delicate flavour of the Lispida product.

The Cabernet vineyards that were planted later on the plain of Treviso, did not give satisfactory results, either because the grapes dropped, or were of inferior flavour, because the vineyards were situated too low, and on damp soil. Much better crops were obtained in vineyards planted later on the hilly land, on "ferretto," i. e., red sandy clay soil rich in iron and free from lime, such as is found at Montello and the hills of Susegana and Conegliano, and extends as far as Vittorio-Veneto. The author thinks that the hills of Pignerola and the surrounding district, where the soil is a sandy clay poor in lime, would suit the Cabernet vines very well but that the friable soils on the left of the Tanaro are particularly adapted to this variety.

Prof. CARLUCCI grew some of these vines in 1882 at Avellino, where they flourished, for as they shoot late, they escape the early frosts and ripen at a favourable time (second period). The grapes are rich in sugar, contain but little acid, have highly coloured skins, high tannin content, and resist rot. Near Rome, in the Balestra vineyards, Cabernets have been grown with great success, the wine made from their grapes being exceptionally choice.

1014 - **Improving the Bicane Vine by Crossing in Italy.** — PIROVANO, A., in the *Rivista di Ampelografia*, Year II, No. 6, pp. 81-86. Alba-Livorno, June 1, 1921.

The Bicane vine, when growing on its own roots, is a very fine table variety with unusually large, loose bunches of big, golden fruit. Where, however, the spread of phylloxera has necessitated its being grafted on American stocks, it has quickly degenerated. The vine has not lost its vigour (therefore the poor crop cannot be attributed to want of grafting affinity), but the grapes it bears, are small, aborted berries without pips and split with the first autumn rains. As these defects show themselves every year they cannot be due to accidental climatic conditions.

Artificial fertilisation with the pollen of very strong vines (Ganzin No. 1, or Rupestris du Lot whether grafted stocks, or direct bearers) results in the production of very fine bunches, if the operation is performed on a Bicane vine growing on its own roots, but is an utter failure (as the author found) if the Bicane is grafted on an American stock. The same holds good in the case of other vines : Schiraz, or Pépin de Schiraz, Caprizzisa or Bizzarria and, etc.

Examination ot the flower of a grafted Bicane reveals no abnormality, it is possible that the abortion is produced by the hypertension of the stigma and the ovule caused by an excessive flow of sap from the American stock.

The author has tried to remedy this trouble by obtaining Bicane hybrids. In the present article he describes the selected products of 3 crosses effected with Muscat de Mandresfield, Poeta Matabon and Pergolese (Almeira), respectively. This method was completely successful.

Four vines with white grapes from the progeny of the cross Bicane × Muscat de Mandresfield — IP (Pirovano cross) 53 — 1P54 — IP64 — IP65 —, and 3 with red grapes : IP52 — IP55 — IP56, were selected, and also 1 hybrid with white grapes obtained from the cross Bicane × Poeta Matabon, IP59, and 2 with red grapes, IP57 and 1P58. Only 1 hybrid (bearing white grapes) from the cross Bicane × Pergolese of these vines, which all produce a large number of very fine bunches, was selected. The author gises a description large berries; they all have, however, the defect that the grapes do not keep well.

1015 - An Experiment with a view to Seasoning Standing Timber and to Obtain an Efficient Means of Exterminating Forest Weeds in Trinidad. — Moor, H. W. (Deputy Conservator of Forests). in *Bulletin of the Department of Agriculture, Trinidad and Tobago*, Vol XIX, Pt. 2, pp. 89-90. Port-of-Spain, 1921.

The lack of seasoned local timber in Trinidad and the difficulty, on account of the high cost of labour and transport, of seasoning it without appreciably raising the already high initial cost of production, led the Forest Department to consider the question of artificially killing trees and seasoning them standing. The accepted method of girdling ("barking") the tree is not successful for all species and is particularly unsuitable in a tropical country on account of the large number of insects always ready to destroy any dead or partially dead vegetation.

An experiment was made in June 1918 with 54 trees of miscellaneous species in the Southern Watershed Reserve with a view to: —

1) Killing trees and seasoning them standing without exposing them to insect damage;

2) Killing forest weeds without the initial cost of cutting and the ever recurring cost of removing fresh growth from the stools.

The treatment consisted of cutting out a ring about 9 in. in width, of bark only, and painting on the undiluted preservative ("Atlas Preservative") (1) with a brush, (in the case of palms a ring about 1 inch deep was cut). At the end of the following July, 19 trees were dead, at the end of August a further 27 were dead and by the end of October all but 5 trees were dead and even these had lost all their leaves and their bark was dry.

---

(1) Particulars of the Atlas Preservative may be obtained from the Chipman Chemical Engineering Company, Liberty St. New York, N. Y. (*Ed.*)

[1014-1015]

Amongst the species most susceptible to the poison were Mahoe (*Hibiscus elatus* Sw.). Gommier (*Bursera gummifera* L.), Bois Cannon (*Cecropia peltata* L.), Redwood (*Sequoia sempervirens*), Angelin (*Andira Aubletii* Benth.), Cooper-hoop (*Alphitonia excelsa*), etc. and those most resistant were Milkwood (*Alstonia schloraris*) and Hog Plum (*Prunus hortulana*), etc.

This and subsequent experiments made on several other species, as well as on several kinds of vines, have given distinct evidence that " Atlas Preservative " when applied to even a narrow ring of the growing tissue, circulates with the sap and not only kills all species of vegetation, but kills the root as well as the portion above ground, and is an ideal means of removing undesirable weeds. The preparation is effective whether applied in the growing season or in the season of rest.

As regards seasoning standing timber, large soft wooded trees were readily attacked by insects, but, on the other hand, mature hard wooded trees, though normally attacked when felled green or killed by simple girdling, when treated in the manner described above, are only attacked in the sapwood, the heartwood being left untouched.

Results have so far demonstrated :— 1) That mature trees of species normally fairly resistant to insect attacks can be made immune, and the wood may be seasoned standing in about 3 years: 2) Atlas preservative effectively kills all trees and plants to which it is applied, and does not touch the surrounding trees, confining its effect solely to the individual tree to which it was applied. One gallon of preservative is sufficient to kill about 80 trees, averaging 2 ½ ft., in girth, and 2 men can poison 100 trees (if near together) in 1 day.

The author states that although Atlas Preservative was employed throughout the experiments here described, there is no reason to believe that any other preparation of a similar nature may not prove as successful.

1016 - **Utilisation of Sycamore Wood for Industrial Purposes in the United States.** — BRUSH, W. D., in *United States Department of Agriculture, Bulletin* No 884, pp. 1-24. Tables 8, figs 3, pl. 4. Washington, D. C., Oct. 12 1920.

The principal supply of sycamore is from that part of the central hardwood region which includes West Virginia and Missouri, and the intervening States, and also Arkansas and Tennessee, and the principal centre of the sycamore industry seems to be at present located near the junction of the Ohio and Mississipi Rivers. The actual output of sycamore lumber, by States in 1899 and 1904 and from 1907 to 1918 inclusive is given and also the average value of the product as reported from the mills. There is considerable fluctuation in the amounts of lumber produced by the same state in successive years, but the author attributes this to the difficulties in transportation of logs and the irregularity in supply, since the timber, being confined so largely to river bottoms, is logged also in a somewhat irregular manner.

Only a negligible quantity of sycamore is used in the rough for such purposes as building contruction, etc. It goes principally, therefore, to factories for the manufacture of various products such as boxes and crates, slack cooperage, furniture and fixtures, sashes, doors, blinds, butchers' blocks, musical instruments, agricultural implements, carpet sweepers, trunks, sewing machines, brushes, vehicles, ship and boat building, saddles and harness, sporting and athletic goods, frames and moulding, etc.

The largest amount of sycamore goes into the box and crate industry and is of special value for use in certain containers, such as slack barrels and plug-tobacco boxes. It ranks low, however, in amount consumed (25 native woods, including 13 hardwoods, are used in larger quantities).

The author describes in detail the general appearance, properties and structure of the wood, and gives the average properties of sycamore wood as compared with white oak as follows (Oak = 100) Per cent. specific gravity 76.7;, shrinkage (*a*) volume 99.3; (*b*) radial 104.1; (*c*) tangential 84.4; strength in bending 75.2; strength in compression parallel to grain 82.7; strength in compression perpendicular to grain 61.9; stiffness 80.9; hardness 58.2; shock resisting ability 56.4; shearing strength parallel to grain 76.6

The average computed weight (in pounds) of sycamore in different forms is given. The standard weight of the National Hardwood Lumber Association for rough sycamore lumber 1 inch thick is 3000 lb. per 1000 board feet and for green sycamore lumber 1 inch 4750 lb. per 1000 ft.

The author also gives details of the limber and timber values, grading rules, etc. The plates include a photomicrograph of a transverse section of sycamore wood.

LIVE STOCK AND BREEDING

1017 - **Cattle Poisoned by Horsetails *(Equisetum palustre)*.** — Hoc, P., in the *Journal d'Agriculture pratique*, Year 85, No. 29, pp. 77-79. Paris, June 23, 1921.

Although the horsetail (*Equisetum palustre*) is not regarded as a noxious plant, it is nevertheless poisonous to most animals. The author mentions some cases of poisoning in cattle, in the Department of Aisne, which were studied by M. Rohr, Army veterinary-surgeon, in conjunction with the veterinary surgeon treating the animals. The animals had been given per head for 3 weeks, a supplementary ration of 3 kg. of hay, of which over one-third was composed of horsetails. Out of 17 head, 5 died in a few days; the others were sold to the butcher.

The symptoms of poisoning are as follows:— Dejection, the animal not raising its head; difficulty in mastication; cessation of rumination; the eyes become hollow and the sight dim; the pulse and respiration are slow, the temperature falls. The faeces are black, and have a strong odour. The sick beast soon leans its chest against the feeding-trough holding its head vertically, and its nose applied to the bottom.

The next day, the animal is in a state of collapse, the eye sinks further into the socket, and complete loss of sight ensues.

Then follows a period of intense excitement, which might be taken for an actual fit of madness, but usually the animal rests its nose on the bottom of the trough, or on the ground, and pushes against the wall; the circulation quickens, respiration becomes difficult and loud, and asphyxia sets in. Then the affected animal falls down and dies, or sometimes rises once more, until it is carried off by another similar fit.

If the cattle have reached the stage of over excitement, the meat has a febrific aspect, but if they are slaughtered at the beginning of the illness, before they have begun pushing at the wall, the flesh has a good appearance and can be eaten without risk.

Hyposulphite of soda, given before the disease manifested itself, seems to have reduced the number of cattle affected. It acts in the digestive tract as an anti-ferment. When once the illness has declared itself, no treatment is of any avail, as the symptoms immediately become serious.

The degree of the toxicity of horsetails is very variable, depending entirely on the soil upon which they grow, the way in which the fodder is kept, and also upon the susceptibility of the animals, susceptibility being greatest when the cattle are young.

This explains why, in some cases, these plants have been eaten by stock with impunity. Equisetaceae are less dangerous when mixed with other foods, when they have been stacked for over 6 months or have been well washed by rain.

The toxic effect is due to an alkaloid, or some other vegetable poison, present in the horsetails. A subcutaneous injection made with 20 cc. of an infusion of the suspected hay, which had been concentrated at a low temperature to a tenth of its original volume, will produce all the symptoms of acute poisoning in a guinea-pig or rabbit.

1018 - **Preparation of Arsenical Solution for the Destruction of Ticks.** — COPEZ DOMINGUEZ, F. A. (Jefe División de Química), in the *Gobierno de Puerto Rico, Departamento de Agricultura y Trabajo, Estación Experimental Insular, Río Piedras, P. R, Circular n.* 24 pp. 11. San Juan, P R, May 1920.

Advice intended for stock-breeders on the preparation of the arsenical solution used for destroying cattle ticks. The formulae are based on the results of studies made in the Chemical Department of the Porto-Rico Agricultural Experiment Station.

The method of preparation recommended is as follows:— 1) Heat the water to the boiling-point; 2) Stir in the soda until it dissolves; 3) add the arsenious acid, stirring all the time, and taking care that the water does not go off the boil; it takes at least 35 minute before the acid is completely dissolved; 4) pour the solution into a barrel, and let it cool to 60° C. that is to say, until a person can hold his hand for some seconds to the outside of the barrel; 5) when the mixture has cooled down to this extent, pour some tar into the barrel, stirring all the while; when all the tar is added, stir for 5 minutes, then add it (being careful to mix it well) to the water already in the tank in the proportion of 5 hectolitres per hectolitre of concentrated solution. Each 100 litres of the solution should contain 12.5 kg. soda, 4.2 kg. arsenious acid, and 4.5 litres of tar.

The solution in the tank in which the animals are washed must be analysed once a month, to ensure that it is not too dilute.

1019 - **Studies and Researches on Epizootic Foot-and-Mouth Disease in Italy and Switzerland** (1). — I. BARTOLUCCI A , in the *Giornale di Agricoltura della Domenica*, Year XXXI, No 20, p. 158. Piacenza, May 15, 1921. — II. *Il nuovo Ercolani, Rivista di Medicina veterinaria*, Year XXVI, Nos. 9-10, pp. 179-182. Turin, May 15-31, 1921. — III. LUDWIG, Traitement de la fièvre aphteuse par le sang d'animaux guéris, in *Schweizer Archiv*, p. 285, reprinted in *Annales de Médecine vétérinaire*, Year 66, No. 5, pp. 210-212. Ixelles-Brussels, May 1921.

I. — Since 1916, on the initiative of the Director General of Public Health in Italy, an expert Commission presided over by Prof. di VESTEA of the University of Pisa, has been experimenting with a view to discovering the means of rendering cattle immune to foot-and mouth disease (aphthic fever). During the same time, the commission has extended its researches to the etiology, pathogenesis, clinical form, epidemiology, etc., of the malady. Early in February 1921, the commission declared its task accomplished, and presented to the Director General of Public Health its final report and the special reports of the different investigators from which the following information has been taken.

Except for the results obtained, thanks to the efforts of M. LÖFFLER on the subject of passive protection due to the use of the serum of immunised animals, which could not be applied on a large scale, for economic reasons, all experiments undertaken for the purpose of finding a practical method of active vaccination have been entirely fruitless.

Therefore, the first place has always been occupied by inoculation with natural, benign virus carried out according to the classical grafting method, commonly known as " aphthisation ", consisting in rubbing on the mucous membrane of the mouth some virus taken from animals affected by a benign form of the disease, in order to communicate the benign form of the malady to all cattle exposed to contagion, or to shorten the course of the epizootic by conferring a more or less lasting immunity upon animals that had already undergone the previous treatment.

This was the state of affairs in 1913, when Prof. TERNI, of the Experiment Station for the Study of Infectious Diseases, at Milan, announced that he had succeeded in making cattle immune to foot-and-mouth disease by a method of his own (systematic aphthisation), which consists in strengthening the immunity conferred by a natural attack of the disease, by means of intravenous or subcutaneous injections of natural virus administered from a very early age, successively and periodically. These injections give a thermic reaction unaccompanied by clinical symptoms, or any fear of the animals treated spreading infection ; this virus apparently is so attenuated when it enter the organism as to be no longer dangerous.

---

(1) For other studies on epizootic foot-and-mouth disease (epizootic aphthic fever) see *R.*, 1911, Nos. 890, 2197, 2783 ; *R.*, 1913, No. 954; *R.*, 1914, No. 644 ; *R.*, 1916, Nos. 661 and 768 ; *R* , 1919, No. 923 ; *R.*, 1920, Nos. 335 and 882 ; *R.*, 1921, Mar. No. 309 July, Nos. 734 and 735 ; Aug. No. 829. (*Ed.*)

The Director General of Public Health was anxious that this method should be tested practically on a large scale. For this reason, the technical commission was entrusted with the supervision of these experiments.

Experiment centres were rapidly organised in the different regions of Italy, animals of various breeds, ages and performance were inoculated, and the Commission was able to arrive at the following general conclusions on the efficacy of the TERNI method:—

1) The regular consequence of a natural attack of foot-and-mouth disease is to induce a resistance to the virus that lasts for months or even years, but there have been cases of a second on third attack, the disease even assuming a severe form.

2) The immune condition resulting from the first attack can be prolonged by successive inoculations of the virus at different intervals, so that most of the animals can be protected for many years from the usual form of the disease prevalent in the district. In the case of malignant foot-and-mouth disease, however, practical experiments have proved this protective measure to be far less efficacious.

The Commission started its labours by supervising practical, large-scale experiments with the aphthisation method suggested by Prof. TERNI. But in the course of their work, they extended its scope to a group of other collateral researches which in turn became of the greatest importance in relation to immunisation against foot-and-mouth disease, and to fresh scientific knowledge of the disease.

Dr. COSCO and Dr. AGUZZI, who have carried out much original research work at the Experiment Station instituted for this purpose at the " Regia Cascina " of Poggio at Caiano (*frazione* of Carmignano, Province of Florence) have amongst other things, discovered hitherto completely unknown facts connected with the virulence of the red blood corpuscles of cattle suffering from foot-and-mouth disease. The properties of these corpuscles render it possible to adopt a method of active vaccination more in accordance with the scientific principle of obtaining immunity, by the use of an easily injected virus of constant toxic properties.

To begin with, the investigators demonstrated for the first time the possibility of fixing a virus of constant virulence in washed red blood corpuscles, whereas the hopelessness of attaining this object had been regarded as a fundamental hindrance to all experimental work based on vaccination.

It was then found that an intravenous injection of virulent, washed, red corpuscles, 2 ½ times as strong as an effective subcutaneous injection, could be given without inducing the disease. The intravenous introduction of these corpuscles in certain doses produces a strong thermic and organic reaction in cattle, without causing the development of aphthic lesions, but after a period (negative phase), which appears to exceed 15 days, the animals are endowed with greater powers of resistance to natural contagion.

The experiments that could be brought to a conclusion proved that with active virus and several inoculations, absolute immunity can be conferred for 3 months, as was shown by the tests.

Other experiments made by the same workers with attenuated or dead virus, and also by Prof. TERNI with dead (autolysed) virus confirmed the statement that if dead vaccines produce greater resistance in cattle, they do not give any immunity of practical value.

After examining the results of these prophylactic experiments, the Commission proceeded to examine and test other researches on the pathogenesis and etiology of foot-and-mouth disease.

Dr. AGUZZI is said to have demonstrated that special corpuscular bodies appear inside the red blood corpuscles during a single phase of the attack of aphthic fever (a phase corresponding to that of the virulence of the corpuscles themselves).

These special bodies, which are visible when examined in a dark microscopic field, are quite distinct from the remains of the nucleus or the nucleolus. He is stated also to have pointed out granular bodies in the blood serum, and in the lymph of the aphthic lesions, which are visible in the dark field of the microscope during each phase of the febrile stage of the malady. This discovery may perhaps throw some light on the etiology of foot-and-mouth disease.

II. — The results of the large-scale application (due to Prof. TERNI), of hyperimmunised blood-serum added a new chapter to anti-aphthic haemotherapeutics and haemoprophylaxis. Recently the Swiss Government has made full use of the prophylactic and therapeutic properties of the blood of animals that have recovered, or have been hyperimmunised; and has instituted and encouraged the establishment of centres for the preparation of this means of protection by methods similar to those adopted in Italy.

III. — As the disease assumed such a malignant form during the last outbreak in Switzerland that 60 % of the animals attacked died, LUDWIG tried various measures, hoping to ward it off or at least attenuate its virulence. He used " superol ", a preparation with a quinine basis, and " aptocura ", an Argentine specific which was advertised to cure foot-and-mouth disease in less than 3 days, but the results obtained were absolutely *nil.*

LÖFFLER'S researches encouraged the author to begin experiments in serotherapeutics. There is no doubt that the blood of animals which have recently recovered from foot-and-mouth disease contains anti-bodies that protect the individual from a fresh attack of this fever; the difficulty consists in the practical use of these antibodies. The author first tried to obtain a serum by centrifuging the blood, but was soon convinced that this method was impractical, and he abandoned it in favour of de-fibrinising the blood. The results of his first experiment with fibrin-free blood were successful, although the quantity of blood used was too small and the animals had been ill for 2 to 3 days. On the first day, the cattle were given a subcutaneous injection of 200 gm., the amount being increased to

300 gm. on the second day. The patients showed no symptoms of disease at the time of injection.

The author always tried to obtain blood from at least 5 animals, and to mix it as completely as possible. As the animals had been cured for about 15 days, nearly 4 weeks had elapsed since the development of the malady. LUDWIG did not take blood from animals that had recovered at an earlier date, because the immunity conferred by foot-and-mouth disease is of relatively short duration. He found no difference in the value of the blood of different individuals; unfortunately there is no means of ascertaining this value and a preliminary test blood cannot be made, as the blood must be used as fresh as possible. So far, no means have been devised for determining how long the blood retains its activity.

It has not yet been ascertained if the blood of animals, that have been vaccinated and have only contracted the disease in a very mild form, can be used with any chance of success. The author employed intravenous injections with a view to rapidly, and thoroughly mixing the blood thus introduced with that of the animal under treatment; young or susceptible individuals were given subcutaneous injections only. He found no difference between the results of the two methods. The average amount to be injected is 500 gm., viz., 600 for cows, 500 and 400 for heifers and calves, respectively. As an experiment, the author injected 2 litres into the vein of an animal without its suffering any ill effects. Further experiments have been made to ascertain the minimum effective dose. Of over 600 animals treated in 50 centres of infection, $1/3$ were ill, and the remaining $^2/_3$ still healthy at the time of vaccination.

In each cow-shed, he kept some control animals, most of which became seriously ill, and some even died.

The results of the experiments may be summarised as follows:—

a) *Treatment of healthy animals.* — After injecting from 600 to 800 gm., of infected blood, most of the animals, provided they were free from fever at the time, gave no apparent signs of having contracted the disease. The disease generally broke out after the injection of 400 to 500 gm., but in a much less severe form than that from which the control cattle were suffering.

It is an interesting fact that the milk production of vaccinated cows hardly diminished; a temporary decrease of more than a half was a rare exception. The course of the disease in vaccinated animals is more rapid and their general condition is less altered.

b) *Treatment of sick animals.* — Cattle which have contracted the fever seem to be less affected by treatment: if large doses are given, however, recovery is hastened. The author mentions several experiments of which the following are the most characteristic:— In one shed 17 cows were vaccinated, and 11 kept as controls. The 17 vaccinated cattle (6 heifers and 11 cows) were not yet ill. Of the 11 cows, 2 contracted the disease in a benign form, and the others remained in perfect health; the decrease in milk production was generally negligible. Of the control animals, 1 cow died of cardiac paralysis, and 2 had to be killed because their hoofs fell off; of the rest one alone gave as much milk as previously; the milk production of the others falling below half. Most of the control animals suffered from serious lesions in their feet.

The author affirms that the injection is harmless if the animals providing the blood are carefully chosen, if all the appliances are scrupulously clean and if the blood is fresh.

The stronger the dose given, the more certain is the effect; 100 to 200 gm. is too little for heifers and cows.

1020 - **Purulent Epizootic Epididymitis in Rams in Former German South West Africa.** — SCHEBEN L., in the *Berliner Tierärztliche Wochenschrift*, Year XXXVII, No. 15, pp. 172-173. Berlin, April 1921.

Observations made on a flock of 100 sheep of the fat-tailed variety bought in March, 1913, for a sheep-farm in German South West Africa.

As castration had not been carried out for some years, a beginning was made at the end of March by castrating all the 7 year-old rams. In 54 animals, unilateral purulent epididymitis (usually on the left side) was observed, and there was even one case which was bilateral.

In May and September, when other animals of the flock were castrated, the same typical form of epiditymitis made its appearance in the rams of all ages.

Symptomatology and diagnosis. — There was no sign of the disease before castration, nevertheless the *intra vitam* diagnosis is easy, and can be effected either by palpation, or by mere examination in advanced cases, as the affected organ is then much swollen. The diseased animals gave evidence of more or less pain, when slight pressure was applied to the distal end of the scrotum. The scrotum itself moves easily over the infected organ, and is free from wounds or scars.

On the other hand, there is an abundant flow of phlegmonous pus from the orifice of the sheath.

In both cases, suppuration of the testes resulting in their complete detachment accompanied the epididymitis.

The *cauda epididymis* was always the part most affected, but in the *vasa deferentia*, large swellings often occurred. A vertical section of the epididymis revealed the presence in the *cauda* of 1 to 5 pyogenic pockets of different sizes containing a white, yellowish, yellow, or greenish substance the consistence of cream, or pulp, which was usually free from odour, but in some cases gave off a nauseating smell. Except in the two above-mentioned cases the abscesses were localised in the distal part of the epididymis, whereas the proximalp ortion was more or less swollen, moist, or congested, according to the intesity of the suppurating process. Except in 2 cases, all the operation wounds closed without subsequent treatment.

The correctness of the author's idea that epididymitis is a specific affection of the genital organs of an infectious character was borne out by the subsequent appearance of the disease in the flocks of sheep and herds of goats on a farm in the same region, the animals having been infected by those of a neighbouring homestead.

The author states that this disease, which seems to be very widespread, has not yet been mentioned in veterinary literature.

1021 – **Intrajugular Inoculation of Rabies Virus into the Sheep and Dog.** — REMLINGER (Directeur de l'Institut Pasteur du Maroc), in the *Recueil de Médecine Vétérinaire* Vol. XCVII, Nos. 8-10, pp. 172-175. Paris, April-May 1921.

According to the received opinion, the inoculation of rabies virus gives very different results with herbivora from those than with other animals. Injection of this virus is said to induce rabies in the former, but to have no such effect upon the latter, even rendering them immune to the disease. In 4 series of experiments on sheep and dogs, the author found, that adult sheep and dogs reacted in precisely the same manner to an intrajugular injection of rabies virus. In fact, the percentage of the sheep and dogs that died of hydrophobia was respectively 31 and 38 %.

1022 – ***Euparyphium suinum*, a New Echinostoma from the Intestine of the Pig.** — CIUREA, J, in the *Comptes rendus des Séances de la Société de Biologie*, Vol. LXXXIV, No. 19, pp 1000-1013, 1 fig. Paris, May 28, 1921.

Of the Echinostomidae only *Echinochasmus perfoliatus* var. Ratz has as yet been recorded as a parasitic of the pig.

In the contents of the intestine of a young pig that had been given 40 tench and 8 bream in 55 days, the author found a new species of echinostomate which he has described under the name of *Euparyphum suinum* . It is probable that the pig became infected by this parasite through eating the above-mentioned fish.

1023 – **The Presence in the Saliva of Healthy Animals of a Virus Producing Kerato-Conjunctivitis and Encephalitis in Rabbits.** — LEVADITI, C., HARVIER, P., and NICOLAU, S., (Institut Pasteur de Paris et Laboratoire de Medecine expérimentale de la Faculte de Médecine de Culj, Roumanie), in the *Comptes rendus des Séances de la Société de Biologie*, Vol. LXXXIV, No. 16, pp. 817-818. Paris, May 7, 1921.

A short pathogenetic description of these affections induced by inoculating into the cornea of a rabbit, some fresh saliva taken from perfectly healthy animals that had never suffered from encephalitis. Certain normal salivas only produce kerato-conjunctivitis, but in 1 case the saliva injected into the cornea also gave rise to keratitis. The animal died on the 8th day, manifesting symptoms of encephalitis. The authors promise to furnish new data.

1024 – **A New Enzootic Disease of Fowls Caused by the Trematode *Prothogonimus intercalandus*, in Germany.** — HIERONYMI, E. (Director of the Veterinary Institute of the University of Koenigsberg) and SLIDAT, L., in the *Centralblatt fur Bacteriologie, Parasitenkunde und Infektionskrankheiten*, First Part, *Medizinisch-hygienische Bacteriologie und Parasitenkunde*, Vol. LXXXVI, Part 3, pp. 236-241. Jena, May, 1921.

In flocks of fowls, serious laying troubles have been observed ending in the death of all the affected birds (1). Death was due to vaginitis and secondary peritonitis caused by a parasite mentioned in the literature and belonging to the genus *Prothogonimus* Lühe. The new species, studied and described by SZIDAT, occupies a position intermediate between *Prothogonimus pellucidas* Linstow, ans *Prothogonimus japonicus* Braun.

---

(1) The disease has been observed in the neighbourhood of Koenigsberg in Prussia, where 12 fowls succumbed out of a flock of 14. The birds were kept on a common where there was a pond from which they used to drink and pick up the small animals on the bank.

Symptoms. — The clinical symptoms that could be observed during the course of the malady were not very characteristic at first. The birds became restless, crouched here and there in a moping condition, with their plumage ruffled, and finally lost their appetite. In all cases, the laying fowls were seriously affected. At first, they laid eggs with remarkable thin shells; subsequently the calcareous portion was entirely lacking, and the eggs had a soft covering. Very soon the hens ceased laying and died after a few days.

Pathological anatomy. — This chiefly consisted in affections of the vagina and peritoneum which are minutely described by HIERONYMI. The other organs showed no particular morbid symptoms. Bacteriological examination failed to reveal the presence of specific micro-organismos.

Treatment and prophylaxis. — No curative treatment of this parasitic disease seemed to be of any use. HIERONYMI advised shutting the fowls, up, and feeding them exclusively on grain. Hens thus treated developed no further symptoms.

In order to prevent the occurrence of the disease, it is suggested that fowls should be kept from drinking at suspected ponds and from eating dragonflies.

1025 - Determination of the Amount of Assimilation Energy Necessary for the Production of Meat and Fat in Young Pigs; Experiments in Germany.

— WELLMANN, O., in the *Deutsche Land-wirtschaftliche Presse*, Year XLVIII, No. 43, pp. 325-326. Berlin, June 1, 1921.

KELLNER has repeatedly recorded the amount of energy expended in transforming the products of digestion into animal tissues; but it was only in 1913, that more specific data were published by HEIDE and KLEIN showing the energy output of the pig (1). Independently of these researches, the authors had determined, by experiments combined with the analysis of young pigs, the work of assimilation required for the production of meat and fat.

As a rule, dynamic changes are determined by respiratory analyses, which have the disadvantage of showing only indirectly the composition of the increase in live weight, and the energy expended in producing it, so that first the one, and then the other, have to be calculated.

The author, by combining his experiments with the analysis of the young pigs and supplementing them by respiratory analyses, has been able

---

HIERONYMI draws attention to the fact that at the time of the outbreak of the disease, the number of *Libellula quadrimaculata* was unusually large. During the same season, an enzootic malady with similar symptoms had been recorded in other parts of Prussia.

See THIENEMANN J., Libellenflüge und weichschalige Eier (*Georgine*, 1920, p. 315, (*Author's Note*)

(1) *Biochemische Zeitschrift*, year 1913, Vol. LV.

to determine directly the output of energy and the increase in weight produced. The maintenance energy necessary for the animal was reckoned by the help of experimental data obtained by TANGELS (1), and the quantity of energy used in digestion determined with the assistance of ZUNTZ and MAGNUS-LOWY's calculations (2) which enabled the amount of energy available for production to be estimated.

The composition of the increase in weight, and the energy consumed in producing it, were determined as follows :— The young pigs used for the experiment and the control animals were taken from the same litter. The pigs were killed and examined, and the energy used in the formation of the tissues was calculated. This was done at the beginning of the experiment with the control pigs, and at the end with the others.

The experiments proved that on an average 11.5 calories are needed for the production of 1 gm. of dry organic matter, not including its fat content. Taking into account the heat of combustion of the fat, the author also found, that the worh of assimilating 1 gm. of fat, 1 gm. of protein, and 1 gm. of fresh meat used respectively 2.1, 6, and 1.1 calories.

The author draws attention to the fact that the results of his experiments connected with the work of assimilation are in good agreement with the data given by HEIDE and KLEIN, except as regards the assimilation of protein, for which the figure obtained by the last-named investigators was higher (1 gm = 7.25 calories).

Taking these data as a basis, it may be said that young pigs make better use of the available energy in putting on fat than in the production of flesh, the use-coefficient of the available energy being respectively 82 and 48. The experiments further showed that the part played by the different nutrient elements in the formation of fat is in proportion to their store of productive energy. The work needed for the assimilation of fat is the same, whether the animal fat is formed at the expense of carbohydrates, or obtained from the fat present in the ration.

One gramme of increased weight, when due to the formation of flesh with the normal water contents, represents the combustion heat of 1 calory as against 9.4 calories in the case of 1 gm. of fat. Thus the production of 1 gm. of meat (reckoning the work entailed in assimilation) uses 1.2 calories of energy, whereas 11.5 calories are needed to produce the same amount of fat. The author also states that in his experiments, the energy used in assimilation was entirely supplied by the nitrogen-free nutrient substances, and this process of assimilation in no way increased the decomposition of animal protein. Hence for the production of meat, should a sufficient amount of nitrogen-free substances be available, all that is necessary is to supply the animal with the amount of protein strictly required for this purpose, plus the maintenance ration of protein.

---

(1) According to TANGELS' experiments, the minimum amount of energy required to support life at the critical temperature of 20° to 33° C, is 1100 calories per sq. m. of surface.

(2) The work of digestion uses 0.8 calory per 1 gm. of digestible protein, 0.4 calory for 1 gm. digestible carbohydrate, and 0.24 calory for 1 gm. of fat. *(Ed.)*

Although KELLNER's starch values (1) are not directly applicable to meat production, it is however advisable to use them (with the following corrections) in practical work.

To produce 1 kg. of fat a pig requires (in addition to the maintenance ration) 3 kg., and not 4 kg. of starch values, because the work of digestion in pigs is less than in cattle.

In order to produce 1 kg. of meat, a pig requires, in addition to the maintenance ration, 0.2 kg. of digestible protein and 0.5 kg. of starch values. It follows from what has already been said, that the production of meat, because of its water content, and the good use made of food proteins, only requires $^1/_6$ of the starch values needed for the production of fat; this fact should be taken into serious account in rearing young pigs.

When fattening pigs, it should be remembered that the youngest, most rapidly-growing, animals are the most thrifty, for they possess most growth energy and, further, the production cost involved in increasing the meat weight is less than in the case of older pigs, which put on more fat (a process involving a greater expenditure of energy), and produce less meat.

According to the author's experiments, a young Berkshire pig, from 6 to 12 weeks old, can produce per 1000 kg. of live weight, 25 kg. of meat daily, which requires 4.5 kg. (or in round number 5 kg.) of digestible protein.

Supposing, for instance, that young weaned pigs which are growing rapidly, are fed according to KELLNER's method (6.2 kg. of digestible protein and 33.8 kg. of starch values), the probable production will be as follows:—

	Digestible protein kg.	Starch values kg
Absorbed	6.2	33.8
Necessary for maintenance of life	1.0	14.3
Available for production	5.2	19.5
The production of 25 kg. of meat required	5.0	12.5
Available for fat production	—	7.0

There remain over from the production of fat 7.0 kg. starch values that can be transformed into 2.3 kg. of fat. The increase in weight is thus 27.3 kg., as against 6.5 kg. when fat is exclusively produced.

These experiments show clearly enough that the starch values, even when corrected, as suggested by HANSSON NILS, are not applicable to meat production, because not only is the utilisation of the protein 40 % higher as compared with the starch values, but the work of assimilation in meat production must also be taken into account. On the other hand, the production of the protein entering into the composition of the flesh cannot be estimated in the same manner as that the milk protein, which requires a very small amount of assimilation energy.

1026 - Fresh Forage versus Silage for Dairy Cows under Nebraska (U. S.) Conditions (1).

— FRANDSEN, J. H., HENDRICKSON J. W., WHITE, G C., NORTH, A. C. and WOODWARD, E. G., in *Journal of Dairy Science*, Vol. IV, No. 2, pp. 124-153, tables21, Baltimore, March, 1921.

Nebraska pastures generally furnish insufficient feed for dairy cows during the dry season and it is found necessary to supplement the pastures with either fresh forage or with silage.

If partial fresh forage feed is employed the conditions in Eastern Nebraska are well adapted, as sufficient rainfall is obtained nearly every summer. According to the statistics obtained from the Weather Bureau at Lincoln the average rainfall for the last 40 years amounted to 29.6 inches; 1914, 26.53 in.; 1915, 29 in.

In addition to this, the soil is equally favourable to forage crops as there is a deep layer of Loess soil over the major portion.

The objects of the experiments undertaken lasting over a period of 2 years (1914-15) were: — 1) to determine the most desirable rotation of fresh forage crops with respect to yield, date of sowing, date of harvesting together with an estimate of the cost of production; 2) to determine the value of fresh forage crops as compared with summer silage in the ration for milk production; 3) to ascertain the comparative economy of butter fat produced by cows fed on fresh forage and silage respectively.

Eight cows were selected for feeding and were kept in dry lots (*i. e.* without pasture). Four were fed with fresh forage *ad libitum.* As a supplementary ration, they were fed with a 4 : 2 : 1 mixture of maize, bran and oil meal (obtained by pressure), in amounts considered sufficient to keep them in normal production condition.

The other 4 cows were fed with the same mixture togther with lucerne hay and maize silage, ratio 1 : 1 : 4.

All costs in money values were eliminated from this study and comparisons were made on the basis of total nutrients of the feed or its protein and energy content and on the basis of hours of labour and production.

In the fresh forage group, the following plants were used rye, wheat, lucerne, oats+peas, white sweet clover, maize, sugar cane, millet, kaffir and cow peas (*Vigna senensis*). Details as to the date of sowing, date of harvest, methods of cultivation. rate of sowing, chemical composition and cost of production both for fresh forage crops and for silage are given in various tables. The result of the 2 years under consideration are collected in the appending Table.

1027 - **Potatoes as a Forage Crop.** — See No. 1047, of this *Review.*

1028 - **Notes on the Inheritance of Colour and Markings in Pedigree Hereford Cattle, in England.** — PITT, F., in *Journal of Genetics,* Vol. IX, No. 3, pp. 281-302, pl. VII IX, figs. 7, bibliography of 12 works.

Notes made on the pedigree Hereford cattle at Bridgnorth, Shropshire.

Before considering the manner in which different characters are inherited, the author gives a short description of this race. A typical Hereford is a deep red beast; face and underparts and feet white; white patch along top of the neck; white at end of tail (1) Points that breeders attend to are the coat colour which should be rich purple red and not yellow: a clear clean nose, without spots and markings; and the horns should be free from pigment at the tips.

The following variations have been observed:

I. — REDUCTION OF THE PIGMENTED AREAS OR EXCESS OF WHITE (2). — This variation is most frequently met, certain families being known to " throw white " occasionally.

---

(1) See Grade 0 on appended Plate.

(2) See Grades 1-2-3-4 on Plate.

The factor " excessive white " acts as recessive to normal colouration. Two producers, namely Lowland Paradigm and Bound's Chance give ample evidence as regards colouration and markings. They were mated with cows homozygous and heterozygous respectively for the characteristic " excessive white. " If these individuals homozygous for the typical markings are indicated by the letters NN, those bearing both factors by NW (i. e. " normal pigmentation " N, and " excessive white " W), then the calves bearing the character " excessive white " should be of the genetic constitution WW. The produce of the above bulls may be set forth as follows.

	NN or NW		WW
Lowland Paradigm **NW** × 5 cows **N W**	12	:	5
Bounds Chance **NW** × 6 cows **N W**	13	:	5
Totals	25	:	10
Expectation . . .	26.25	:	8.75

	NN o NW		WW
Lowland Paradigm **NW** × 5 cows **NN**	13	:	0
Bounds Chance **NW** × 13 cows **NN**	39	:	0
Totals	52	:	0
Expectation. . . .	52	:	0

	NN		NW		WW
Bounds Chance **NW** × 4 cows **WW**	0	:	7	:	9
Expectation. . . .	0	:	8	:	8

The above evidence shows that the factor W in Hereford cattle acts as a simple Mendelian recessive to the normal type of markings, normal and badly marked cattle occurring in the ratio of 3 : 1 where heterozygous individuals are mated together.

In addition to this, though the somatic effect of the white factor varies somewhat, each beast having white beyond the shoulders may be confidently assumed to be a homozygote of the constitution WW.

II. EXTENSION OF THE PIGMENT OR DARK NECK. — The ordinary white-necked marking has disappeared and the " dark necked " type of pigmentation shows a distinct tendency to dominance (1).

In the case of a cow called Shelsey Cypress that was dark-necked, only 2 out of 6 calves, all by normally marked bulls, have shown any white on the neck. Presumably the cow was a pure dominant for the character " dark-neck, " the sires being heterozygous. However, dominance is not always complete seeing that white shows in some of the heterozygous offspring. This is evident in the adjoining pedigree table (page 1300) in which D indicates the character " dark-neck, D" the normal colouration and W excessive white.

According to this evidence, it may be concluded that when the factor N alone is present, D is dominant, whilst it becomes more or less recessive in the presence of the factor W.

III. RED-EYES. — A character quite common in English Herefords about $^1/_4$ of the cattle showing it (out of 110, 73 showed more or less colour, about their eyes), though it has never been the subject of selection, the breeders not regarding it as of any importance (1).

The coloured area varies considerably from a comparatively large circle of red round each eye to only a slight trace of pigment.

A study of the factor (R) has shown that the presence of pigment round the eyes is dominant which is allelomorphic to its absence, and this factor segregates independently of other pigmentation factors in the simple ratio of 1 : 2 : 1. But dominance is not so complete in every case, so that the RR and Rr classes are not always easy to distinguish with certainty. It is possible and even probable that the factor N has a modifying or partially inhibiting effect on the full somatic expression of the factor R, so that a normally marked red-eyed beast would not have such well-marked eyes as a dark-necked red-eyed one, though both would transmit the factor R in equal purity to their offspring.

IV. DARK OR DIRTY NOSE. — The pigment sometimes appears on the nose in Hereford cattle in quantities varying from a mere spot or two up to completely dark nose. The black or "blue" (dilute black) spots are considered the worst. Observations concerning the black and brown and black combined have already been made. This form of "dirty nose" is usually found accompanying that deep rich coat colour known as claret. Out of 41 Herefords examined, which were of this tint, 15 had pigment on the nose and 26 had clean noses. The dirty nose is clearly a unit character dominant to the factor R and segregating independently of the other factors with the possible exception of the factor for the rich claret coat. The author for example noted a very white cow (grade—3) with a heavily spotted nose and dark cattle (grade +3) with perfectly clean noses. The figures collected in relation to this transmission of character are as follows:—

	Clean nose	Spotted	Heavily pigmented
Dark-necked + 3 and + 2	7	1	0
Very white — 2 to — 4	7	0	1
Claret coloured	26	0	15
Pale brown	9	0	2

The matings of clean-nosed (pp) with dirty-nosed cattle (PP) may be summarised as follows:

---

(1) In certain countries, for example in Jamaica, cattle with pigment made their eyes are actually preferred on account of their supposed immunity to the attacks of flies and certain eye diseases. (*Author's Note*)

	PP		Pp		pp
Newton Plum **PP** × Newstead **pp**	0	:	2	:	0
Newton **PP** × Bounds Chance **pp**	0	:	2	:	0
Total	0	:	4	:	0
Expectation	0	:	4	:	0
6 clean-nosed cows **Pp** × Newton Glance **pp**	0	:	3	:	3
Expectation	0	:	3	:	3

V. — COAT COLOUR WITH REFERENCE TO THE CLARET AND PALE BROWN SHADES. — The rich claret is the deepest shade found in Hereford cattle, yellow (actually a pale red brown) being the lightest, but intermediate shades are often met with.

The claret factor (C) proves to be recessive to that of pale brown (B) as the matings of 7 yellow Herefords with 2 bulls rich claret colour, resulted in 14 pale brown calves to 1 dark. This is somewhat surprising as, judging by analogy with chestnut and bay horses, it would be expected that the paler colour would prove recessive.

The matings claret × pale brown and claret × claret show the following results:

7 matings **BB** × **CC** = 14 **BC** : 1 **CC** Expectation 15 **BC**.
10 » **CC** × **CC** = 33 **CC** : 1 **BC** » 34 **CC**.

The factors for coat colour segregate independently of others controlling the distribution of pigment, but the factor C is often associated with factors R and P; this may be as follows:

Excessive white

Pale brown	Claret
$\overbrace{1\ \mathbf{WW} : 10\ \mathbf{NN}\ \text{or}\ \mathbf{NW}}^{11}$	$\overbrace{2\ \mathbf{WW} : 39\ \mathbf{NN}\ \text{or}\ \mathbf{NW}}^{41}$

Dark neck

Pale brown	Claret
$\overbrace{3\ \mathbf{DD}\ \text{or}\ \mathbf{DN} : 8\ \mathbf{NN}}^{11}$	$\overbrace{8\ \mathbf{DD}\ \text{or}\ \mathbf{DN} : 33\ \mathbf{NN}}^{41}$

Dirty nose

Pale brown	Claret
$\overbrace{2\ \mathbf{PP}\ \text{or}\ \mathbf{Pp} : 9\ \mathbf{pp}}^{11}$	$\overbrace{15\ \mathbf{PP}\ \text{or}\ \mathbf{Pp} : 26\ \mathbf{pp}}^{41}$

Red eyes

Pale brown	Claret
$\overbrace{7\ \mathbf{RR}\ \text{or}\ \mathbf{Rr} : 4\ \mathbf{rr}}^{11}$	$\overbrace{37\ \mathbf{RR}\ \text{or}\ \mathbf{Rr} : 4\ \mathbf{rr}}^{41}$

[1028]

Notes on the history of Hereford cattle with reference to their markings and variations show that the pigmentary characters are survivals from earlier times when no selection was practised of colour or markings. Hence the faults which appear and reappear in the present-day Herefords should not be attributed to spontaneous variations, but are due to Mendelian factors carried by the animals which cause the characters concerned to appear, when suitable combination of gametes gives them the opportunity.

1029 - **Cyrenaica as a Stock-Breeding Country.** — FRANCHI, Q. (Veterinario coloniale presso il Governo della Cirenaica), in *Il nuovo Ercolani*, Year XXIV, Nos. 15-19, Bibliography of 15 works. Turin, August 15-September 30, 1919.

Observations and suggestions based on the study of what other authors have written on the subject, together with a comparison between these data and the facts observed by FRANCHI himself during his stay in the Colony, which lasted for several years.

The author thinks that, in spite of the present depression, stock-breeding and the allied branches of industry will ultimately become the chief source of wealth in Cyrenaica. Good results can, however, only be expected, if thrifty animals are obtained which can live upon the wild herbage, and support periods of scarcity of forage. Thus, sheep-breeding (the travelling method is the most suitable and is usually adopted) occupies the first place, and cattle-rearing the second. The physiological condition of the native cattle is deplorable, but could be radically improved by adoption of better breeding methods.

The massif of Cyrenaica is formed of limestone rocks ; the large amount of " terra rossa " (red earth) being only the ferruginous, calcareous, residual clay typical of regions where the limestone has undergone alteration.

Next to the limestone, but confined to the coast district, there is a sandstone, which although very soft and friable in the West, becomes much more compact and hard towards Bomba and Toubrouk. The thin strata of clayey limestone that predominate near Solloum, are intercalated with these sandstones. At Solloum, the red earth disappears, but the soil remains of a clayey-calcareous type. Other thin strata of compact, impermeable marl or clay are interbedded with the great limestone mass of the plateau.

Although the flora of Tripolitania is typical of the Sahara region, that of Cyrenaica is of the Mediterranean type.

The author rapidly reviews the districts that may be regarded as of real agricultural importance ; he mentions all the coast zones and those situated in the mountainous region, and on the plateau which is a continuation of the hilly country but leaves out of account the interior zones of the oases and the pre-desert.

The innumerable oases serving as pastures, which are scattered along the coast and over the plateau are the most suitable grazing-grounds for animals reared in the open. They represent fertile patches which have escaped the inroads of the desert sands, and the encroaching of bushes and shrubs.

The stock-breeding problem of Cyrenaica may be stated as follows: It is necessary to provide means for increasing the herds and flocks, improving the stock, and finding a market for the produce.

It is impossible to distinguishe any varieties or sub-groups in the domestic animals of Cyrenaica. Each breed is descended from a single ancestral stock, yet the progeny are not fixed enough in character for it to be possible to classify them as distinct types. The differences between the animals of the same race are almost entirely due to their place of origin, and the manner in which they have been reared.

The *horses* are few in number and are evidently of Berber breed, although some individuals show traces of inter-breeding with oriental-mesomorphic types. It is difficult to find animals with the distinct characters of the Arab horse. All the horses of the Colony have 3 fixed characters:— Convex frontal region (hare's head), thick neck, sloping croup, somewhat narrow at the gluteus.

Extreme measures of ordinary native horses taken by the author.

Circumference of thorax	»	158	»	179	»
Circumference of fore cannon-bone	»	17	»	20	»

Rearing, in the strict sense of the word, does not exist. The horses are sufficiently strong for riding (for which they are generally used), and also for draught work.

The *donkeys* are small; they usually have a grey coat with the mule stripe, or cross, or else a brown coat with light areas on the belly, on the inner part of the thigh, and round the eyes and mouth. Black coats are an exception. There are not many donkeys, and they decrease in number as one advances towards the interior. On some parts of the coast, larger donkeys are found which are of the Pantellerian type, and are probably descended from imported animals of that breed.

Mules are very rare.

The *dromedaries* belong to a special breed, produced by crosses with animals from Egypt and the Sudan. There is a fairly large number of these camels; some droves contain excellent specimens. They are used as beasts of burden, and by caravans. None are specially bred as running-camels or "méhari." Their coat is usually of different shades of fawn.

Cattle are the animals that suffer most from the unfavourable conditions of the environment; there are, however, some individuals that would well repay selection. There is but one breed, and this the author does not believe to belong to the Iberian stock. The coat is generally wheat-coloured, sometimes spotted, rarely black. A large number of the cattle suffer from cysticercosis. The cows, though bad milkers, have well-shaped udders.

Extreme measurements of dromedary taken by the author.

The *sheep* belong to the Syrian breed (Berber variety), but they are of different sizes, and show no uniformity of type. They have abundant wool of an open texture and varying in colour from dirty white to black with apical pigmentation. It is surprising to see the number of anomalies in shape and form presented by these animals: horns and supernumerary members, monorchidia, cryptorchidia, hermaphrodism, epispadias, and hypospadias. Usually, they are in good condition, and not infrequently, the dead weight of the sheep at the local butchers is over 40 kg.

As the author has observed, there are two forms of steatopygia:—

(1) In which the fat deposit is strictly confined to the tail;

(2) in which it extends to the croup; this is called the " fat rump type ". These forms occur independently of the animal's state of nutrition.

Extreme measurements of sheep taken by the author.

Depth of chest	»	21	»	25	»
Circumference of thorax	»	88	»	104	»
Circumference of fore cannon-bone	»	9	»	11	»

The *goats* are fine animals and in good condition: few of them are, however, kept and then usually reared with sheep. The goats of Cyrenaica belong to the breed of *Capra hircus* Helleri. Their hair is long, and their coats generally white, grey, or spotted, seldom black. The females as a rule, yield abundance of milk.

The *fowls*, which all belong to one native race, are very numerous, and excellent layers although they are rather small, light birds.

The *pigeons* are of different types belonging to various breeds, and are somewhat small.

In conclusion, the author points out the course to be followed in order to improve the stock of the Colony and says that it is absolutely necessary for the Government to take the initiative. The first thing is to increase the native domestic breeds, which present no difficulties, as pastures are not lacking. This should be followed by the draining of the marshy land.

In order to encourage stock-breeding in Cyrenaica, it is requisite to: 1) Increase the domestic animals as rapidly as possible; 2) Improve the local species, especially by crossing and selection; 3) Change the environment and solve the forage question; 4) Ensure sufficient reserves of water for the stock and for irrigation purposes; 5) turn to best account the capabilities of the animals, and place their products on the market; 6) found a Stock Breeding Station provided with all the apparatus required for experimental work. Affiliated to the chief Station, there should be zonal stock-breeding sub-stations for the purpose of propaganda and supervision; 7) develop the Veterinary Service for prophylaxis and sanitary inspection; 8) make quarantine stations for stock that is to be imported or exported; 9) encourage the installation of cold-storage plants in the chief coast-towns.

As regards the means of selection, the author advises:—

For *horses*, the use of eastern stallions and mares to the total exclusion of European animals.

For *mules*, extensive breeding with donkeys imported from Pantelleria.

For *dromedaries*, the selection of good local types, and the castration of the young males not needed for breeding purposes, in order to increase the meat supply.

For *cattle*, the selection of native animals, the larger importation of the Sicilian breeds that have given good results and the castration of calves not needed for breeding. In the marshy districts (Bomba), zebus and buffaloes might be tried.

For *sheep and goats*, careful breeding and choice of breeding-animals, for the stock is already good. The castration of lambs destined for the butcher is also necessary.

For *fowls*, the introduction of early-maturing breeds.

1030 – **The Present Condition of Stock-Breeding in Hungary.** — VON KONKOLY-THEGE, A., (Secretary of the Hungarian Agricultural Society) in the *Deutsche Landwirtschaftliche Presse*, Year XLVIII, No. 42, p. 318. Berlin, May 1921.

A short report on the Twentieth National Show of Breeding-Stock at Buda-Pest. This show, which was the first since the outbreak of hostilities, demonstrated that in spite of the war, Hungary still possesses sufficient cattle to form the basis of a national industry.

Considering the reduction of Hungarian territory, the number of exhibits was very satisfactory. Most of the cattle were pure-bred Simmenthals, but there were a large number of crosses between the Simmenthal and the local pied-red breed. The grey Hungarian steppe cattle had few representatives.

Most of the sheep were either combing-wool Merinoes, or early-maturing Merinoes, the Peace Treaty having deprived the country of most of the sheep farms where the animals supplying wool for textile fabrics used to be bred. The pigs consisted almost entirely of animals belonging to the Hungarian Mangalicza breed, there being but very few of the early-maturing foreign breeds, although these are now in great demand.

The following prices are paid for breeding-animals (males and females): — Cattle 38 000 to 150 000 kronen; pigs 10 000 kronen; sheep 8450 kronen.

1031 - **Study of the Cattle-Breeding Situation in South America (Brazil, Uruguay, Argentina) Especially as Regards a Possible Market for Swiss Cattle.** — LUTHY G, (Gérant de la Commission des Fédérations suisses des syndicats d'elevage bovin), in the *Annuaire agricole de la Suisse* Year XXII, Pa,, vol. 2, pp. 49-70. Lucerne, 1921.

Report on the present condition of cattle-breeding in South America, especially in Brazil, and of the cattle shows at Rio de Janeiro, Montevideo, and Buenos-Ayres in 1920.

The author, who was one of the judges of the dairy-cow division at the Rio Janeiro show, has studied the present condition of cattle-breeding in the country, the improvement obtained by the introduction of foreign, especially Swiss, races, and the possibility of finding a sale for Swiss cattle in South America.

BRAZIL (1). — Among the cattle on show at the third National Cattle Exhibition, opened on July 4, 1920, there were 67 of the Brown Breed and 20 of the Spotted Breed; the Black Spotted Breed, on the other hand, had not a single representative.

In the milch-cow division, there were amongst others, Dutch, Norman and Flemish animals, as well as specimens of Jerseys and Guernseys. The following figures show the proportion in which the various breeds were represented at the Show:— Zebu 294; Caracu 14; Hereford 301; Polled Angus 20; North Devon 16; Shorthorn 39; Red Poll 20; Simmenthal 20; Schwyz 67; Limousine 16; Normandy 15; Flemish 13; Dutch 108; Guernsey 20; Jersey 30; Local breed ("Animaes Nacionaes") 12; Red Lincoln 5; Milch cows of various breeds 7; Total: 1027 head.

The author thinks that Swiss cattle would find a ready sale in Brazil, if more active propaganda were made by sending well selected animals of the Swiss breeds to shows in that country, but they would find serious rivals in the English beef breeds which are already well-represented there.

---

(1) See: *R* Jan. 1915, No. 80; *R.* Nov. 1915, No. 1183; *R.* July 1921, Nos. 700 and 767. (*Ed.*)

The Brazilian breeders are now fully aware of the necessity of paying serious attention to the improvement of the native races. Good results will certainly be obtained as soon as there are better means of communication, and when the control of "tristeza" is more effective, and the question of breed solved. The author has had the opportunity of visiting many large farms and "fazendas" in which he found cows belonging to the Brown breed, and the Red spotted breed; some of the animals being pure-bred, others cross-bred. The "Posto zootechnico de Pinheiro" which is State property, is a model farm on which are kept the most different races of cattle of Brazilian or European origin. Amongst others, there are 80 head belonging to the Brown and Spotted Red breeds, that were purchased in Switzerland in 1919; some of the consignment succumbed to "tristeza". The animals have retained their shape and points, but have lost flesh, owing, it is supposed, to the condition and situation of the land.

On another large "fazenda" at Paysandu, belonging to Dr. JONQUIERRE, there was a herd of 880 cows belonging to the brown breed, mostly hybrids, but still showing the breed characters; the animals were in good condition. The author believes that great improvement could be effected though the infusion of fresh blood by bulls imported directly from the home of the breed. Further, since the price of milk is rising, the milk-industry will undoubtedly develop in this region. According to the proprietor, the average daily milk yield is 8 litres, wich in proportion to the total returns obtained from the estate, is very satisfactory.

On another farm (Santa Cecilia à Volta Redonda), the herd consists of 1000 head of cattle, of which 60 belong to the brown breed; the rest being the products of a cross between that breed and the local « "Caracu" race.

Afterwards, the author visited CARNEIO's farm situated in the basin of the Parahyba, in the State of Minas Geraes, where the dairy industry has made more progress.

Cattle-breeding is chiefly practised in the south, whereas in the north horse and mule-breeding are more in favour.

A large number of the beef cattle (local breed) required to provision Rio de Janeiro comes from the above State. The remainder are sent from a greater distance, from the States of Matto Grosso and Goyaz, but as the animals make three journeys, which takes from 2 to 3 months, on foot, they lose much of their weight on the way, and have to be re-fattened on the pastures in the States of Minas Geraes and Rio de Janeiro before being sent to the abattoir. No Swiss cows were met with, except some animals, resembling the Simmenthal bieed to a certain extent as regards their coat but having more or less assumed the shape of the indigenous races ("Caracu") or of the zebu. It is in this State that Swiss cattle, especially the brown breed, would have the best chance of success.

The "Campo Alto" fazenda in the State of São Paolo, possesses several bulls of the Swiss Brown breed, which in spite of their age (one is more than 10 years old) are still vigorous and fit for service. Two young bulls (11-15 months old), bred on the premises, left much to be desired as regards symmetry and development, and their coat was too light in colour. Splendid results have been obtained by crossing Swiss Spotted Red cattle with the local (" Caracu ") breed. Two oxen ($^3/_4$ Simmenthal ¼ Caracu), which were being fattened, showed no signs of mixture of blood in their horns, ears, muzzles, or hoofs. Eighty cows, the products of a cross between the Caracu and Spotted Red breeds (although only of ½ or even ¼ Simmenthal blood), were superior in shape and milk yield to the pure-bred Caracus, and weighed on an average from 200-250 kg. more per head. The average daily milk-yield of this herd was 8 to 9 litres per cow, whereas that of the Caracus never exceeded 3-4 litres. Amongst other estates, the author also visited that belonging to the São Paulo Stock-Breeding Station. In the model cow-shed there, he saw imported Shorthorn, Jersey, Guernsey, Limousine and Dutch cows which were being acclimatised, and undergoing immunisation; the results obtained by inoculation against tristeza are said to be most satisfactory. In short, the author found that the brown breed is well represented numerically in Brazil, but that the quality of the animals is very inferior. The Spotted Red breed, on the other hand, is but little known As regards the breeding conditions in Brazil, the author does not think that the English beef breeds are likely to establish so firm a footing there as to crowd out all other races, which has hitherto been the case in Argentina and Uruguay. The Dutch cattle, however, though represented by many specimens in farms situated near the towns, do not appear to have succeeded as well as the Swiss dual-purpose breeds.

So far, land-owners have manifested a market preference for the zebu imported from India. Zebus belong to a primitive race, and are very thrifty, and resistant to diseases, thus needing little care, which is a great advantage in Brazil. They are well enough adapted to regions where cattle are kept to provide manure, but as the demand for animal products increases in other countries, the zebu of the Brazilian farm will be obliged to retire in favour of European breeds.

Taking these data as a basis, the author has sketched out the outlines of a scheme for importing Swiss cattle into Brazil

He demonstrates the necessity of establishing agencies and creating a Swiss-Brazilian Society to purchase or rent an estate where a large herd of cattle can always be kept, so that the animals are immunised against " tristeza " and can become accustomed to living in a climate, and under conditions, differing greatly from those obtaining in their native country.

According to the author, the most formidable rivals of the Swiss cattle on the Brazilian market will be British and North American animals. Powerful associations, with much British and American capital behind them, have already been formed in the State of São Paulo for the purpose of installing abattoirs and cold-storage plants. It is certain, that, by these means, an impetus will be given to the rearing of English beef-breeds of cattle, and to their exportation to Brazil. The great difficulty in the way of importing Swiss cattle is the deficiency of means of transport. As regards show cattle, the author advises their being sent in good time, so as to be able to spend at least 2 months in Brazil, and thus become somewhat acclimatised before exhibition.

URUGUAY (1) has followed the example of the Argentine Republic in the measures taken for improving its cattle and in organising large annual shows. The results obtained in a short time are most encouraging. Uruguayan breeders have specialised in Herefords, and seem to have a clear idea of the objects for which they are breeding.

With the exception of Herefords, which are preferred, almost the only European cattle in Uruguay are Shorthorns.

Thus, at the Fifteenth Show at Montevideo, there were 104 Hereford, 93 Shorthorn, 5 Normandy bulls (one being 2 ½ years old), 1 Jersey, and 1 Dexter bull. Hardly any cattle are reared in Uruguay for the frozen-meat trade, and it would be difficult, at all events for the present, to introduce other breeds into the country. Huge cold-storage plants have been installed by the important firms of SWIFT and ARMOUR at Montevideo.

Another institution existing at Buenos Ayres, as well as at Montevideo, and which deserves serious attention is the many public auctions where Herefords and Shorthorns are sold. A first-class Shorthorn bull was purchased at such a sale for 110 000 pesos (270 000 francs at the then rate of exchange); other bulls fetched respectively 70 000, 100 000, 170 000, 130 000, 150 000, 180 000, 200 000, and 250 000 fr.

ARGENTINA (2). — The conditions of cattle-breeding in the Argentine Republic are quite different. Although the English beef-breeds, Short-horns, Herefords, Polled and Aberdeen Angus, still take the first place, more attention has for some years been devoted to dual-purpose cattle. The Brown breed is wholly unknown in Argentina, but there are several specimens of the Black Spotted Fribourg cattle; these, however, show marked signs of degeneration. The Red Spotted breed is only known by name.

When importing Swiss cattle, it is of paramount importance to Argentina that the animals should be healthy, vigorous, and accustomed to mountain pastures.

The Show opened on Sept. 4 1920, included among the exhibits, representatives of the following breeds:— Shorthorn 1315; Polled Durham 4; Hereford 229; Aberdeen Angus 130; Red Poll 2; Shorthorn (red) 4; Flemish 9; Jersey 4; Normandy 11; Fribourg 7; Dutch-Friesian 31; Holstein Friesian 34; total: 1780 head.

In paying the above-mentioned high prices for service bulls, the Argentine or Uruguayan breeder pays for a pure-bred animal of long and good pedigree which is vouched for by absolutely trustworthy documents. Further, the author found on enquiry in both Argentina and Uruguay, that all the regulations connected with the Herd-books emanate from a single source, and are identical for all breeders of the same cattle. There is only one Herd-book for the shorthorn, Hereford, and Aberdeen

---

(1) See: *R.* May 1917, No. 466 and June 1917, No. 517. (*Ed.*)

(2) See: *R.* Mar. 1916, No. 264; *R.* Aug., 1917, No. 1123; *R.* July-Sept. 1919, No. 950. (*Ed.*)

Angus breeds respectively. In the Argentina Shorthorn Herd-book, no animal is registered whose pedigree cannot be traced back to the English Herdbook of 1850. More importance is attached to the pedigree of stock in Argentina than in any other country in the world, except England. Brazil is still in the preliminary stage, but is taking an interest in this matter. In all the states of South America, the greatest efforts are being made in the direction of systematic improvement of the different breeds of cattle.

Both in Argentina and Uruguay, the annual cattle shows are organised by Agricultural Societies, and not by the State. To these Societies are also intrusted the keeping and supervision of the Herdbooks, and of all the pedigree-registers of every kind of animal; while to their initiative must be attributed the efforts made to improve the agricultural conditions of all the large estates.

Since cattle shows have been instituted, and especially since the Centenary exhibition of 1910, the cattle exhibited have always been judged by English judges who are experts, in as much as they supplied the selected stock. Very severe supervision is exercised.

As regards how much show animals should be fattened, which is a question much discussed in Switzerland, Germany, and elsewhere, the author has observed, that all the beasts exhibited in Argentina are in prime condition. The prize breeding-stock (bulls and cows), which head the list are extra-fat cattle although the breeders admit that so much fat is injurious to the health, and diminishes the reproductive powers of the animals yet the idea is so well established that even breeding stock should be fat, that a lean bull or cow, would have no change of bring awarded a prize.

1032 – **The Guernsey Breed in Latium** (1). – SENNI, G., in the *Rivista agricola romana*, Vol. XLVII, No 8, pp. 210-214. Rome, August 1921.

In reply to questions sent to him by the President of the Comizio agricolo di Roma, the author makes the following statements :—

One bull-calf and one cow-calf (6 months old) were imported by him from Guernsey in 1910, and 4 cows in 1912. These animals were successfully crossed with Swiss and Dutch cattle, but finally it was resolved to specialise on the pure Guernsey breed.

The weight of the adult animals varies from 350 to 400 kg. The third generation hybrids obtained by the author appear to put on weight in a very satisfactory manner, as has been observed in the United States (2). The average milk of yield adult cows fed on local ordinary forage is about 3000 litres. The milk retains its characteristic richness in cream, its flavour is very delicate, and its colour generally yellowish.

The breed is easily acclimatised. To ascertain this fact, the author made a special experiment on his farm at Grottaferrata where he kept some Guernsey cows in the open winter and summer, for several years. They were given local forage, often even to the exclusion of concentrates. The readiness with which this breed becomes acclimatised is also proved by its being exported to France, England, Denmark, Sweden and the most different parts of the United States, where very pure-bred herds have been formed.

---

(1) See : *R.* July 1916, No. 777.

(2) See. *R.* Jan. 1917, No. 61. (*Ed.*)

The 60 animals bred by the author, though examined every year, were found to be free from tuberculosis; but occasionally they suffered from sublingual abscesses due to the forage which was sometimes coarse. The cows that were first imported are now 11 yeais of age, yet still give plenty of milk. The author has seen in the island of Guernsey a cow of the native breed, 16 years old, with a fine little calf of 2 months, and still giving abundance of milk. Such cases are not rare, indeed as a general rule, cows belonging to breeds that have been greatly improved, continue to serve their special purpose much longer than less well-bred animals.

The author does not think it advisable that Guernsey cattle should be widely kept at present in Latium, for it is necessary that much progress should first be made in the production of forage and the care of stock. Under present conditions, this breed can only be reared successfully in exceptional cases, by a few expert breeders.

1033 - **Sorghum for the Intensive Feeding of Pigs.** — GOUIN, A., in the *Comptes rendus de l'Académie d'Agriculture de France*, Vol. VII, No. 27, pp. 588-592. Paris, July 13, 1921.

The author calls attention to the feeding value of sorghum grain, and shows the excellent results he obtained with it in intensive pig-breeding.

There is only one cereal superior to sorghum as a pig-feed and this is maize, which has a higher fat content.

Sorghum is as nutritious as wheat, barley, rye or manioc :— 100 kg. of sorghum is equivalent to 125 kg. of oats or 140 kg. of buckwheat.

The nutritive quality of sorghum is as high as that of groundnut cake, although its composition is completely different. Sorghum is 15 % more nutritious than palm-oil cake, and 30 % more than oil-free palm-oil meal. It is readily eaten by stock.

In the author's experiments, young pigs fed sorghum and skim milk gained 5 kg. per week, as soon as they had attained the weight of 20 kg.

When given skim milk and 200 kg. of sorghum, a young pig can put on 75 kg. of fat meat in a little less than 4 weeks. This meat costs very little, as sorghum can be bought for 35 francs per 100 kg. in those districts in France where it is cultivated.

If there is no skim milk obtainable, 500 gm. of groundnut cake and a good handful of bone-meal per pig must be added to the sorghum. In this case, it may be calculated that 220 kg. of sorghum, 70 kg. of groundnut cake, and 10 kg. of bone-meal will be needed to produce 75 kg. of fat meat.

The Nantes experiment centre is engaged in trying to make sorghum popular among small breeders.

1034 - Experiments Made in the United States on the Respective Values of Green Feeds as a Preventive of Intestinal Disorders of Growing Chickens. — PHILIPS, A. G. (Chief in Poultry Husbandry), CARR, R. H. (Associate in Nutrition), KENNARD, D. C. (Assistant in Poultry Husbandry, Purdue University Agricultural Experiment Station), in *Journal of Agricultural Research*, Vol. XX, No. 11, pp 869-873. Washington, D. C., March 1921.

Report on experiments carried out in 1919 at Purdue University Agricultural Experiment Station, with a view to finding some appropriate means of checking intestinal putrefaction, the principal cause of mortality of chickens raised in confinement. It was decided to try a series of different compounds which might be expected to have an antiseptic effect or might serve to prevent constipation.

The stock used was 160 White Leghorn day-old chickens which were divided into 10 lots of 16 chickens each.

During the first 4 days, the chickens in all lots were given water and maize. Each bird was marked and the weight was recorded.

Each lot was then given its respective ration. The basal ration given to all lots consisted of 50 parts cracked maize, 35 parts maize meal, 15 parts maize bran, 3 parts ash, 8.86 parts meat scrap, and 10.9 parts soybean meal (all parts by weight). To this basal ration was added the substances indicated in the adjoining Table.

The addition of copper sulphate appeared to have the most beneficial and antiseptic effect as regards a preventive of intestinal putrefaction and consequent mortality. As to the use of sprouted oats, thought by some to be effective in lessening mortality, especially when fed for a short time only and when given as a supplement to a somewhat monotonous ration, in the present experiments no directly beneficial effect was evidenced.

The sulphur caused a continued looseness of the bowels; however, up to 8 weeks of age this was one of the best lots.

The retarding effect of tobacco was pronounced and resulted in stunting the growth during the first 8 weeks. There was a tendency, however, for the chickens to recover somewhat by the age of 14, weeks, but they always seemed more wild and nervous than those of any of the other lots.

The use of hydrochloric acid in the drinking water seemed to be of some benefit seeing that the mortality was somewhat less than the average and the growth was consistent throughout the experiment.

Strawboard pulp, supplied to the ration for the purpose of adding bulk and thereby lessening the danger of impaction of the small intestine and caecum common when feeding a grain ration, did not seem to aid in reducing mortality.

The lots given a litter of oat straw to encourage the chickens to exercise, did not prove successful as regards growth nor was the mortality lessened. This ration has proved its efficacy in promoting growth but has also proved its inefficiency in checking mortality, especially during the 8th and 14th weeks.

Lactose added to the ration did not seem to aid in lessening mortality or in promoting growth. This may be due to the fact as stated by MENDEL and MITCHELL (1), that birds, unlike mammals, have no sugar-splitting enzymes in the small intestine ; hence the sugar fed was not converted into lactic acid to any considerable extent. In addition to this, the faeces contained the normal amount of uric acid and no soluble ammonium salt where hydrochloric acid was used in the drinking water.

The experiments have shown that hydrochloric acid, sulphur and particularly copper sulphate offer interesting possibilities in raising chickens in confinement.

Substances added to the basal ration and mortality of chickens.

Lot No.	Ration	Age 8 weeks		Age 14 weeks	
		Weight	Mortality	Weight	Mortality

1035 - **The Introduction of the Italian Bee into Brazil.** — *Chacaras and Quintaes*, Vol. XXIII, No. 6, pp. 456-457. São Paulo, June 15, 1921.

In November, 1920, Prof. E. SCHENK imported twenty swarms of Italian bees which were sent to the Borges de Medeiros Institute. No time was lost there in raising queen-bees according to the most modern methods, and by the end of February 1921, only 10 % of the swarms at the Institute still had black native queens, all the rest having yellow (Italian) ones.

Where an Italian queen-bee was present in a native swarm, it was necessary perforce to allow her to be fertilised by the native males, but since eggs producing males are not fertilised, these queens only produced yellow and not black males. At the present time, all the fertile bees are of the Italian breed, the black males and queens having died or been destroyed.

(1) MENDEL, LAFAYETTE, B., and MITCHELL, P. H., Chemical Studies on Growth. — I. The inverting enzymes of the alimentary tract especially in the embryo, in *American of Journal Physiology*, Vol. XX, No. 1, pp. 81-96, 1907.

(2) Strawboard reduced to pulp with water. The pulp after most of the water is expelled is mixed with the dry mask.

In its new home, the Italian bee shows its usual characters of gentleness, great activity, and resistance to disease.

1036 - **Results of the 1919-1920 Season of Silkworm Egg-Breeding in France.** — *Ministère de l'Agriculture, Directeur de l'Agriculture, Bulletin Mensuel de l'Office de Renseignements agricoles*, Year XIX, July-December, 1920, p. 353. Paris, 1920.

During the season 1919-1920, the work of the service for the supervision and control of silkworm egg-breeding was carried out by 2 inspectors and 12 controllers; the number of establishments inspected was 62, a larger number than in preceding years.

The weight of the cocoons sent after sorting to the egg-rearing establishments showed a considerable increase in comparison with that recorded for other seasons and rose to 206 256 kg. as against 116 929 in 1916-1917, 115 661 in 1917-1918, and 94 174 in 1918-1919, but was about the same as the pre-war average (of about 207·500 kg.) for the period 1911-1914.

In proportion to the larger weight of cocoons sent to the rearers, the "seed" production showed a great increase, being as much as 14 597.144 kg. (8503 in 1917-1918; 6342 in 1918-1919).

Of the total weight produced 884 6.354 kg. (corresponding to 400 568 boxes) were provided with the official mark, as against 269 727 guaranteed boxes supplied in 1917-1918, and 176 231 in 1918-1919.

These guaranteed silkworm eggs were chiefly despatched to Syria (1382 kg.), Serbia (1157 kg.), Spain (807 kg.), Italy (711 kg.), Japan (472 kg.), etc. A large quantity was also sold in France.

The number of batches of eggs sampled at the rearing establishments and examined at the Draguignan sericultural Station totalled 2142, of which only 1 was found to have been attacked by pébrine, and this but to a limited extent, only 3 % of the eggs being infected.

The results of the season 1918-1919 show, on the one hand, that the silkworm-egg breeding industry, though it has suffered from the general economic depression has recovered, and has now attained its prewar level, and on the other, that the efforts made by the officials of the control service to improve the quality of French silkworm eggs have borne good fruit, as is shown by the manner in which the silk worm rearers and suppliers of "seed" have evidently profited by the advice given to them by the Inspectors on the occasion of their visits to the rearing establishments.

1037 - **Crossing Pure Breeds of Silkworms in Relation to Modern Theories of Hybridisation and Heredity.** — I. GRANDORI, R., (Directeur de l'Institut Séricicole de Trente), in the *Annuario della R. Stazione bacologica di Padova*, Vol. XI-XIII, Part. 2, Padua, 1920. — II. BOLLE, G., in *Allevamenti*, Vol. II, No. 4, pp. 107-108. Palermo, April 10, 1921.

I. — From a careful study of the results of experiments in silkworm crossing made principally by COUTAGNE, QUAJAT and TOJAMA, GRANDORI has arrived at the following conclusions:—

1) On crossing pure breeds of silkworms, the Mendelian laws are found to hold good only to a certain extent, probably on account of the great difficulty of obtaining really pure-bred specimens for the experiment. In any case, whether one character or another follows the laws of Mendel or not, is of little importance in securing new breeds that are resistant to " flacherie ". Nevertheless, the work hitherto accomplished has yielded results that can serve as a guide for further experiments which it is hoped will provide the silkworm industry with new breeds of vigorous hybrids. No steps have so far been taken to attain this practical result by scientific methods.

(2 Mendelism alone would not suffice. In order to obtain the desired breed by this means only, it would be necessary to find, fix and perpetuate as pure dominants, a very large number of characters. Further, in the same combination, numerous other characters, that it is wished to suppress would have to act as absolute recessives. To accomplish all this is practically impossible.

(3 If Mendelism by itself is inadequate, it can nevertheless be of valuable assistance to us in attaining our object, for it may be regarded as a rapid means of resolving the complex of race characters into its component parts. Then is the time for selection, which has been rigorously practised for many generations, to take up the task with the twofold object of reproducing the combinations answering to requirements, even if only to a small degree, and of fixing these combinations in such a manner that they may be reproduced *inter se*. These combinations should above all include those physiological characters that, in spite of their great complexity, and the large number of inherent non-transmissible factors by which they can be modified during the embryonic and post-embryonic development of the progeny, themselves appear to have in the germ-plasm a material *substratum* capable of being transmitted.

The most vigorous oriental breeds must be chosen for crossing with our finest and most profitable breeds, and whatever Mendelism cannot give, must be sought for by means of the careful selection of combinations obtained by segregation, and autonomy.

4) Among the breeds likely to furnish good results, the oriental bivoltins and univoltins must not be forgotten when it is desired to obtain hybrids combining the best qualities of our native silkworms with the disease-resistance characteristic of these foreign breeds.

5) The continued selection that may be necessary to restrain the variability of self-bred hybrids within minimum limits is not so great a disadvantage as repeating the crossing operations every year.

II. — Prof. BOLLE has arrived at similar conclusions from the results of his experiments on the white Japanese breeds which he studied in Japan, and afterwards reared and crossed for several years at the Gorizia Experiment Station. Silkworms become more vigorous, not only through crossing, but also by change of country. The author fround, both in China and Japan, breeds that were much prized, though they had the defect of great susceptibility to " flacherie ", which on being brought to Europe, proved most resistant to that disease. The same fact has been observed in Europe; some regions even, especially the districts of Ascoli and the Abruzzi in Italy, and of the Var and Basses-Alpes in France, have a good reputation for the production of vigorous native breeds of silkworms, which when reared in other countries, are much less attacked by the malady.

1038 - **Silkworms Mounting on Broom.** — FAVERO, P., in the *Bollettino del Consiglio provinciale d'Agricoltura*, Vol. XXXIV, No. 10. p. 189-192, figs. 2. Trent, May 30, 1921.

A mistake very frequently made by silkworm rearers is to feed the caterpillars too soon after the 4th moult, which causes them to grow unequally, and also makes them all mount on the broom as soon as the first ones are ready. In this way, some of the larvae will get on the broom after having again eaten a meal, and therefore will produce a smaller quantity of silk.

Another error consists in covering the branches with cloths, etc., so as to hinder the circulation of air, thus inducing cocoon rust or destroying the lustre of the silk.

The author therefore advises the adoption of the system used in Piedmont and the Abruzzi, which is figured in the text. At suitable intervals in the trays used for breeding, hedges or tunnels should be made of light elastic material (any dry, clean branches can be used). The silkworms which are kept thus separated, are fed uninterruptedly during the pupation period so that they go on to the broom as they become ready, which under normal conditions, means in 3 or 4 days, counting from the first caterpillar to the last. No covering of any sort is put over the branches. With this system, heavier, flawless, cocoons with a larger yield of silk are obtained, and double cocoons never occur.

FARM ENGINEERING.

1039 - **Motor Ploughing in Cyrenaica.** — GORINI, P. M., in *L'Africa Italiana*, Vol. XL, Part III, pp. 122-123. Naples, May-June 1921.

The author shows by the following data, the great advantage of hiring motor-ploughs for tilling the land in Cyrenaica.

In the plain to the south of Bengasi, the Arab, if he has no better implement at his disposal, hires a native wooden, pointed plough drawn by a camel for preparing the seed-bed. He pays for each workday a minimum of about one " measure " of wheat, or two of barley, payment being nearly always made in kind. A " measure " equals $^1/_8$ *saa*, which weighs on an average 90 kg. in the case of wheat, and 60 kg. in that of barley, It takes two days and a half to plough 1 hectare with a camel and native plough. To the cost of hire must be added other small expenses, and the camel-driver's food. Therefore, the cost of native labour for 1 hectare is nearly equal to that of a day's work with a motor-plough (reckoned by the author at 70.87 lire), and the work is not nearly so satisfactory.

Deep ploughing can be done once every 3 years, and followed by autumn harrowing in the 2 following years.

Motor-plough trials were carried out from March 4 to 6, 1921, in the Bengasi Colony at Rahba, under the auspices of the Colonial Government Agricultural Office. The " Romeo " tractor of 12-25 HP was used ; it is very well adapted to the conditions, and its work is excellent.

1040 – **Trials of Gianetti Motor Cultivators** (1) **in Capitanata, Italy.** — GRAMAZIO, I. (Direttore dell'Ufficio Agrario di Capitanata e dei Consorzi Viticoli di Foggia, San Severo, Torremaggiore), in *La Propaganda agricola*, series II, Year XIV, No. 14, pp. 194-198. Bari, July 31, 1921.

Tillage trials made with GIANNETTI motor cultivators, on the initiative of the *Ufficio Agrario di Capitanata*, in the district of Foggia, on May 30, on gravelly land covered with stubble ; on May 31, in a kitchen garden ; on June 2 and 3 on fallow land, and in vineyards, at Sansevero ; on June 7 and 8 at Cerignola, in a nursery of American vines ; on fallow land, and in a mown meadow. According to the work to be done, two machines were used, the one of 30, and the other of 6 HP.

The work taken as a whole was satisfactory, and the tests prove that the Gianetti motor cultivator is well adapted for preparing the ground for sowing, especially for the secondary operations, for it breaks up the stubble, even in gravelly soil, and eradicates the weeds.

On fallow land, the width of ground worked by the large model is 1.10 m., and it will penetrate to a depth of 20 cm. (the depth can equally well be fixed at 10, or at 28 cm.) ; it works 800 sq. metres an hour, consuming 5 litres of benzine. In kitchen-gardens planted with trees, the width of ground worked by the small model was 60-70 cm., and the depth penetrated was 8-15 cm. ; it worked 870 sq. metres an hour, consuming 2.5 litres of benzine. In vineyards, this model can work nearly 0.6 hectares daily to a depth of 8-18 cm., the cost per day being only 120 lire.

1041 – **The Couten Watering Appliance.** — *Génie rural*, Year 12, No. 107, pp. 17-19, figs. 2. Paris, February-March 1921.

The COUTEN watering appliance, shown in plan in the appended figure, is based on the principle of the tourniquet, or water drum.

This apparatus consists of a small drum that waters a radius of 6 metres, and actuates, by means of two toothed wheels, and two endless screws, another larger drum furnished with short arms. Owing to the reducing action of gearing the large drum only makes one revolution a minute. This reduction in speed permits the maximum projection allowed by the resistance of the air, so that the 4 arms of the large drum (as the diameter of each is different), represent the work of 4 men revolving slowly on themselves, and each watering a given perimeter. In this way, the watering is done perfectly regularly from the centre to the periphery, a result almost impossible to attain with a watering-can or hose. With a pressure of 1.5 kg. to 3.5 kg., a diameter of 20 to 40 metres can be watered (1200 square metres).

---

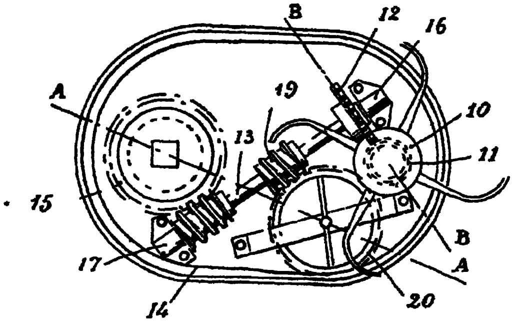
(1) See *R.* July-Sept. 1919, No. 970, (*Ed.*)

With water under a pressure of not less than 1500 gm. it is possible to water a garden in these different ways :—

1) By means of a sprayer on a tripod connected by tubing or a water-tap. This is very easily moved, as soon as one part of the ground is sufficiently watered.

2) By means of sprayers fixed on vertical iron pipes connected with a system of pipes that can be worked in succession, or in series of sprayers fixed on the same line of pipes.

3) In order to avoid the need for a man to open each set of pipes one after the other, a special patent arrangement makes it sufficient for the first tap to be opened. Then in succession, and alternately, all the taps open and close at the right moment. Thus it is possible, without manual labour, to water any extent of ground, and to give each part the amount of water it needs.



Plan of Couten Sprayer

4) It is also possible to use a motor-pump on a wheel-barrow, which sets in motion 3 sprayers simultaneously.

In order to water crops with this apparatus it is necessary to :—

1) Lay down 80 to 100 mm. cast-iron pipes in parallel, 150 metres apart.

2) Have water-cocks every 25 metres along the pipes.

3) Have 2 or 3 movable tubes, that can be attached to the fixed pipes, each supplying a certain number of sprayers. Each of the sprayers gives out, by means of its interchangeable arms, 5 000 to 10 000 litres per hour. The movable tubes of rubber, leather or canvas, are wound round a reel that can easily be worked by two men. While one set of tubes is in use, another set is being rolled up. In this way, 2 men are able to water 4 to 5 hectares a day.

Agriculturists having tractors at their disposal, can use their motor to work a powerful pump, and water a very large area automatically.

[1041]

1042 - **Martinotti Apparatus for Preparing and Bottling Sparkling Wines.** — MARTINOTTI, F. (Stazione enologica di Asti), in the *Giornale Vinicolo Italiano*, Year 47, No. 28, pp. 273-276, 1 fig.; No. 29, pp. 282-285, 1 fig.; No. 30, pp 292-294, 1 fig. Casale Monferrato, July 10, 17 and 24, 1921.

I. APPARATUS FOR FERMENTING SPARKLING WINES IN AN AUTOCLAVE. — The object of the apparatus described by the author is to make wines effervesce in a short time (a few months) by means of fermentation, and thus to supersede the old classical champagne system of keeping the wine on stands and afterwards stirring and drawing it off, which required 2 or 3 years. The wines to be treated must have quite settled, and finished.

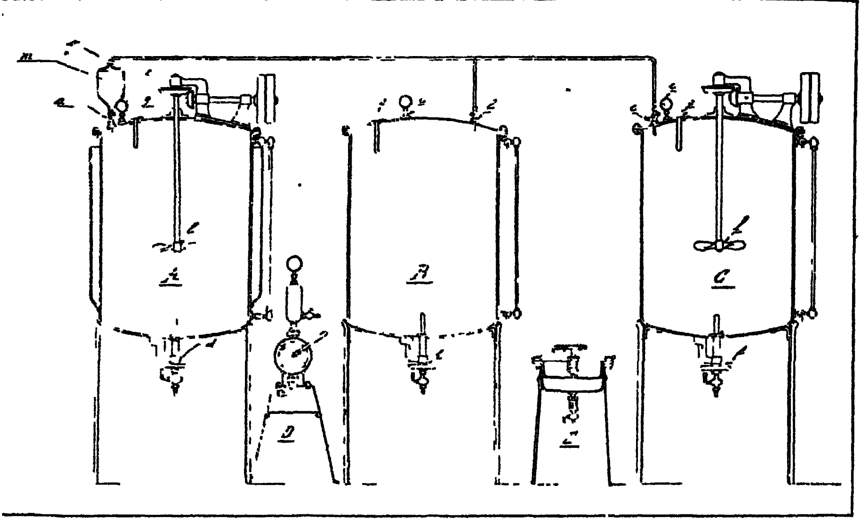


Fig. 1. — MARTINOTTI Apparatus for the Autoclave Fermentation of Sparkling Wines. Vertical Section.

The apparatus (fig. 1) consists essentially of 3 enamelled-iron autoclaves, A B C, of the same capacity, and able to resist the pressure of 8 atmospheres (in the figure, for the sake of clearness, the pump and the filter are drawn on a larger scale than the autoclaves).

Autoclave A, in which the fermentation takes place, is put in surroundings favourable to the process, while autoclaves B and C, which are intended respectively for clarification and to receive the filtered wine, are put into a properly cooled room, in order that the clarifying and bottling may take place under the best conditions.

Autoclave A is surrounded by a vessel in which circulates a freezing mixture for cooling down the wine after fermentation; further, the screw l keeps the ferments in the wine in continual suspension, in order to hasten fermentation.

The 3 autoclaves are all fitted with an attachment on the cover, to contain the thermometer to show the temperature of the wine; at the bottom of each autoclave, is a movable tube furnished with a tap that allows the wine to be drawn off from above the sediment.

The screw of the autoclave C serves to mix the mass with the liquid and the metasulphite solution, unless it is thought best to add the latter to the wine before bottling.

Pump D has a float, and is provided with a rather large air-chamber and a manometer.

The filter E is made of cellulose.

The *manufacturing process* is as follows:— The wine is brought to a temperature known to be favourable for inducing satisfactory fermentation, good ferments are added, as well as the amount of sugar necessary to obtain the required amount of effervescence. Then the wine is put into autoclave A, care being taken to maintain the temperature required, and to set the screw revolving slowly, but continuously. When fermentation has taken place, the motion of the screw is accelerated, so that the wine circulates round the sides more rapidly, then the freezing-mixture in the jacket is made to circulate in order to bring the wine almost to the freezing point. When cooled down to this extent, the wine is left to settle, should it be a little turbid, and as soon as it is clear, it is passed into autoclave C.

The operations are carried out in the following manner:— The pressure in autoclave C is regulated so as to be equal to that in A, then the two autoclaves are put into communication by means of a pipe placed above them, the taps a and c being opened. After regulating the tube to touch the surface of the deposit in autoclave A, the pump D is fitted on the one hand to the tap d and on the other, to the lower tap of the filter E, the upper tap of this filter being attached to tap f of the autoclave C. When f is opened, the pressure in the whole apparatus, autoclaves, filter and pump is the same.

Then tap d of autoclave A is opened, and the pump set going, care being taken to ensure that the manometer in the air-chamber swings slightly, and registers a pressure about 0.4 of an atmosphere higher than that in the autoclaves, this being necessary to make the wine pass through the cellulose layer.

If the wine is turbid it is clarified with gelatin, which is dissolved in the amount of hot water required, and poured into the copper receptacle m. The tube communicating with the other autoclaves is unscrewed from o, and another tube is screwed on which communicates with a cylinder of carbon dioxide; a pressure not exceeding that in the autoclave *A* is then produced in m.

The tap A is opened to allow the gelatin to pass gradually down into the wine, the screw I being made to revolve a little faster to mix the contents thoroughly. The wine is then pumped into the autoclave B, without filtering, operating in the manner described above if the wine is slightly turbid. In B, the wine clears, and as soon as this operation is finished, the lower tube maintaining the level is raised above the deposit and the wine is made to pass through the filter E into the autoclave C, from which it goes into the bottles. As fermentation lasts about 15 days, and clarification about 4 days, it is possible to have 2 to 3 autoclaves for fermentation, and a single one for clarification; in this way, the output of the apparatus is increased.

Autoclave C can be dispensed with if the filter is made to work by difference of level. Then the wine passes from the filter into a small tank, and thence through a coil of cooling pipes to the bottling-machine.

II. APPARATUS FOR INTRODUCING THE GAS INTO EFFERVESCING WINES. — As in wines which effervesce through gas artificially introduced, the bubbles are larger and the effervescence less persistent than in naturally sparkling types, the author set himself the task of selecting an apparatus to introduce the carbon dioxide in the maximum degree of subdivision, so as better to imitate its action when present in a nascent condition in naturally effervescent wines; for this purpose, he chose the CHAMBERLAND filter.

Already twenty years ago, Dr. CARPENÈ (*Giornale vinicolo italiano*, No. 4, 1901) suggested the use of porous cells for the carbonification of wines, but he subsequently abandoned this idea, and used canvas tubes as being more practical He noticed that the smaller the pores of the BERKEFELD and CHAMBERLAND filters (1) which were immersed in the wine and filled with carbonic acid, the smaller were the bubbles formed in the wine.

As the solubility of carbonic acid in wine is greater the lower the temperature, the author has tried to obtain the maximum subdivision in wine kept at the lowest possible temperature.

Description of the apparatus. — This (fig. 2) consists of an autoclave A, made of enamelled iron, or tinned copper, a compresser B, a pressure reservoir C, and a receptacle D for the gas under reduced pressure. It is provided with a cylinder of carbon dioxide E, a reduction valve G., a glass observation bottle H, and a receptacle F, in which the gas is purified.

Around the inner walls of the autoclave are carried one or more coils a-a-a of tinned copper tubing to which are hermetically screwed BERKEFELD and CHAMBERLAND filters with heads of tinned-copper. The filters, as is shown in the left-hand figure, are arranged like the spokes of a wheel, and placed horizontally, for the purpose of presenting the largest contact surface to the wine that ascends from below on account of the motion imparted to the mass by the screw B. These filters are fixed in a circle so as to be on the same vertical plane, in order that the wine that has touched a CHAMBERLAND filter may not come in contact with it at a higher level.

---

(1) CHAMBERLAND filters are marked from A to F, the latter being the most porous BERKEFELD filters are more porous than F CHAMBERLAND filters. For large apparatus, special porous cells can be made. CHAMBERLAND filters are 20 cm. long, with a diameter of 3.5 cm. The length of BERKEFELD filters is 25 cm., and their diameter 4.5 cm. (*Ed*)

In the cover of the autoclave **A**, is a closed tube **k** containing a thermometer showing the temperature of the wine, a manometer, and several taps The autoclave is sorrounded by a jacket in which is a freezing solution supplied by the taps **u** and **d**.

As the compresser **B**, in order to work regularly, must be supplied with gas at zero atmospheric pressure, it was necessary to interpose the reservoir **D**, in which the pressure of the gas coming from the autoclave is reduced because the power of the compresser is greater than the amount of gas coming out of **W**.

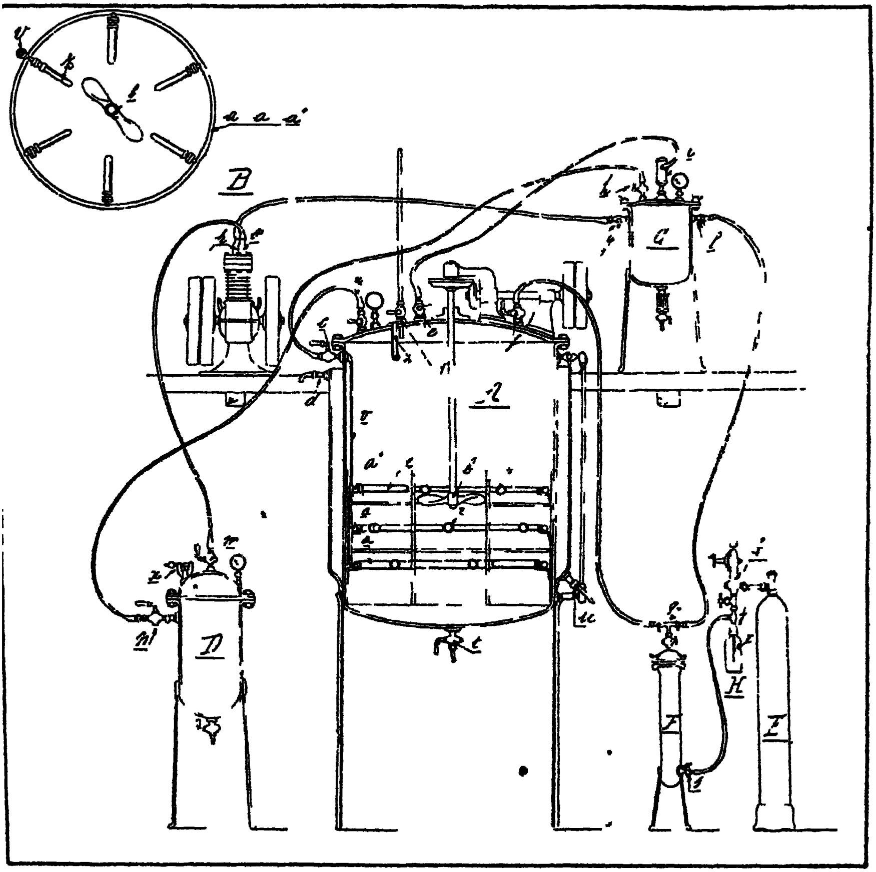

Fig 2 — Martinotti Apparatus for Introducing Gas into Effervescent Wines.

Since the compresser heats the gas in compressing it, the gas is cooled before passing into the reservoir **C**, by traversing a coil (not shown in the figure), immersed in water and ice

The pressure reservoir C protects the filters from the blows of the ram of the compresser, and prevents any drops of oil that may be projected with the gas from getting into them. On the cover of the reservoir, there are a manometer and a spiral safety valve enclosed in a case I; the safety-valve is so arranged that there is never such a pressure in the filters as to prevent their regular working.

On leaving the safety-valve the gas is admitted into the autoclave by the tap e.

Working of the apparatus. — The required pressure is first brought to bear upon the CHAMBERLAND filters by putting into action the carbon-dioxide valve and opening the taps g, l, h, c. Then tap c is opened by unscrewing the cover; subsequently tap y is opened, and through it, either by means of a pressure pump, or by some other arrangement, the wine is let into the autoclave A until it flows, mixed with gas, out of tap e. In this way, it can be secured that all the air has been driven out of the autoclave. Then the tap is turned, the cap of the tube coming from i is screwed on again, tap t is opened, and the wine rises to the right level. The screw is made to revolve so as to increase the pressure to the necessary amount inside the autoclave.

Tap W is then opened to allow sufficient gas under the determined pressure to supply the filters, that is to say, until the manometer of the autoclave A indicates no further reduction of pressure. When this point is reached, tap f of autoclave A is opened, the reduction valve G is adjusted, so as to maintain the required pressure. The glass observation bottle along the tubes h-c and w-n enables the observer to estimate the amount of gas passing through, and test the regular working of the apparatus. The compresser continues to work, and the gas goes on circulating through the mass owing to the action of the CHAMBERLAND filters, until the wine, being quite saturated, absorbs no more gas, and it can be seen through the observation bottle H, that no more carbon dioxide is passing. Then the bottling operation can be begun by turning tap t.

If it is desired to impart continuous action to the apparatus the mass is saturated in the way described above; then, while the autoclave is supplied by tap y in such a manner that the level remains constant, bottling is begun by opening tap t, care being taken not to remove, during the time required for complete saturation, more than $^4/_5$ of the wine in the autoclave. The introduction of carbon dioxide should never be uninterrupted, in order that no diminution of pressure may be caused.

In the case of ordinary or continuous work, alike, the pressure on the CHAMBERLAND filters may only be reduced when, at the close of the operations, there is no more wine in the autoclave, for wine must not be allowed to enter these filters.

The experiments made by the author were carried out under a pressure of 3 atmospheres, the temperature of the wine being —4° C, which corresponds to about 6 atmospheres at 15° C with BERKEFELD filters and CHAMBERLAND filters (*B*). The first work under a pressure of 1 atmosphere, and the second under a pressure of 3 atmospheres. Thus in the reservoir C, there were, respectively, 4 and 6 atmospheres. The safety-valve **i** was set for ¼ atmosphere more.

Advantages of the apparatus. — According to the author, these may be summarised as follows:—

1) The possibility of driving all the air out of the apparatus, for air, as is well-known, is very injurious to the quality of the effervescence.

2) The saturation of the wine at a temperature near freezing point.

3) Maximum speed of introduction of CO_2 by the use of the right number of CHAMBERLAND filters, which are indestructible.

4) The certainty that the wine is saturated with carbonic acid.

5) Possibility of obtaining a wine with sparkling properties resembling in their excellence and persistence that of natural sparkling wines.

6) The maximum facility and rapidity of bottling, since the low temperature allows of the work being done under the pressure of 3 atmospheres.

7) The apparatus takes little room, and is inexpensive.

III. APPARATUS FOR BOTTLING AND CORKING EFFERVESCING WINES UNDER PRESSURE. — With the present machines used for these purposes, it is impossible to clean the lower part of the cork before putting it into the neck of the bottle, so that pieces of cork on other substances are liable to be introduced into the wine. Further, when the ordinary corks (which have a diameter of about 35 mm.), used for exported wines are employed, these machines are not able to compress them to the required size, or if they succeed, the corks become broken and damaged in the process. In order to overcome these difficulties, the author has had the happy idea of adapting to the corking-machine the apparatus for bottling effervescing wines under pressure.

For this reason, the ramming machine has been altered in such a way, that its jaws on closing, form a cylindrical space of 15 mm., instead of a conical one. The cork must be at once reduced to this diameter throughout its entire length, because the ordinary diameter of the piston, 22 mm., has had to be reduced to 15 mm., in order to permit of its passing through the aperture of the ring placed beneath it, which at this diameter and place, corresponds to the space inside the bottle. In order to overcome the necessarily great resistance encountered in tightening the jaws, the shaft of the lever working them is longer than in the ordinary type of machine.

Beneath the opening formed by the jaws, there is a movable ring worked by the arm **a** (fig. 3) which also has in the centre an aperture **d**; this in its normal position, communicates with the cylindrical space formed by the jaws.

Into this central aperture of the ring open two other holes, made in its thickness. The wine passes through the one, and the gas through the other. Two tubes, each with a tap **b** and **c**, are screwed into these two holes on the outside.

The central part of the ring is provided on its lower surface with a rubber covering against which the edge of the bottle neck presses, this hermetically closes the bottle when the latter is pushed into place by a special eccentric apparatus worked by a lever with rack and pinion o.

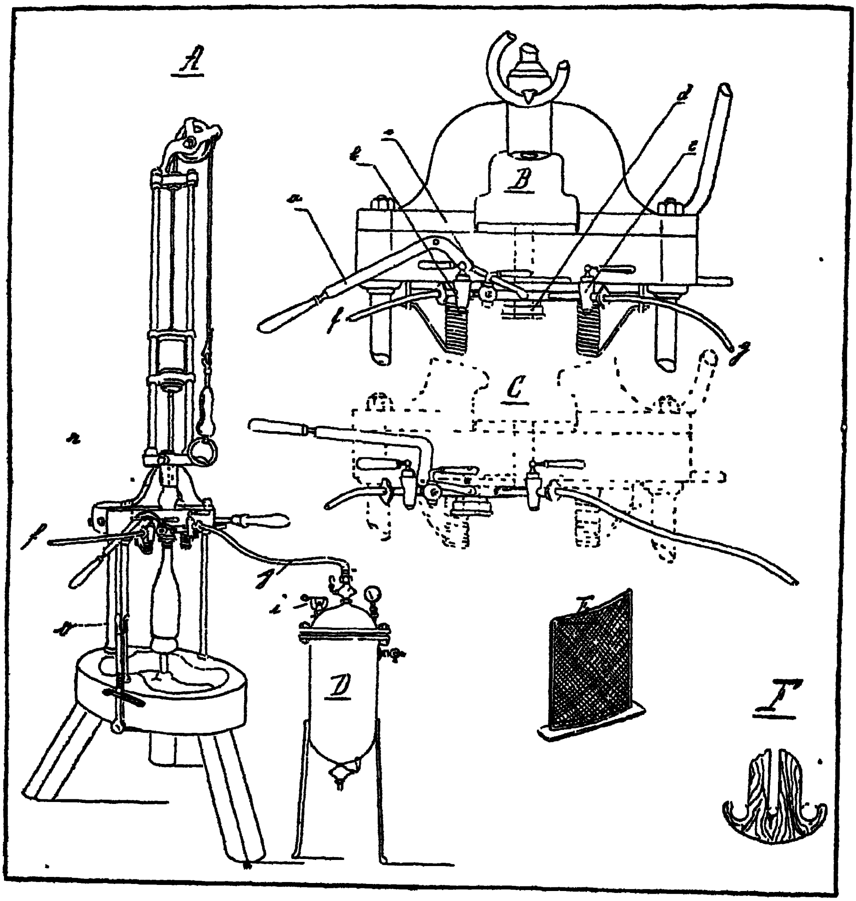

Fig. 3. — MARTINOTTI Apparatus for Bottling Effervescent Wines under Pressure.

The bottling operations are carried out as follows. The ring is placed in the position indicated by figure C (fig 3):

a) The cork is put between the jaws of the bottle-corker and pressed tight. By means of the ram, the cork is pushed in, until it just touches the lower part of the jaws; this is effected by interposing at n a piece of hard wood of the required thickness and shaped like figure F. When this has been done, the lower surface of the cork is wiped over with a sponge.

b) By means of the lever **a**, the ring is pushed into its normal position, as shown in fig. **B**, and by means of the lever **o** working the eccentric, the bottle is pressed against the indiarubber covering.

c) The thickness of the piece of wood at **n** is altered, and with a blow from the rammer, the cork is driven into the aperture of the ring in such a way as not to stop up the 2 holes through which the wine and gas pass. By means of the ring, the bottle thus remains in uninterrupted communication with the receptacles containing the wine and the gas.

d) The screen **E** is put in front of the bottle; the tap is opened through which comes the gas producing the required pressure in the bottle. This gas leaves the reservoir **D**, where it is under a pressure of about $^2/_{10}$ of an atmosphere less than the pressure upon the wine.

e) The wine tap **b** is opened, and the wine, owing to the higher excess can pass out through the safety-valve **i**, which is regulated to allow it to escape (1).

f) When the bottle is full (2), a thinner piece of wood is interposed at *n*, and with a blow from the rammer, the cork is driven into the bottle to the required distance, then after having removed, by means of the lever, the eccentric compressing the bottle and the last shaving of wood regulating the descent of the rammer, the cork is driven entirely through the aperture of the ring by a blow from the rammer, and the bottle is removed in this way, being no longer supported by the spring found at the bottom of all corking-machines of this type.

g) The cork is wired on to the bottle by means of the usual appliances.

How far the cork should be inserted into the neck of the bottle, depends upon whether it is coated with paraffin or not. Paraffined corks must be pushed in further than unparaffined ones, to prevent them from flying before they can be wired down.

To prepare the paraffin, some benzine is taken to which 10 % of paraffin is added and the mixture is warmed until the paraffin melts; the corks are dipped into it, and quickly withdrawn, being then exposed to the air until all the benzine is evaporated.

In order to impart the necessary elasticity to the corks, they are exposed to the action of steam for some time before use. This, together with the paraffin covering them, greatly facilitates the corking operation.

By decreasing the pressure in the vessel **D**, at the right time, it is possible to cork bottles, even if the wine comes from apparatus placed at a lower level than that of the corking-machine.

---

(1) This arrangement prevents the air in the bottle from entering the gas-supplying apparatus, which would interfere with the effervescence and prevent the wine keeping.

(2) Tap **C** is to carry off the wine from the bottles, if they are too full. (*Author's notes*)

[1042]

1043 - **The Suvino Rice Drier** (1). — TARCHETTI, A., in the *Giornale di Risicoltura della R. Stazione sperimentale di Risicoltura e delle coltivazioni irrigue*, Vol XI, No 6, pp. 83-91, figs 6. Vercelli, June 30, 1921.

The author gives a detailed description of the different parts of this apparatus, which works as follows :—

The paddy to be dried is poured into a hopper, whence it is raised by an elevator, and discharged into the drying chamber, where it falls on a sheet-iron apron placed over the drying chamber, and having a slight oscillating motion. The paddy is thus uniformly and automatically distributed in the chamber. It falls from the top of the chamber and finds its way out at the bottom by means of three hoppers with spouts, from which the rice falls upon an oscillating sieve, that frees it from soil, seeds, stones, etc. ; it then passes before the pipe of a fan where it is further cleaned, all the glumes and light substances being removed, and finally falls into the hopper of a second elevator which carries it to the storehouse.

The course of the drying air is as follows :— At the back of the drying-chamber there is a hot-air store, bearing two fans on the bottom and sides ; these suck in the surrounding air at the height of the store, obliging it to pass along the heating pipes into a collecting chamber, and then, after it has passed through all the mass of paddy to be dried, carry it into another chamber, where the pressure is kept below that of the atmosphere by means of an aspirator, which absorbs the damp air and drives it outside.

AGRICULTURAL INDUSTRIES

1044 - **The Industrial Manufacture of Alcohol From Carobs.** — MEZZADROLI, G. (Vice-Direttore della R. Stazione sperimentale di Bieticoltura, Rovigo), in the *Bollettino dell'Associazione Italiana delle Industrie dello zucchero e dell'alcool*, Year XIV, No. 3, pp. 53-61. Bologna, June 1921.

The object of this article is to inform practical distillers how carobs (which are difficult to ferment) should be treated in order to obtain alcohol from them. The author therefore describes the plant and the work done at the distillery of MONACO and son of Catania by G. VINCENTI (engineer) of Rome in collaboration with the author, who attended to the chemical side of the operations.

The carobs are carried by an elevator into a disintegrator with double cones, and provided with knives that cut up the pods, while leaving the seeds intact ; the latter are then separated by a sifter and put into a sack ; the remains of the pods pass into the extracting apparatus. The latter consists of 10 extractors, each containing about 100 hectolitres, and furnished at the bottom with a filter that catches the solid particles, but allows the sweet juice to pass from one receptacle to the other.

---

(1) Constructed by F. SUVINO and Co. at Mortara. For a detailed description of rice-driers see. Ing. V. MARAGHINI, *Gli essiccatoi da riso ed i concorsi internazionali di Vercelli*, Milan, Soc. Ed. Libr. 1914. (*Ed.*)

Each extractor has a juice-heater, and a set of circulation pipes through which, owing to the difference of level, the water and the juice pass from one vessel to another.

From 30 to 40 quintals of the triturated carobs are put into each extractor ; the extraction takes place at from 95°-105° C. As a rule, the operation is carried on, at a high temperature, to 15-20° Brix, which reppresent about 20 % of sugar. An extractor only needs filling every 20-24 hours. The extracted carobs contain scarcely 0.30 % of sugar (their original sugar content was 40 %). The extracted juice passes into 2 measured vessels and thence into 2 other receptacles situated in the highest part of the building. One of these receptacles is provided with means for providing complete aeration and inducing certain oils present in the carobs to rise to the surface ; in the second is effected the slight sulphiting necessary to correct the natural acidity of the pods ; this process also serves to remove the butyric forms, frequently present in carob musts.

From the sulphiting receptacle, the juice descends through a copper refrigerating tube to the fermentation chamber where it reaches 22° C In the fermentation chamber, there are 2 small machines for the preparation of yeast, each with a capacity of 100 litres, 2 copper vessels each holding 10 hectolitres, 3 intermediate vessels of 10 hectolitres each, and 6 large receptacles, each holding 320 hectolitres, in which the actual fermentation process takes place.

In order to start fermentation, a few flasks of must similar to that to be used in the fermentation-chamber are prepared and sown with pure selected cultures of suitable ferments (the author employed his 120-2 and M N.) When the culture has developed well in the balls, some 70 litres of the same must are prepared in the two little yeast receptacles, the ferments on the culture balls are transplanted into this, and left to develop, for which 24 hours is usually enough. On the following day, 9 hectolitres of boiled must cooled down to 30° C. are put into the two receptacles, and sown with the contents of a small vessel, the mass then being aerated with sterilised, or filtered, air. When it has reached 7°-9° Brix, the ferment is allowed to pass from the small receptacles into those of intermediate size, and continually supplied with must out of the extractors. As soon as the intermediate receptacles are also full, the volume is reduced to one half by letting the must at the bottom pass into a large vessel, and the intermediate receptacles are refilled with juice from the extractors.

The rapid growth of the ferment takes place in these intermediate receptacles, for which reason they are well aerated and given plenty of phospho-nitrogenous matter, to which are added special zymogenetic salts for the purpose of keeping the ferment always active and pure. The large receptacles are never aerated, but are supplied with nutrient substances until full, when they are left to themselves. For the complete filling and fermentation of a receptacle, 32-36 hours are normally required. As soon as the fermentation process is finished, the receptacle and its contents are sent to be distilled. The stills used are composed of ordinary BARBET continuous columns and a rectification column.

Industrial distillation yields 5 to 10 %, or an average of 8 % of alcool di testa (product of first distillation); 82 to 92 %, or an average of 87 %, of alcool di buon gusto (product of second distillation); 3 to 8 %, or an average of 5 % of alcool di coda (product of third distillation).

According to the quality of the carobs and their sugar content, 18 to 25 litres of alcohol can be obtained from a quintal of pods. Carobs with a total sugar content of 40 % will yield with proper treatment from 22 to 24 litres of alcohol.

The daily output of the distillery described is 70 hectanhydres with a fermentation chamber a with capacity. of 1800 hectolitres. The seeds are collected (being used abroad for making gum, paints, and a substitute for coffee), as well as tannic acid, the residue (which is dried and employed as a fuel), and carbon dioxide (given off from the fermentation receptacles), which is purified and compressed.

1045 - **Sugar and Alcohol from the Agave: Electrical Process of Juice Clarification.** — DELAFOND, E., in *The Louisiana Planter and Sugar Manufacturer*, Vol. LXVI, No. 25 p. 395. New Orleans, June 18, 1921, and in *Facts About Sugar*, Vol. XII, No. 25, p 491. New York. June 18, 1921.

Sugar of an excellent quality has been produced from the juice of the agave, and DELAFOND who has patented in all the sugar countries in the world, a process of electric treatment for the clarification of the juice of sugar canes, sugar beets and sorghum, etc. has now successfully applied this process to the juice of the agave, and has obtained some very fine sugar perfectly crystallised. Without clarification this juice is not fermentable, and the failure hitherto in the attempt to utilise the by-products of the henequin industry was due to the difficulty in fermentation of the juices. The author, however, expresses the opinion that by the use of the electrical clarification process a great alcohol industry can be established, and as it seems likely that in the future alcohol will be utilised to a large extent as fuel (1), this industry is of increasing importance.

Besides sugar and alcohol, various other useful products can be obtained from the residues now discarded in the process of henequin production among them being potash, phosphoric acid, paper pulp and glue.

1046 - **Contribution to the Study of Grape-Pip Oils.** — ANDRÉ, E., in the *Comptes rendus de l'Académie des Sciences*, Vol. 172, No. 21, pp. 1296-1298. Paris, May 23, 1921.

The data on the composition of grape-pip oil are fairly numerous but they vary so much, as to be almost contradictory. With a view to solving the question, if possible, the author examined 11 different samples of this oil, and obtained the results of which the extremes are given in the following Table. He shows (thereby confirming all the data previously published) that no limit can be fixed for the chemical and physical constants of grape-pip oils. This is not extraordinary, when it is remembered that the varieties of *Vitis vinifera* are very numerous, and have been fixed so long as to render it probable that the oils obtained from their seeds would be very different in character.

---

(1) See *R.* July 1921, No. 764 (*Ed*)

Extreme values of the physical and chemical constants of some samples of grape-pip oils.

Density	0.9103 — 0.9334
Refractive index	1.4708 — 1.4772
Saponification index	171.0 — 191.1
Iodine index (Hanus)	94.3 — 135.0
Saponification index of the acetylated oil	189.7 — 231.8
Acetyl index	13.3 — 49.3

1047 - **Utilisation of the Potato as Stock Feed, Source of Alcohol etc, Manufacture of Dehydrated and Dried Pressed Potatoes, Flour and Starch.** — Gore, H. C. (Bureau of Chemistry, U. S. Dept. of Agriculture), in *State of New Jersey, Department of Agriculture, Bulletin* No 28 (Report of Proceedings of the State Potato Association and the State Alfalfa Association). Trenton, N. J. March 1921.

The necessity of providing some outlet for surplus potatoes during exceptionally favourable seasons, has led to the utilisation of potatoes for various purposes. The author here reports the progress made in the United States in this respect:—

Stock feed. — One of the difficulties of profitable feeding of potatoes is the necessity of providing an adequate supply of sound stock throughout a long period. It now seems probable, however, that this difficulty can be overcome by the practice of ensiling; potato silage is eaten freely by cattle and can be used also for pigs; it appears to be as palatable as the best maize silage.

An experiment was made at the Dairy Farm at Beltsville comparing the gain in weight of 6 cows, 3 fed with potato silage and 3 with maize silage for 30 days, at the end of which time the rations were reversed, allowing 10 days to make the changes and extending the length of the experiment another 30 days. The following table shows the milk and fat produced, feed consumed and the gains in weight:

Manufacture of dehydrated potatoes. — There is at present no wide market for dehydrate potatoes ed (dried) although during the war the use was considerable.

Manufacture of dried pressed potatoes. — The equipment needed for converting the potatoes into dry feed is easily constructed; the washing is done in a continuous paddle machine of the type used in washing potatoes for starch making. from the washer the potatoes are ground until liquefied and passed into a stock box, provided with a gate valve, and then passed into the hydraulic press as needed. About 1 ton of ground potato is pressed at one time, the process taking from 15 to 20 minutes. The yield of dried pressed potato is about 20 % of the weight of potatoes.

		Produce		Feed consumed				Gain in weight
		Milk lb	Fat lb	Grain lb	Hay lb	Potato lb	Maize silage lb	lb
Maize silage groups	First 30 days	1 719.3	79.95	780	540	—	2 700	60
	Second 30 days	1 611.5	83.62	810	540	—	3 000	78
	Total	**3 330.8**	**163.57**	**1 590**	**1 080**	—	**5 700**	**138**
Potato silage groups	First 30 days	1 546.0	77.64	808	540	3 000	—	86
	Second 30 days	1 732.2	80 09	780	540	2 700	—	71
	Total	**3 269.2**	**157.73**	**1 588**	**1 080**	2 700	—	**157**

MANUFACTURE OF ALCOHOL. — The work carried on under the direction of WILEY (*Bureau of Chemistry*) U. S.), started in 1910, permits the following estimates to be made as to the cost of alcohol manufacture in small plants: Approximately 0.66 gall. of 180 proof alcohol can be produced from 1 bus. of potatoes of 14 % starch content. The potatoes used daily will weigh about 8000 lb. to obtain 100 gall. per day; and this necessitates the mashing of 320 lb. of malt.

A summary of the cost per gall. of alcohol (180 proof.) is given as follows (in dollars): Raw material 0.279, investment 0.124, operating 0.159. Total $0.562.

There will be about 1000 gall. of spent mash worth $0.04 per bus. of original potatoes, or $5.33 or 0.053 per gall. of alcohol produced; this makes on an average the net cost per gall. $0.509.

This may be compared with the cost of manufacturing alcohol from potatoes in a plant of German manufacture, in which alcohol of 180 proof is produced at the rate of 263 gall. per day, and the total cost amounts to $0.478 (i. e. the net cost per gall. $0.425).

Owing to present conditions these figures would now be considerably increased, and whether or not the production cost can be decreased still remains an open question for further experimentation.

Potato flour. — The most important process developed is a steam drying method in which the potatoes are converted into potato flakes which are later milled into flour.

The raw potatoes are washed in a machine commonly used in distilleries or starch factories and then conveyed by an elevator to a steamer erected over the drying apparatus, where they are cooked by means of low pressure steam. After steaming, the potatoes are allowed to fall by gravity into hoppers and through the emasculators, where they are reduced to pulp, and in this shape are forced on to the drying drum. These drums turn in opposite directions at 5 revolutions per minute. The heat dries off the moisture of the pulp and leaves a firm mass that is scraped off by means of knives set parallel to the main axes of the drums. The dried mass falls into a spiral transformer fitted with revolving arms where it is broken into flakes and conveyed to the pracking room. Numerous factories are now established in various American States, and the capacity of a single unit plant is about 8000 lb. per day. The flour is used principally to improve the quality of bread, but has other baking uses. There is, however, still much to be done in developing this industry. The price at present is about 9 cents per lb. in wholesale quantities. The author considers that this flour does not possess the same glutinous quality as rye and wheat flour, but has peculiar properties as yeast food and a good flavour.

Potato starch. — This is more extensively manufactured than any other potato product. All grades of potatoes have been found to yield starch of good quality. The author describes the methods employed in the American factories including the processes of washing, grinding, sieving, settling and washing the starch, the treatment of "brown starch" (soft layer of sticky brownish sludge 2 to 6 in., in thickness, consisting of fine particles of cell-wall tissue from the potatoes and other impurities and a certain quantity of starch), and finally, the drying and bagging. The average capacity of the starch factory with its dryer is 4 tons of dry starch per day.

The author considers the "JONES" factory at Caiibon, Maine, as an example of the best type of the more modern Maine potato starch factories. It differs from the earlier types in the arrangement and operation of the settling and washing tanks.

As regards the value of potato starch compared with other starches, the author states that it is more valuable than maize and cassava starch, but somewhat inferior to wheat starch. The actual starch content amounts on an average to 15 %.

It has, however, value in the finishing and weaving of textiles which no other product possesses, especially fine grade cotton goods. It is also the source of the best grade of white dextrin used in making finer grades of library paste.

1048 - **Experiments in Drying Green Peas.** — MESSINA, M., in the *Rivista di Agricoltura*, Vol. XXVI, No. 27, pp. 384-386; No. 28, pp 396-398. Parma, July 8 and 15, 1921.

Peas that have been dried when quite ripe, that is to say, when they have turned yellow, are little in demand, in the first place, because they are indigestible, and in the second, because they are often attacked by *Bruchus pisi*.

If, however, peas are dried while still green and immature, they are most digestible and nutritious, and still retain to a great extent their original flavour and tenderness. According to analyses made by PAYEN, the percentage composition of dried yellow and green peas respectively is as follows:— Starch, dextrine and sugars 58.7 and 53.5 %; nitrogenous matter 23.8 and 25.4 %; fats 2.1 and 2.0 %, crude protein 3.5 and 1.9 %; salts 2.1 and 2.5 %; hygroscopic water 8.3 and 9.7 %. For removing the peas from the pods, the author recommends the Navarro sheller with which he obtained the following returns:— From 100 kg. of unripe pods, 22-24 kg. of peas; from 100 kg. of completely ripe pods, 30-35 kg. of peas, the general average being about 30 %.

For separating peas of different sizes, the Navarro sorter gives good results, dividing the peas into 6 classes indicated by the figures 0-5; these figures give the quality;— 0-1 extra-fine; 2 very fine; 3 fine; 4 average No. 1; 5 average No. 2. The returns obtained by the author for these different qualities were: 10, 20, 40, 20, and 10 % respectively.

The peas are then scalded by immersion for 3to·4 minutes in boiling water containing 1 % of common salt, after which they are dried in the air, previous to bring put into the drier. A good apparatus for drying peas is the "Ryder" made by Messrs P. H. MAYFARTH and Co. In his experiments the author used an American drier, consisting of a wooden chamber 2 m. in length, and inclined at an angle of about 20°. In this chamber circulates the air heated in a small oven attached to the apparatus. There is an ingenious arrangement for regulating the heat of the current of air. Care must be taken to dry the peas slowly at first, and to increase desiccation gradually. The author obtained the best results by using the following temperatures; 35° C. for the first 3 hours; 40° C from the 3rd to 6th hour; 45° C from the 6th to the 10th, 50° C from the 10th to the 14th. It takes from 12 to 14 hours, according to their size, to dry the peas.

As much as 25 kg. of dried peas can sometimes be obtained from 100 kg. of fresh ones, but the usual quantity is between 20 and 22 kg.

1049 - **Larch (Venice) Turpentine from Western Larch (*Larix Occidentalis*) in the United States.** — MAHOOD, S. A. (Chemist in Forest Products), in *Journal of Forestry*, Vol. XIX, No. 3, pp. 271-282, tables 8. Washington, D. C., March 1921.

Oleoresin or Venetian turpentine has been obtained for some time past from bore-holes made in the trunk of the European larch (*Larix decidua* Mill. (= *L. europea* De Candolle) which is grown for resin producing purposes in the Tyrol, in Piedmont, and in France in the vicinity of Briançon.

Owing to the fact that during the war importation of this product States into the United practically ceased, experiments were begun by the Forest Service in 1917, to determine what were the possibilities of obtaining a similar product from western larch (*L. occidentalis*) which occurs in large stands in the Northwest. Holes were made in the trees and plugged with dry larch to prevent loss by evaporation, and the bores were made "breast high". On 3 areas on the National Forests in Montana, trees were tapped between May 22 and June 12, and collections of oleoresin were made between mid October and mid November. Single taps were made on 30 trees in each area and double taps on 20. The trees with double taps yielded on the average nearly 3 times as much oleoresin as compared with the others.

Out of the 150 trees tapped, the total number of productive taps was in 1917 and 1918 respectively, 77 and 111, and the average per tap (in ounces), 1.8 and 0.8. The average for productive taps in ounces was respectively 2 6 and 1.4.

The yields were smaller than it was hoped they would be, but it is possible that by boring the holes near the ground, selecting the most favourably located stands, and continuing the observations over a longer period, the yield of oleoresin could be materially increased. Further experiments along these lines are being contemplated.

The material sent to the Laboratory consisted of 2 distinct products, one a thin liquid and the other a thick gum. The former is apparently the sap of the tree, has a specific gravity of 1.110 at 20° C. and was shown to contain 22.1 % of ε-galactan (*Journal of Industrial and Engineering Chemistry*, Vol. 8, p. 34). This gave crystals that melted at 212° when oxidised with nitric acid. The oleoresin has the consistency of honey, is light amber in colour, slightly bitter in taste and has an agreeable terebinthic odour. The Tables show physical constants and the results of steam distillation after the material was strained through cheese cloth. The averages obtained were as follows: specific gravity 1.0054, optical rotation (20 % alcoholic solution) 24.78, volatile oil 15.8 %, resin 81.2 % moisture 2.8 %, trash 0.2 %.

The average chemical constants on the same three samples were obtained as follows: acid number 90 2, saponification number 97.6, ester number 6.4.

The oleoresin was found to contain approximately 16 % of a volatile oil consisting chiefly of α-pinene together with smaller amounts of β-pinene and α-limonene. The non-volatile portion is a resin possessing acid properties but yielding no crystalline product by the usual methods of crystallisation.

Oleoresin did not conform to some of the accepted tests for Venice turpentine. The acid value is high and the ester low as compared with the commercial standard. However, the values agree very well with the results obtained by BECKERTS and BRUCHE (1) and more nearly approach the values for the oleoresin from *L. decidua* than do the results obtained by SCHORGER on Douglas fir turpentine (Oregon fir balsam) (*Journal of American Chemical Society*, Vol. 39 (1917) p. 1040).

Unlike that from *L. decidua*, oleoresin from *L. occidentalis* does not dissolve completely in 3 pts. of 80 % alcohol, nor does its alcoholic solution remain clear when made alkaline with 10 % potassium hydroxide. On the other hand, both oleoresins possess a slight greenish fluorescence in reflected light, and neither solidifies with $^1/_{16}$ its weight of magnesium oxide.

Two properties make Venice turpentine of value for particular purposes: it does not readily become hard on exposure, and after standing, crystals do not form in it. The oleoresin from western larch possesses these properties, and tests made by a commercial firm indicate that western larch turpentine is a satisfactory material for all those industrial purposes for which Venice turpentine is ordinarily used.

---

(1) Analysis of Resins, Balsams and Gum Resins DIETERICH (1901) (*Author's Note*)

1050 - **Pasteurisation of Milk in Bottles and Jars** (1). — KUFFERATH, H., in the *Annales de Gembloux*, Year XXVII, Part. 6, pp. 196-202. Brussels, June 1921.

In the course of tests carried out at the Intercommunal Laboratory at Brussels for the purpose of controlling the milk supplied by the Intercommunal Dairies, it was found to be quite impossible to pasteurise milk completely with the usual type of continual pasteurisers (the " holding process "), under normal industrial conditions, and further that from the hygienic standpoint, the results obtained were disastrous. Thus, from 1915 to 1918, 22 samples out of 29 examined were declared to be bad, and not to answer to the description of pasteurised milk ; only 4 samples were good, and 3 were fair. On an average these milks contained 349 379 bacteria per cc. and in 10 cases (or 34.4 %), coli bacilli were discovered. Until the end of 1919, out of 7 samples of pasteurised milk 1 would be found satisfactory and 6 unsatisfactory ; 4 times coli bacilli were present, and the average number of micro-organisms was 910 693.

On testing the milk on the market, this was also proved to be insufficiently pasteurised.

Subsequently, the author together with M. BOCK, carried out some pasteurisation experiments at the Boitsfort dairy. They used simplified apparatus consisting of a steam generator, and a small metal boiler heated over an open fire ; the steam was conducted by a tube to the pasteurisers, properly so-called, which were placed in another room. These consisted of simple vessels of galvanised iron with an internal diameter of about 1 metre, and a depth of 70 cm., having at the bottom, an opening for the admission of the steam, and also a waste-pipe. The experimental data that follow refer to the heating of milk in bottles and jars.

It was found that in order for the pasteurising process to be carried out satisfactorily, heating, when bottles are used, must be continued from $1\frac{1}{2}$ to $1\,{}^{3}/_{4}$ hours, counting from the first admission of the steam to the end of pasteurisation. With jars, 50 to 60 minutes is reckoned to be sufficient. The 19 samples examined all proved satisfactory, the average number of micro-organisms being 472 per cc. In no case were coli bacilli present ; the only micro-organisms discovered being spore-forming bacteria.

1051 - **Storage of Vegetables** (1). — DIFFLOTH, P., in *La Vie Agricole et Rurale* (1) Year 10, Vol. XVIII, No. 19, pp. 293-297, figs 7., bibliogr. of 4 works. Paris, May 7, 1921.

Description of the various types of cellars, caves and silos, etc., which may be employed advantageously for vegetable storage purposes, and

---

(2) See : *R.* Oct. 1916, No. 1120. — For pasteurisation in general, see also *R.* 1916, Jan. No 110 ; April, No. 449 ; *R.* Mar. 1917, No. 283 ; *R.* May, 1918, No. 579 and Dec. 1918 No. 1403. (*Ed.*)

(1) Number devoted entirely to Horticulture, containing in addition to the article in question, other articles of interest concerning fruit and flowers : P. HOC, Le nitrate de soude et les cultures maraîchères. — P. DUBOIS, Trufficulture. — A. TRUELLE, La bonne tenue du fruitier. — A. ROLET, Le changement de coloris de fleurs par la culture. — P. DUBOIS, Notes de floriculture. (*Ed.*)

the treatment recommended for beans, peas, turnips, carrots, celery, potatoes, sweet potatoes, Jerusalem artichokes, and salsafy.

Cellars. — Emphasis is laid on the need of adequate ventilation, and the author suggests the placing of a bent pipe fixed into one of the windows or air-holes. Care should also be taken to prevent contact between vegetables stored and soil, in order to avoid maggot attack, etc.

Outside cellars are preferable from the point of view of temperature and air regulation; it is advised to keep the vegetables entirely apart from the fruit when in storage.

The use of cement is considered distinctly advantageous from the point of view of protection, impermeability and insect attacks. The size of a cellar lined with cement should not exceed 9.8 ft. or 11.4 ft.

Only where the weather is very severe is it necessary to construct subterranean cellars, but where mild, protection with turf or straw is sufficient, placed on planks supported by a double line of stakes. If it is fairly cold and damp it is advised to adopt the aforesaid method, but making the partition between 9.8 to 11.7 in. thick and filling the intervening space with sawdust, hay or turf.

Another type of cellar found to be useful is constructed on the semi-subterranean system with the walls only reaching up to the ground level, and only the roof being above ground.

Silos. — Careful drainage essential; the vegetables should be placed in regular layers on a bed of straw or rushes and covered with similar materials and a final outer covering of 2 to 2 $^3/_4$. in depth of soil. If the weather is exceptionally cold, a further layer of soil, straw, etc. can be added. A good thickness of straw will ensure aeration, and if necessary a triangular arrangement of wood can be made.

For winter vegetables the author advises the piling up of several species of vegetable in the same silo in order to avoid the uncovering of each silo every time in order to obtain the required vegetable. When one pile is finished, the next may be resorted to, and by following this method the constant repeated repiling of the various silos is rendered unnecessary

TREATMENT OF VARIOUS VEGETABLES. — 1. *Beans and peas.* — For runner beans and peas, the pods should be collected and placed in the sun until completely dry. Dwarf beans can be pulled up in clumps when the majority of pods have matured, these can be dried after pulling off the leaves, and then crushed with a hand beater.

2. *Beets.* — All the forms of storage pre-described are suitable to beets, but if possible the piling up in small heaps by the wall of the storehouse is preferable.

3. *Cabbages.* — Similar treatment to beets; a further method employed is the pulling up the whole plant with its roots and placing in a silo roots upward in rows of three, or placing in trenches (9.8 to 12 in. in depth) side by side, covering the roots with soil or sand; above the trench, stakes are put, 2 ft. high with soil piled up at the sides; planks are then

placed on top and covered off with a layer of straw, leaves or compost sufficient to protect the cabbages from frost.

If the tops are cut as required, leaving the roots in place, the old stumps will give new shoots the following spring which will serve as an excellent green vegetable and at a time when other fresh vegetables are rare.

It is not considered advisable to store in the house cellar owing to the strong odour which invariably accompanies storage.

Carrots. — All forms of storage are possible : the silo method is, however, the best, and as they are not easily damaged by frost, they need only be lightly covered.

Celery. — This can be preserved in its original position, and when the cold weather is approaching, it is sufficient to earth up round the plant and if necessary to add a layer of straw. Another method adopted is the digging of a trench 9.8 to 11.7 in. wide and 2 ft. deep ; the bottom of the trench should be well broken up and after earthing up the celery planted out in rows therein and watering once or twice, the trench is left open until the upper leaves start to yellow ; no watering should be done after this and when the first frosts are likely to start, it is sufficient to cover, adopting the plank system, with straw, etc. If the celery is, on the other hand, stored in a cellar etc., care should be taken to cover as much as possible with fine soil or sand.

Onions. — Onions, shallots and garlic should never be stored until quite mature and absolutely dry; sacks, boxes, barrels, etc. are suitable.

Potatoes. — Apart from the generally recognised forms of storage for potatoes, a covering of straw or compost over the piles is considered advisable. The author recommends silo storage in preference to cellar.

Sweet potatoes and Jerusalem artichokes. — Dry for some days before storing ; a dry place and a medium temperature is preferred.

Salsafy. — Similar methods as employed for beets and carrots.

Turnips. — Turnips are resistant to frost but spoilt by alternations of frost and thaw: they can be well preserved either in hemps or silos. They should not be stored in the house cellar on account of their strong odour.

1052 - **Freezing Injury to Potatoes when Undercooled.** — WRIGHT, R. C., and TAYLOR, G. F. (Office of Horticultural and Pomological Investigation), in *United States Department of Agriculture, Bulletin* No. 916, tables 8, figs. 1, pl 1, bibliogr. of 9 works. Washington, D. C., June 13, 1921.

There are 2 general classes of frost injured potatoes, those frozen solid and liable to collapse immediately on thawing, and those that show evidence of injury only on being cut open a few hours after being warmed. The first class is easily identified by the soft, wet condition that develops on thawing and is due to potatoes being subjected to freezing at very low temperatures or to prolonged exposure at higher freezing temperatures. The second class is not apparent on superficial examination, and is due to exposure to temperatures just below freezing point or to a very low temperature for a short time. If after the potato has been thawed a few hours, it is cut open, evidences of this type of freezing injury are apparent by the presence of vascular discoloration of 3 types or a combination of any of the three.

In order to apply to the handling of potatoes the knowledge of the process of undercooling and freezing already gained, a series of experiments was conducted at the Arlington cold storage plant of the Bureau of Plant Industry, U. S. Seven standard varieties of potatoes, all true to name and grown under the same conditions at the Aroostook Farm of the Maine Agricultural Experiment Station, were used; namely: Triumph, Irish Cobbler, Spaulding No. 4, American Giant, Rural New Yorker, Russet Rural and Green Mountain. They were all kept in a temperature of 40° F previous to experimental use.

At the conclusion of each test, the potatoes were removed and held at ordinary room temperature for about 24 hours before being cut longitudinally for exanimation.

Attention is called to the fact that potatoes when undercooled are liable to freeze when jarred. This is important both from the cultivators and shippers' point of view. Experiments were conducted to determine the amount and character of the disturbance necessary to cause freezing when different varieties of potatoes are held at temperatures between 28° and 25° F. The same 7 varieties were employed.

When undercooled at 28° F. dropping from a height of 2 ft. caused potatoes to bruise badly. and to show extensive freezing injury. When dropped 1 ft. they did not bruise, but showed frost injury. When dropped 6,4 or 2 in. once, no injury resulted, but when dropped 6 times frost injury followed. When wet, injury also resulted. Potatoes supporting a 100 lb. weight were not injured (a mixed lot of 12 potatoes was held at 28° F. for 72 hours while supporting a 100 lb. bag of sand no injury was apparent).

When undercooled at 28° F. and rolled across the floor for a distance of about 50 ft. in bags, freezing injury resulted; undercooled at 28° F and dropped 6,4 and 2 in. once showed signs of frosts injury After freezing commenced it was evidently progressive; the amount of injury caused within a stated time seemed to depend upon the surrounding temperature.

Immediately after inoculation the temperature of the potato rose to its true freezing point and remained for a varying length of time, depending upon the surrounding temperature.

Some varieties are apparently inoculated more easily than others, even though their freezing point is higher, Spaulding No. 4 appeared to be less injured in each case than the other varieties; Rural New Yorker and Irish Cobbler were more subject to injury.

1053 - **Storing Sweet Potatoes in Trinidad.** — BRUNTON, L. A (Assistant Superintendent, St. Augustine Experiment Station, Trinidad), in *Bulletin of the Department of Agriculture, Trinidad and Tobago*, Vol. XIX, Pt. 2, p 88. Port-of-Spain, 1921.

Results of an experiment in storing sweet potatoes made last year at the Experiment Station, St. Augustine, Trinidad.

Two lots of potatoes, one of 400 lb. and one of 200 lb., were stored separately on March 6 and 11 respectively, directly after digging.

A thick bedding of thoroughly dry banana leaves, to a depth of 6 in., was spread on a flat level piece of ground; upon this the potatoes were heaped in the form of a cone, and covered with a layer of dried banana leaves 6 in. thick; finally the heap was covered with 4 in. of earth well beaten down and smoothed over. To ensure thorough drainage a trench was dug around the heap. For the purpose of ventilation a bamboo pipe was inserted in each heap to allow the escape of heated air during the first 14 days, the projecting end being fitted with a plug.

A month later both heaps were opened, but the 400 lb. layer shewed half the contents rotted (the only sound potatoes were found on the outside of the heap and these were taken and re-treated as described above, but with similar results). On the other hand, the potatoes in the 200 lb. heap opened on the same dates, were with few exceptions found to be in sound condition, and when re-opened a month later on June 12 were still in good condition, and on July 8, four months after storing, although some root growth had taken place, they were still perfectly sound, palatable, and cooked dry and floury and with an excellent flavour. The loss in weight due to drying and the few which had rotted amounted to 40% (The rainfall during this experiment did not exceed 6.42 in.).

It is therefore apparent that sweet potatoes can be stored for 4 months, *provided the heaps are moderate in size*, and the contents are kept from direct contact with the soil by a liberal covering of dry trash.

An experiment on a larger scale is in progress this year (1921).

1054 – **Some Changes in Florida Grapefruit in Storage.** – HAWKINS, L. A., and MAGNESS, J. R. (Scientific Assistant, Office of Horticultural and Pomological Investigations, Bureau of Plant Industry U. S. Dept. of Agriculture), in *Journal of Agricultural Research*, Vol XX, No. 5. tables 7, Washington, D. C, Dec. 1, 1920.

The present investigation was taken up to determine the effect of storage at various temperatures on the fruit and particularly on the sugar and acid content of the pulp, seeing that these substances constitute the major portion of the dry matter of the pulp or interior of the fruit excluding the seeds.

In the 1917-18 season experiments were made with Silver Cluster fruit part of which was stored at 86° F. and part in a commercial cold storage at 32°. The juice alone was analysed but comparative percentages of peel and pulp were determined in some cases.

In 1918-19, the Davis and "Common Florida" grapefruit varieties were employed, and cold storage temperature of 36°, 36° and 40° F. were used as well as common storage at a mean temperature of about 50° (with probable 5° fluctuations) and 2 warm storage temperatures, about 70° and 86° respectively. In most cases the fruit was weighed when placed in storage in order to determine the shrinkage.

From the results obtained it may be concluded: 1) There is a general decrease in titrable acids during storage e. g. fruit placed in storage contained on an average 1.02 to 1.28 % acids (as citric), after 60 to 62 days 0.92 to 0.96 %, after 178 to 179 days, 0.80 to 0.92 %. These were at varying temperatures of 32°, 36° and 40° F. In warm storage there appeared to be scarcely any decrease in acidity in the fruit stored in cans, i. e. unventilated packages, either at 70° F. or at 86° F. after 50 to 86 days storage.

2) There is an apparent increase in sugar content in cold storage, calculated to percentage of pulp, which seems to be due to loss of water from the fruit; the sucrose content, however, remains about the same during storage. Apparently the breaking down of the sucrose keeps on a par with the shrinkage of the fruit. The increase in total sugars, as the season advances, may be attributed to an increase in free-reducing substances. When placed in storage the sugar content averaged 4.33 to 8.96 %, and after 178 to 179 days, 4.85 to 9.84 % (temperatures as above). In warm storage it seemed probable that in these experiments there was a decrease in the sugar while the sugar content of fruit stored in unventilated packages showed always a decrease in % of total sugars present, while in ventilated storage the increase in sugar content is in no case more than sufficient to account for the probable shrinkage of the pulp.

3) Dry matter increases during storage. This is probably due to the loss of water from the fruit as well as to losses from respiratory activities, both of which are included in shrinkage.

4) Shrinkage of the fruit increases with the length of time the fruit remains in storage and is as a general rule from 5 to 8 % in cold storage to about 23 % in warm, ventilated storage.

5) Decrease in thickness of peel during cold storage is about 30 %, due probably to the loss of water; there was also a relative thinning of the peel during warm storage. An undesirable feature of cold storage is the breaking down or pitting of the peel at the temperature of 40° F. or lower; the sunken portions may coalesce making a large sunken area of dark-brown tissue, which, however, does not extend into the pulp as the flavour is unaffected; the fruit kept in a temperature of 40° was that most seriously affected, — it was less marked in 36° storage and almost unnoticeable at 32° F.

6) The flavour of the fruit improves in cold storage.

7) Fruit does not deteriorate rapidly after removal from cold storage.

8) The best storage temperature seems to be 32° F.

1055 - **Spontaneous Combustion in a Heap of Sacks.** — MEZZADROLI, G., in *L'Italia vinicola e agraria*, Vol. XI, No. 29, p. 452. Casalmonferrato, July 17, 1921.

Spontaneous combustion is known to take place in hay (1), in grass if made into heaps while still damp and in pulp of sugar factories, but for sacks thus to catch fire is a rarer occurrence.

The causes determining this combustion are the usual ones, viz., the renewed activity of the dormant enzymatic principles in the interior of the mass or heap, owing to the latter having attained a certain degree of humidity, or else the awakening of certain special micro-organisms.

---

(1) See *R.* April 1921, No. 440. (*Ed.*)

The consequences of these changes are the slow rise in internal temperature of the mass, the successive growth of different microflora and a continually higher optimum temperature, until the flameless combustion of the pile of sacks is produced. The final products of this process are :— Charcoal, carbon dioxide, acetic acid, formic acid, small amounts of butyric acid, and several kinds of gas

The author records a similar occurrence that took place in a fruit distillery.

As the fruit was emptied out of the sacks, the latter were piled up just as they were, dirty and impregnated with sugary substances which would have been removed by washing, a process carried out as a rule regularly every 10 or 15 days, but which had been put off owing to press of work, so that a large heap of about 1 500 sacks had been left in a corner of the room for 20 to 35 days. When were taken the sacks for washing, it was found that the heap had become as hard as stone and black like coal. The carbonised mass which was solid and stratified, and contained the remains of the textile fibres, emitted a pungent odour ; it was so hard, that it had to be broken with a pick-axe.

Nothing remained of the sacks, but some pieces of material on the outside of the pile; these were burnt, or so much charred, as to fall to pieces when touched ; all they were fit for was to burn under the boilers.

A like misfortune occurred in a store of dried pulp at Cavanella Po (Province of Rovigo), and in Sicily where a heap of carobs was destroyed. Spontaneous combustion is invariably due to incomplete drying of part or all of the material in the heap.

PLANT DISEASES

DISEASES NOT DUE TO PARASITES OR OF UNKNOWN ORIGIN.

1056 – **"Red Leaf" of Cotton, Prevalent where Potash is Lacking in St. Vincent, West Indies.** — See No. 1004 of this *Review*.

1057 – **The Wilt Disease of Java Indigo (*Indigofera arrecta* Hochst) in Bihar, India** (1). — HOWARD A., and HOWARD, G. L. C. (Imperial Economic Botanists) with the assistance of CHOWDRAY RAM DHAN SINGH and MAULVI ABDUR RAHMAN KHAN, in *Memoirs of the Department of Agriculture in India, Botanical Series*, Vol. XI, No. 1, Pt. II, pp. 1-26, figs. 5, pl. IV, Calcutta, Sept. 1920.

When first introduced into Bihar from Java in 1898, *Indigofera arrecta* Hochst. did exceedingly well, yielding heavy crops of leaf, rich in indican, as well as abundant seed. After some years, however, the plant began to show increasing signs of want of vigour and finally began to die of wilt during the second half of the rainy season; at the same time the yield of seed diminished. The wilt usually makes its appearance after the first cut during July and August, the severity of the attack depending on the season. At first there is a slowing down of growth, and the leaves become folded longitudinally and assume a yellowish green slaty colour. Leaf-fall is then rapid until only a tuft of stunted foliage is left at the tips of the branches followed by a gradual dying off of the plant, one branch at a time.

The investigations on the agricultural and botanical aspects of the indigo industry were transfered from Sirsiah in 1913 to the Botanical Section of the Agricultural Research Institute at Pusa, and attention has been devoted to the causes of indigo wilt and to its prevention in view of the fact that many planters have been obliged to abandon the cultivation of indigo, while others have considerably restricted the area under this species owing to the damage caused by wilt.

A brief reference is first made by the authors to the chief factors underlying the cultivation of Java indigo in Bihar as regards soil, and rainfall.

As regards the actual cause of wilt, since the last publication on the subject (2) new investigations have been made and the former conclusions have been confirmed in all respects. When the roots and nodules of the indigo plant have suffered extensive damage, wilt invariably results from any cause which interferes with normal root regeneration. The chief source of damage to the active roots and nodules arises from the complete cutting back of the plant, which results in the destruction of practically all the fine roots and nodules. It is important, therefore, to understand fully the factors concerned in root regeneration, and the results obtained by following the root development throughout the year have proved of the very greatest value in the elucidation of this interesting problem. The root systems of numerous healthy and wilted plants have been compared in detail, the occurrence of wilt in Bihar has been studied under various conditions extending over many years, actual cases of wilt having been produced artificially in 5 different ways, while many examples of recovery have been closely examined. The conclusions arrived at, as a result of these experiments and observations, have been confirmed by a study of the behaviour of other crops during the rains at Pusa, and also by the growth of indigo on soils differing widely as regards aeration, in other parts of India: —

---

(1) See *R.* July 1914, No 128; *R.* Feb. 1917, No. 136. (*Ed*).

(2) See *R.* Feb. 1917, No. 136. (*Ed.*)

1) Early bush types in which all the laterals arise at right-angles and are concentrated near the surface are the least affected by wilt;

2) Deep rooting types such as (*a*) types with a vertical habit in which nearly all the laterals are concentrated near the surface but all point downwards; (*b*) late bushy forms with a development of lateral roots from the surface to far down the main root; (*c*) late types of vertical habit with lateral roots pointing downwards arising at regular intervals down the long main root; (*d*) types with hardly any side branches but a deep tap root; these are all the types most affected.

In 1919, every case of wilt examined in detail during the monsoon was found to be associated with deep rooting, while the healthy plants were all found to be surface-rooted.

The most striking cases of recovery from severe attacks of wilt occurred in the lysimeter experiments of 1918, when plants exceedingly badly wilted, completely recovered in March 1919.

Confirmatory evidence has been obtained with *Hibiscus cannabinus* L., *H. Sabdariffa* L and *Crotalaria juncea* L. Only the surface rooting species thrived in each case during the monsoons and if waterlogged.

The stopping of selection, the mixing of kinds which is such a characteristic of native agriculture and the resulting crossing with types which do not suit Bihar, soon completely altered the botanical composition of the crop and rendered it unsuitable for growth under monsoon conditions. Indigo wilt is, therefore, another example of degeneration through vicinism.

A considerable amount of selection work has now been done on the ordinary indigo crop (1) and on the samples obtained from Java, and several of these selections have already been tested on an estate scale. Seeing that wilt has arisen from unrestricted natural cross fertilisation, the problem is now to recover the original type which suited Bihar conditions and to maintain it by continuous selection.

[1057]

DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS.

1058 - The Decomposition of Copper Fungicides on the Surface of Vine Leaves. —

CERASOLI, E, in the *Rivista di Patologia vegetale*, Year XI, Nos. 5-6, pp. 70-72. Pavia, August 1, 1921.

Experiments have been made to determine the comparative efficacy of Bordeaux mixture, and "Bordeaux powder," a preparation with a copper-sulphate and lime basis recently put on the market as a substitute for the ordinary copper-lime mixture used to control vine mildew.

From the results of these experiments, the author is inclined to believe, that owing to atmospheric agency, and especially to the carbon dioxide present in the air, the copper compounds in mixtures sprayed on the leaves tend to become transformed into bicarbonates of copper with the subsequent production of colloidal solutions of hydrate of copper.

Perhaps after a given time, and under favourable condition the bicarbonates and colloidal solutions of copper hydrate, after having attained a certain chemical equilibrium, give rise to carbonates of copper of a different "physical character" from that of ordinary carbonates, inasmuch as they are not affected by the carbon dioxide of the air; in which case, the colloidal solution of copper hydrate, which should prevent the development of the parasite, would not again be formed.

By studying the activity of the copper in Bordeaux mixture and "Bordeaux powder," the author has been able to determine that the leaves of vines suffering from mildew have an acid reaction. He carried out his experiment as follows:— choosing some leaves from vines that were respectively healthy, very slightly attacked by the parasite, completely withered, or still covered with the characteristic white powdery deposit, he immersed samples of each set of leaves in four glasses of distilled water, taking care that the blade alone was in contact with the liquid. After some days of exposure to the air, it was seen that only the glass of distilled water containing the healthy leaves gave a neutral reaction. The reaction of the water in the other glasses was acid, the acidity being more marked for leaves covered with white "mildew," and less for both the other samples.

In conclusion, the author thinks that the decomposition of the copper salts he studied is to be attributed to very feeble acids, or acid salts, excreted by the fungus during its passage into the leaves of the vine. Such pathological acidity would easily react upon the colloidal hydrates of copper, (but not upon the copper carbonates formed in the above mentioned manner), thus giving rise to the copper ions upon the presence of which the anticryptogamic action is supposed chiefly to depend. When these acid substances fail to find copper in a colloidal condition on the leaves, they produce such serious functional disturbances and changes, that the physiological equilibrium of the plant's economy is destroyed, and this occasions the death of the leaf or of the entire vine, that has been attacked. The author suggests that this is possibly the reason why the leaves should have at their disposal a sufficient reserve supply of efficacious copper, that is to say, copper in the colloidal state, before the spores of the fungus even begin to germinate.

1059 - **Wheat Downy Mildew (*Sclerospora macrospora* Sacc.) in Tennessee and Kentucky, U. S.** (1). — WESTON, W. H. Jr., in *United States Department of Agriculture, Department Circular* 186, pp. 1-6, Washington, D. C., June 1921.

Wheat downy mildew (*Sclerospora macrospora* Sacc) which although widely spread in Europe, especially in Italy (2) has hitherto been unknown in the United States (3) but has recently been found in Tennessee (Jackson County and Obion County) and in Kentucky (Fulton County). It seems probable that it will be found in the adjacent Illinois and possibly also in Arkansas and Missouri. In addition, diseased specimens in the pathologic herbarium at the California Agricultural Experiment Station show that the downy mildew occurred on wheat in Kings County Calif. in May 1919.

A preliminary study in Tennessee and Kentucky has shown that the disease is restricted almost entirely to low-lying, poorly drained fields in which the young seedlings of winter wheat have been subjected to excessive moisture. In such localities *Sc. macrospora* occurs especially along depressions where water has stood, whilst few if any cases are found on higher land in the same field.

The general indications from field conditions in the infected regions are that the disease is not of sudden nor recent appearance, but has been in existence for many years.

The disease is found not only on the three or four varieties of soft " Red Winter " wheat grown in these localities, but also on *Bromus commutatus* Schrad, a grass very common both in the wheat and around field borders.

After giving a description of the symptoms associated with diseased wheat plants, the author points out that the losses occasioned in the west Tennessee and Kentucky districts are apparently slight. In wet, poorly drained localities which favour the disease, large numbers of plants are affected and destroyed, but as such areas represent a very small proportion of the whole district, and as the disease is closely restricted to such localities, the total loss is not very great. This loss is, however, persistent, for the fungus survives, between wheat crops on *Bromus* or in the soil and continues, year after year, crop after crop, taking a toll, which, although slight, represents a considerable loss in the aggregate.

HALL. *Diseases of Economic Plants.* New York, Macmillan and Co., 1910, p. 342 indicate the fact that this fungus' is parasitic on maize in the North American Confederation, where according to F. L. STEVENS in *The Fungi which cause Plant Diseases,* New York: Macmillan it C° 1914 p. 90 it has already been noted on wheat. (*Ed.*)

Effective methods of control are now being studied by the Office of Cereals Investigations, Washington.

1060 - **Diseases of Cotton in St. Vincent' West Indies.**— See No. 1004, of this *Review*.

1061 ***Colletotrichum Agaves*, a Deuteromycete Injurious to *Agave* spp., in Indo-China, the French Sudan and France.** — CHEVALIER, A., in the *Revue de botanique appliquée et d'Agriculture Coloniale*, Vol. I, No. 1, pp.21-23. Paris, May 15, 1921.

The author had already for some time noticed the presence, on the lower leaves of specimens of sisal (*Agave rigida*) in both Indo-China, and the French Sudan, of elliptical brown patches elongated in the direction of the long axis, and more or less confluent. Some of the tissues of the portions attacked decay, and very badly infected leaves are wholly useless.

During 1915 and 1916, the author sometimes found similar patches on plants of *A. americana* growing in France, on the Côte d'Azur (Nice, Monaco, Mentone).

In March, 1921, he reported that many specimens of *Agave* in the Roucas Blanc Park near Marseilles, especially those growing in places where they were exposed to the wind, had on their old leaves, brown patches similar to those disfiguring the agaves in Indo-China, French Sudan and the Côte d'Azur.

Examination of the diseased leaves enabled M. PATOUILLARD to state, that the spots were produced by the Melanconia *Colletotrichum Agaves* Cav. originally described as occurring in Italy.

The malady either appeared for the first time in Roncas Blanc Park last winter, or else developed there then to an unusual extent, but the brown spots on the leaves were at first attributed to the effect of the severe frosts on December 15 and 17, 1920, which killed or injured so many foreign plants that had been acclimatised in South France.

The fungus has only been recorded as attacking *A. Americana*, *A. Salmiana*, and their variegated forms. Specimens of *A. applanata* growing amongst the preceding species were not infected.

The disease shows itself in the form of a small, brown spot, that gradually increases in size, finally attaining the diameter of 3.4 cm. At this point, the parasite stops growing, and the patch assumes an irregular shape, its long axis bring parallel to the length of the leaf.

According to the statement made by the owner of Roncas Blank Park, the disease is little to be feared at present, for though it impairs the beauty of the leaves of the host-plant, it does not affect the plant's vigour.

Nevertheless, in the opinion of the author, the malady should be controlled by cutting off the diseased leaves and burning them in a brazier after first sprinkling them with petroleum. It is particularly advisable to take this precaution in large tropical plantations, where there are many plants whose the leaves show the characteristic brown patches, to be attributed, at all events for the present, to the action of *Collet. Agaves.*

In 1913, Mr. SHAW recorded this disease, under the name of " anthracnose of sisal hemp, " as occurring in several parts of India. He obtained pure cultures of *Colletotrichum* and was able to reproduce the disease artificially. The fungus is one of the wound-parasites often found on leaves, especially after periods of drought producing longitudinal cracks. SHAW recommends spraying with Bordeaux mixture as being the best means of preventing the spread of the disease.

There is in the cryptogamic Herbarium, in the Paris Museum, another Melanconia, *Gloesporium Agaves* Sydow, that was found in 1918, on a species of *Agave* in Brazil. Nothing is so far known as to the injury it can do.

As the genera *Colletotrichum* and *Gloesporium* are very nearly akin, further researches are necessary, in order to find out the relations that may exist between the two above-mentioned fungi.

1062 - **Bacterial Wilt (*Bacterium Solanacearum*) of Castor Bean in Georgia, Florida and Alabama, U. S.** — SMITH, E. F., and GODFREY, G. H., in *Journal of Agricultural Research*, Vol. XXI, No. 4, pp. 253-262, figs. 1, pl. 13. Washington, D. C., May 16, 1921.

The bacterial wilt of castor beans caused by *Bacterium Solanacearum* E. F. S., was first brought to the attention of the authors in May 1918, when spècimens of diseased plants were received from Townsend (Georgia) and was notified shortly afterwards in Florida and in Dothan (Alabama). It is very likely that the disease occurred also in North and South Carolina and in Mississippi.

The highest reported loss was 30 % in a field in southern Georgia.

As regards the distribution of bacterial wilt the east coast section, where the disease appeared to be absent, differs from the interior and west coast sections of Florida rather strikingly in that an abundance of lime is present in the soil.

In addition to this, it was noted both in Florida and in Alabama that plants on newer land appeared to be more subject to attack than land that had been longer under cultivation.

The disease produced by *Bact. Solanacearum* in the castor bean as in Solanaceous plants is a true wilt of the green leaves and growing points, without previous yellowing or other partial or complete discoloration. It may occur when the plants are small in which case it is likely to prove fatal. It is also found in plants of all sizes. In smaller plants a single leaf may wilt and the vascular system near the base of the plant may show internal browning or even the entire plant may droop. The wilting may come about very suddenly or slowly. The first manifestation of wilt often appears after a period of wet weather of several days duration, such weather apparently favouring infection. Wilt is found more frequently in hot, dry weather. Often a plant may recover temporarily during moist weather or during a cool night after a hot dry day which has resulted in the appearace of wilt. Sometimes this recovery leaves a shrivelled tip or margin on some of the leaves. The ultimate result of the wilt in the more severe cases at least is the complete death of the plant. In many plants infection occurred late in the season but was not severe enough to cause permanent wilting or death. In such cases marked dwarfing was evident.

The wilt can be distinguished easily from the other diseases of castor bean known up to the present by the typical browning of the vascular system near the base of the plant. In the more severe cases this browning is seen in the entire vascular ring penetrating more or less deeply into the woody part of the stem. In cases of light infection, such as in the dwarfed plants mentioned heretofore, the browning may be seen in only a few bundles all possibly on one side of the stem. In addition to the browning it is always possible with the aid of a good lens, to observe drops of bacterial exudate at the freshly cut ends of the vascular tubes, particularly if the plant is still green. Sometimes it is necessary to pinch the end of the stem to force these drops to the surface.

The Ricinus organism was inoculated successfully not only into other Ricinus plants but also into tomato plants, jimson weeds (*Datura stramonium*), common nasturtium (*Tropaeolum majus*), cotton, vanilla (*Vanilla planifolia*), sunflower (*Helianthus annuus*), balsam (*Impatiens Balsamina*) and fuchsia.

1063 – *Fumago* sp., a Hyphomycete Injurious to the Myrtacea *Metaleuca Leucadendron* var. *viridiflora*, in New Caledonia.

– NICOLAS CH., in the *Bulletin de la Société de Pathologie exotique*, Vol XIV, No 7, pp 396-397 Laval, 1921.

As long ago as 1919, the author had observed that the leaves and branches of several specimens of *Melaleuca Leucadendron* (the Myrtacea furnishing essence of niaouli), growing on a spot situated between Honaïlon and Pouérihouen in New Caledonia, were attacked by *Fumago*, which had also infested other trees in the neighbourhood.

The found that the disease gradually spread during the following two years, and it now extends from Houaïlon to Poindimié, a distance of 70 km., although it is still rarely met with at either end of the line, the centre of the disease being at Mouet and Monéo.

The author studied the behaviour of the trees first attacked. For a long time, they resisted the parasite, and seemed at first to get the better of it by means of putting out a number of fresh shoots. In the long run, however, the leaves fell and the trees succumbed after about two years.

Microscopic investigation revealed the presence of a fungus on the surface of the parenchyma of the leaf, which in MOLLIARD's opinion, could be none other than a variety of *Fumago*, a saprophyte of but little importance when growing upon the " honey dew " produced in consequence of the punctures made by a coccid belonging to the genus *Ceroplastes*, which is said to be the primary agent.

The disease does not confine itself entirely to *Melaleuca*, and it is to be feared that one day it will attack the coffee plantations, and perhaps the coconut-palm groves.

1064 – *Phyllosticta Caricae-Papayae*, Leaf Spot of the Paw-Paw (*Carica Papaya*) in Natal, South Africa. — VAN DER BIJL, P A, in *The South African Journal of Science*, Vol XVII, Nos. 3-4, pp 288-290 Johannesburg, July 1921.

A leaf-spot disease of the paw-paw (*Carica Papaya*), characterised by discoloured spots is not uncommon in Natal; these spots may be circular or angular, or more or less elongated in one direction. They are frequently surrounded by a yellow or brownish ring which passes into the normal green of the leaf. On the upper leaf surface, small black dots are evident in these discoloured areas, and they are the pycnidia of the causal fungus.

The leaf tissues in the infected areas become brittle and ultimately fall out, giving the leaves a "shot-hole" appearance.

The fungus was isolated from infected leaves, Pieces of mycelium from a pure culture were artificially inoculated into leaves of *C. Papaya*, and after a few days, the characteristic symptoms of this disease were reproduced. The assimilating area in attacked leaves was diminished.

The infection of a paw-paw through a puncture would indicate that this fungus may also play some part as a causal agent of a fruit rot of *C. Papaya*.

The fungus here described is referred to as *Phyllosticta Caricae Papayae* Allesch. generally recognised as living on *C. Papaya* in Brazil.

1065 – *Phoma Ferrarisii*, n. sp., a Deuteromycete Causing Tomato Rot in Piedmont, Italy. — CIFERRI, R, in the *Rivista di Patologia vegetale*, Year XI,. Nos, 5-6 pp 65-69. Pavia, August 1, 1921.

Towards the end of June, 1921, a tomato was gathered in the vicinity of Alba (Prov. of Cunéo), which was externally shrivelled and flaccid, as well as a little discoloured, though the skin was intact, except at one place, where a brownish cavity could be seen; the cavity extended into the interior of the fruit. On being cut, the fruit was found to consist chiefly of a mass of decomposed almost black pulp. The healthy remainder of the parenchymatous tissue was separated from the diseased portion by a reddish layer. From the rotting pulp, there emerged numerous black bodies (pycnidia) of a fungus which, after microscopic examination, was referred to the genus *Phoma*, and is provisionarily described in the present preliminary note, as a species new to science, under the name of *Ph. Ferrarisii*.

By means of artificially inoculating sound, green fruits, symptoms identical in every respect with those observed in nature were induced in a very few days, hence there is no doubt, that the disease is due to the parasitic action of the above-mentioned spherioïdea.

One fact worthy of notice is that the disease — called by the author tomato rot — if not too far advanced, does not prevent the green tomatoes ripening, but the course of the disease is not checked by maturation.

From the results of the observations hitherto made, it would appear that the parasite penetrates into the fruit through a break in the epidermis.

The disease is of very rare occurrence; only a very few infected fruits were discovered on two of the tomato-plants growing in a kitchen-garden.

Subsequent observations have shown that on certain of the diseased fruits a greyish-white, or whitish, mucidinea (*Ramularia* sp), is present on the surface or in some of the superficial layers, which may also perhaps have a metagenetic relation to *Ph. Ferrarisii* or be merely a secondary parasite.

1066 - ***Bacterium marginatum*** **n. sp., Injurious to *Gladiolus* spp. in the District of Columbia and in Illinois, U. S.** — MC.CULLOCH, L., in *Science*, New Series, Vol. LIV, No. 1388, pp. 115-116, Lancaster, Pa, Aug. 5, 1921.

Preliminary description of a bacterial disease of *Gladiolus* spp. caused by *Bacterium marginatum* n. sp. The author gives the morphological characteristics and states that the micro-organism is pathogenic in leaves of the plant, forming circular or elliptical lesions rusty red in colour, becoming dull brown or purplish. These spots may occur on all parts of the foliage, but are often confined to the lower leaves. Observation and experiment indicate that the disease makes rapid and dangerous progress only in warm and moist weather when the rot spreads widely and deeply into the tissues, causing collapse of the aerial part of the plant.

The disease is very prevalent in and round the District of Columbia. In the fields examined 80 to 90 % of the plants were affected but in the majority of these cases not so severely as noticeably to arrest the development and bloom of the plant.

Specimens of *Gladiolus* with the same disease have been received from Illinois, with the information that it has caused loss to the growers. Some plants from California apparently had not the same disease but the case was not completely proved.

The organism has been isolated repeatedly and its pathogenicity proved by the inoculation of healthy plants.

1067 - ***Phytophthora*** **sp. Peronospora Injurious to Peonies in Pennsylvania.** — THURSTON, H. W., and ORTON, G.R., in *Science*, New Series, Vol. LIV, No. 1391, pp. 170-171, Lancaster, Pa., Aug 26, 1920.

Early in May, 1921, the authors received from Eric (Pennsylvania) some blighted peonies for examination. Since the cause of the trouble was not at first apparent, cultures were attempted from the diseased portions. These gave at once a pure growth of *Phytophthora*, a Peronospora which had not previously been reported as parasitic on this host-plant.

On the plants in question, the disease was manifest as a necrotic condition of the bud, involving also the surrounding leaves and extending for several inches down the stem. In general appearance, the symptoms are similar to those caused by *Botrytis*, although the infected areas are a darker brown or black. No evidence of external fruiting of the parasite was found either upon the original specimens or upon plants subsequently artificially infected. Inoculations of the pure culture into healthy peonies, however, readily produced infections and the characteristic symptoms, from which the organism was re-isolated with ease. Inoculations were made upon plants growing outside, with pure culture, using pieces of mycelium and zoosporangia, and these were successful both with and without wounding of the host. The characteristic symptoms appeared in from 3 to 6 days.

The disease in question develops rapidly upon a variety of artificial media, and in this respect differs from *Phyt. infestans*.

The measurements of the zoosporangia which are produced in abundance, correspond closely to those for the zoosporangia of *Phyt. infestans* but are somewhat broader than those of *Phyt. Thalictri* which would appear to be its closest relative so far as hosts are concerned. Oospores have not been observed either in cultures or tissue sections of the infected plant.

1068 – **Diseases and Pests of Citrus Fruits in the United States, Porto Rico and India.** — See No. 1011 of this *Review*

WEEDS AND PARASITIC FLOWERING PLANTS

1069 ***Cascuta Racemosa*** **Recorded on Lucerne in Rio Negro, Argentina.** — BARCIA TRELLES J., in *El Campo*, Year V, No 58, pp 921-927, figs. 9. Buenos Aires, August 15, 1921

Small patches of *Cuscuta racemosa* Mart. have been observed in some lucerne fields of Rio Negro, and it would therefore appear that this much-dreaded parasite has attacked the leguminous crop which constitutes the chief source of the agricultural wealth of the district.

For the moment little injury has been done, as the parasite has only just begun to attack the crops.

C. racemosa is, however, the most common species of the genus in Argentina, and the only one that has hitherto found its way to Río Negro. Its appearance is a serious menace, for it can easily in time develop into a veritable pest, if efforts are not made at once to extirpate it before it has taken much hold. The multiplication of the parasite would not only greatly reduce the local forage production, but also bring discredit upon the Río Negro lucerne seed, which has hitherto been regarded as the best in Argentina, owing to its purity, and especially to the fact, that it has always been found free from dodder.

The author describes the morphological characters of *C. racemosa*, as well as its life-history, and the best means known at present for controlling it.

1070 – **Leafy Spurge (*Tithymalus Esula* = *Euphorbia Esula*) Harmful Weed in the United States.** — BRITTON N. L., in *Journal of the New York Botanical Garden*, Vol XXII, No 256, pp 73-75, fig 1. Lancaster, Pa, April, 1921.

About 100 years ago, possibly even earlier, the leafy spurge (*Tithymalus Esula* Hill [= *Euphorbia Esula* Linn.]), a native of Europe, obtained a foothold in Essex County (Massachusetts). The actual date of its introduction is not definitely known, but a specimen preserved in the Torrey Herbarium of Columbia University, deposited at the New York Botanical Garden, was collected at Newbury (Massachusetts) by OAKES in 1827. For many years, this Euphorbiacea was not noticed elsewhere in the United States. But in 1848, GRAY stated that it was likely to become a troublesome weed. In 1880, ROBINSON records it as very abundant near Newbury port; this is probably OAKE'S locality. In 1886, DUDLEY records the plant as found at Groton (New York) and remarks on its rarity. In 1881, WHEELER and E. F. SMITH record it as having escaped cultivation and somewhat rare in Michigan State. By 1913 the plant had apparently extended to Maine, Ontario and New Jersey; it is only in recent years, however, that GRAY'S surmise has become a fact and farmers in Orange County (New York) and elsewhere now find this weed a menace to pastures. Measures to prevent propagation or to eradicate completely are being taken, but the task is not an easy one, as the plant has horizontal rootstocks formed anew each year.

If the weed is detected it is advised to fork or dig it out of the ground and burn, taking care to destroy all the underground parts.

INJURIOUS INSECTS AND OTHER LOWER ANIMALS

1071 - **Observations in Italy on the Polyphagous Nature of the Macrolepidopteron, *Attacus cynthia*.** — ZANON, V, in the *Rivista Agricola*, Year XXVI, No 36, pp 511-512 Parma, September 9 1921

The macrolepidopteron, *Attacus cynthia*, was introduced from China into Europe where its caterpillars had always confined themselves to a single plant-host, *Ailanthus glandulosa*; in October 1920, the author found them living at the expense of the plane-tree, some specimens of which had been seriously injured by the larvae in different localities. In November the insects attached their cocoons to the trees. Later on, in the course of the winter, ZANON found numerous cocoons of *A. cynthia* hanging from the boughs of pear, cherry and plum-trees growing in other gardens of the same district.

During the first fortnight of June 1921, the author obtained from cocoons he had collected from the plane-tree the preceding winter and laid aside, a certain number of the adult macrolepidopteron; the females after mating laid eggs, which yielded caterpillars at the end of the same month; the caterpillars were placed on pear and plum branches kept in vases full of water in a room, where they lived on the leaves

The author believes that the adult insects of the first generation that hatch in June from the cocoons attached to the plane-tree, seek out their true host, *Ailanthus glandulosa*, where they deposit their eggs, but that those of the second generation, owing to the scarcity of this plant, are obliged, in order to rear their more numerous progeny, to have recourse to other species. Hitherto, they have manifested a predilection for the plane, but as has been seen, they also attack pear, cherry and plum trees

If the first generation should also develop upon fruit-trees, the danger would be of a serious character. In order to avert it, the only way is to collect the winter cocoons, or to pull up the *Ailanthus* trees, which do not yield good wood, or even brushwood, and only encumber the ground.

1072 - **On the Resistance of the Adult Cockchafer to High and Low Temperatures.** — FAES, H. and STAEHELIN, M., in the *Comptes rendus hebdomadaires des Seances de l'Académie des Sciences*, Vol. CLXXII, No 1, pp 61-64. Paris, 1921

It has often been stated by agriculturists that the return of cold weather, especially when accompanied by severe frost, kills a certain number of cockchafers.

In order to see how far this idea was correct, on May 21, 1921, the authors exposed some adult specimens to different degrees of low temperature in the cold storage chamber belonging to the new Federal Vine-Growing Experiment Station at Lausanne (Switzerland).

At first the temperatures employed were not below —8° C. but it was found that greater cold was necessary to kill the adult cockchafer.

The results of the experiments are as follows

Date of experiment	Temperature (n degrees C.)	Length of exposure	Number of cock chafers	Results of examination on May 21	
				Dead cock chafers	Living cock chafers
18 May	—18° — 16°	1 hour	6	6	0
»	—14° — 12°	»	6	6	0
»	— 8°	»	6	2	5
»	— 6°	»	6	1	5
11 May	— 4°	»	30	6	24
»	— 2°	»	30	5	25
»	0°	»	28	3	25
»	+ 2°	»	30	2	28

So that the conditions should be as far as possible natural the authors also left in the cold chamber different lots of cockchafers that were exposed respectively to low temperatures of long duration, and to progressive lowering and raising of the temperature. One lot was placed in a vessel filled with sand, which allowed the insects to escape from the cold, should the temperature be too low for their liking.

In this new set of experiments, the cockchafers exposed for 30 hours to temperatures between +5° C. and —6° C. or for 174 hours to temperatures varying from +7° C to —6° C. did not all die; on an average, one third of then were able to resist the action of the cold.

When subjected to temperatures of nearly 0° C. or below 0° C, adult cockchafers usually become motionless or freeze. They, however, thaw rapidly, and as a rule, run about after they have been removed 1 hour from the cold chamber.

As soon as they felt the cold, the cockchafers in the vessel filled with sand quickly dug themselves in, burrowing to a depth of 10 cm.

It is thus seen, that these insects when full-grown can easily stand the lowest temperatures produced in Europe by the return of cold weather in spring. In order to destroy them all, the temperature of the air would need to fall below −8° C. which never occurs under the climatic conditions obtaining in spring. These experiments also prove that the adult cockchafer will bury itself in the ground, in order to escape from any cold that might injure it.

The authors thought it would also be interesting to determine the resistance of adult cockchafers to high temperatures For this purpose, they exposed several lots of these insect to different temperatures in a gas-heated dessicator provided with a regulator. The following results were obtained . —

Date of experiment	Temperature (in degrees C.)	Length of exposure	Number of cockchafers	Results of examination on May 21	
				Dead cockchafers	Living cockchafers
13 May	+ 35°	1 hour	14	7	7
»	+ 40°	»	15	9	6
»	+ 45°	»	15	15	0
»	+ 50°	»	15	15	0
»	+ 55°	»	16	16	0

With a view also that the conditions should be as far as possible natural, the authors exposed one lot of cockchafers to a hot air current. As in the experiment in the cold chamber, a certain number of insects were placed in a vessel filled with sand which enabled them to escape excessive heat.

The following results were obtained :—

Date of experiment	Temperature in °C.	Length of exposure	Number of cockchafers	Results of examination on May 21	
				Dead	Living
May 13	+ 35° to 55°	8 hours	5	15	0
Lot in the vessel containing sand:					
May 13	+ 35° to 55°	8 hours	15	15	0

Although the adult cockchafer is remarkably resistant to cold, it is on the other hand, relatively susceptible to a great rise in temperature. At +55° C all the insects succumbed.

[1072]

In order to escape from too high a temperature, most of the insects shut up in the vessel filled with sand buried themselves to a depth of 10 cm., but whether they remained on the surface, or burrowed beneath it, they were all destroyed during the 8 hours' exposure, the temperature at the bottom of the vessel being probably +45° C., their limit of resistance.

The adult cockchafer is perfectly adapted to this climate, and is little affected by the lowest or highest temperatures our spring has to offer.

1073 - **Barley Varieties Resistant to *Heterodera schachtii* in Sweden.** — See No. 994 of this *Review*.

1074 - **The Introduction into Southern France of the Australian Coccinellid, *Cryptolaemus montrouzieri*, a Natural Enemy of Scale Insects (*Pseudococcus*)** (1). — MARCHAL, P., in the *Comptes rendus hebdomadaires des séances de l'Académie des Sciences*, Vol. CLXXII, No. 2, pp. 105-107. Paris, 1921.

In July, 1918, the Insectarium at Mentone received from the similar institution at Sacramento (California), 15 larval and 3 adult specimens of *Cryptolaemus montrouzieri* Muls. a coccinellid of Australian origin, which has proved to be a most determined enemy of scale-insects. Amongst the latter must be reckoned the members of the genus *Pseudococcus*, which in company with " fumagine," cause the destruction of the orange and lemon gardens in Southern France, as well as injury to the various crops grown there. A second consignment consisting of about 500 insects was sent to Mentone from Sacramento in the beginning of 1919.

In the spring of that year, the coccinellids on the apple-shoots infested with *Pseudococcus* in the laboratory cages at Mentone had multiplied to such an extent as to admit of their being set free.

Colonies of *Crypt. montrouzieri* established themselves during 1919 and 1920. In 1919 each colony contained 50 to 60 of the insects. Altogether a thousand were set at liberty in different lots on the estates, or public walks of Mentone, Garavan and Cabbé-Roquebrune. In 1920, new centres of dispersal were formed, each provided with a thousand insects, in other parts of Mentone, and in the Principality of Monaco. In addition, some colonies were dispatched to Algeria and Italy.

This year, the insects have been found in large numbers in the various places where colonies were established in 1919, and in places far off from the 1920 centres. It has thus been proved that *Crypt. montrouzieri* paspass the winter in the open at Mentone, in spite of the abnormal cold it experienced, and had managed to exist from the one year to the next, and further to reproduce itself.

In an orange garden in which a colony of these insects had settled in August 1919, they succeeded in multiplying to such an extent, in spite of the very unfavourable conditions occasioned by a thorough pruning, that all the trees infected with *Pseudococcus*, bore a larger or smaller number of *Cryptolaemus*, so that the invasion of the scale-insects had been checked.

---

(1) See on this subject, *R.* July 1914, No. 697; *R.* March 1916, p. 354; *R.* July, 1921, No. 872. (*Ed.*).

From what has been said, it is clear that *Crypt. montrouzieri* is in process of becoming acclimatised on the French portion of the Mediterranean coast, where it also will do good service in attacking the scale insects (*Pseudococcus*), which are so injurious to the southern crops, and have proved exceedingly resistant to all the control measures hitherto taken against them.

1075 - **The Natural Enemies of *Xylotrechus quadripes* and of *Chlorophorus annularis*, Beetles Injurious to the Coffee-tree and the Bamboo Respectively, in Tonkin.** — KIEFFER, J. J., in the *Bulletin agricole de l'Institut scientifique de Saigon*, Year III, No. 5, pp. 129-140. Saigon, May 1921.

In Tonkin the larva of the Cerambycid *Xylotrechus quadripes* Chevr (1) makes galleries in the trunk of the coffee-tree, thus hindering its growth, and greatly reducing the crop. The larva of another Cerambycid, *Chlorophorus annularis* Fairm. destroys the stems of the bamboos in a similar manner.

The Entomological Station of Cho-Ganh has begun to combat these insects by breeding and setting free their natural enemies which belong to the order of Hymenoptera, and are here described by the author from a systematic standpoint : — (A) fam. *Braconidae* :— 1) *Duportia cinticornis* n. gen. and n. sp., parasitic on the larvae of *Chlor. annularis* ; 2) *Promiscolus sesquistriatus* n. gen. and n. sp., parasitic on *Xyl. quadripes* and of *Chlor. annularis* ; 3) *Pristodoryctes striativentris* n. gen. and n. sp., parasitic on the larvae of *Xyl. quadripes* ; 4) *Doryctes tristriatus* n. sp., parasitic on the larvae of the two Cerambycides ; 5) *D. strioliger* n. sp., as above ; 6) *D. picticeps* n. sp., as above ; 7) *D. bistriatus* n. sp., as above ; 8) *D. brevipetiolus* n. sp. as above.

(*B*) fam. *Ichneumonidae :— Paraglypta tubigera* n. gen. and n. sp., parasitic on the larvae of *Xyl. quadripes.*

(*C*) fam. *Evaniidae :— Pristaulacus nigripes* Kieff. var. *Duporti*, n. var. obtained in large numbers from the larvae of *Xyl. quadripes.*

(*D*) fam. *Bethylidae :—* 1) *Sclerodermus domesticus* Latr.; very common as an ectoparasite of the larvae of *Xyl. quadripes*, and of *Chlor. annularis*, also destroys the above-mentioned larvae and adult forms of the fam. *Braconidae* ; 2) *Misepyris grandiceps* n. sp. parasitic on the larvae of *Xyl. quadripes.*

1076 - **Animal Pests of the Cacao Tree in the Dominican Republic.** — WOLCOTT, G. N., in the *Revista de Agricultura de Puerto Rico*, Vol. VI, No. 6, pp 11-12. San Juan, P. R., June 30, 1921.

Rodents and birds do considerable damage to the cacao-tree in the Republic of Dominica, where they devour the seed of the fully-grown fruits and in some places nearly half the crop is lost by this means.

When grown on virgin soil, these trees are usually attacked by the larvae of a beetle, *Strategus titanus* Fabr., which feed upon their roots, but these pests can be got rid of by carefully and thoroughly cleaning the ground.

---

(1) See *R.* May 1911, No. 1338. (*Ed.*)

The larvae of *Bocchoris pharaxalis* Druve devour the young leaves of the shoots, producing irregularly-shaped holes in them. The larvae could probably be destroyed by the use of arsenical sprays, but under the present conditions the best method of control is to pick them off by hand.

Still more dreaded enemies of cacao are the aphis *Toxoptera aurantii* Boyer, and the scale-insect *Pseudococcus citri* Risso. The first is found on the youngest leaves, the floral buds and the peduncles of the fruits while they are small. The scale insect also frequents the peduncles of the flowers and fruits, and even occurs on the fruits themselves, especially in the least exposed places, where two fruits touch one another or one touches the trunk of the tree. Owing to the punctures made by the insects in the peduncles, the floral buds wither before unfolding, and the already-open flowers wither and fall; the large number of mummified fruits show that development has been checked by the presence of the scale-insects.

The aphids and the coccids are accompanied and protected by the formicide, *Solenopsis geminata* Fabr. If the latter is prevented (by a band of " tanglefoot " round the trunk) from ascending the tree, or if the ants are killed by flooding their nest several times with an emulsion of carbolic acid and soap, the aphids and coccids very soon decrease greatly in number. It would certainly be advisable to destroy these two species of insect directly, but it is useless to spray cacao-plantations where the trees grow close together without any order, and are left unpruned, as is generally the case in the Republic.

1077 - ***Lonchaea aristella*, a Dipteron Injurious to the Fig-Tree, and New to France** (1). — POUTIERS, R., in *Le Progrès Agricole et Viticole*, Year XXXVIII, No 38, pp. 285-286. Montpellier, September 18, 1921.

For two years, the author has noticed that certain varieties of figs at Mentone are covered with punctures, and infested with the larvae of a dipteron, which by eating out the interior of the receptacle (syconus), cause it fall prematurely.

Since May he has reared many adult insects from these larvae which have been identified as *Lonchaea aristella* Beck, thus proving the truth of the suspicion that this pest has found its way to France.

No natural enemies of the dipteron have so far been found at Mentone by the author.

GENERAL INFORMATION.

1078 - **The Agricultural Development of the State of Minas Geraes (Brazil): The Message of H. E. Dr. Arthur de Silva Bernardes in the Third Session of the Eighth Legislature.** — *Lavoura e Criação*, Year VI, No. 7, pp 134 150 Rio de Janeiro, July, 1921.

The Message of the President of the State of Minas Geraes on the occasion of the third ordinary session of the eighth Legislature, which was opened on July 15, 1921, treats of the finances, agriculture, and industries of that flourishing country, and draws special attention to the work done by the Government for the encouragement of agriculture and stock-breeding.

The most important data relating to these efforts and to the conditions of agriculture figure in this report.

SCIENTIFIC AND AGRICULTURAL INSTRUCTION. — 1) *Agricultural Veterinary College.* — The institution of this College was decreed by Law No. 961, dated September 6, 1921: Decree No. 5623 of March 7, 1921, allocates for this purpose a sum of 1000 *contos de reis*. The organisation has been entrusted to Dr. P. H. ROLFS.

2) *Institute of Industrial Chemistry.* — This will be attached to the Bello Horizonte " Escola de Engenharia, " and is now being erected. It was hoped that the Institute would be ready for opening in 1921.

3) *Agricultural Institutes.* — There are three of these supported by the State viz., the João Pinheiro Institute, near Bello Horizonte, the Don Bosco Institute at Itajubá, and the Bueno Brandão Institute in the Municipality of Mar de Hespanha. In 1920 these three Institutes cost

the State respectively 16 014, 59 742 and 41 051 *milreis*. To the João Pinheiro Institute is attached the Gamelleira farm, which is used for purposes of demonstration, and for practical instruction of the students. Young men of at least 18 years of age, and desirous of obtaining a certificate testifying to their fitness for the exercise of the duties of "mestre de cultura" (agricultural teachers) are also admitted to this Institute.

4) *Schools of Practical Agriculture, or "Aprendizados"* — Of these there are 2, both founded and supported by the State: the José Gonçalves School at Ouro Fino, and the Borges Sampaio at Uberaba. For these the sums of 32 649 and 38 816 *milreis* were expended in 1920. These schools are entirely devoted to practical instruction in agriculture; their aim is to produce good country workers having a thorough knowledge of modern methods of mechanical cultivation, irrigation and the use of fertilisers, etc.

In addition the State subsidises the "Aprendizado" which is annexed to the "Colonia indigena" of Itambacury in the municipality of Theophilo Ottoni.

5) *Subsidised Institutions*. — In accordance with the "Lei orçamentaria" (Budget Law) of 1920, the State allocated the following subsidies to these Institutions of Professional and Agricultural Instruction: — Escola de Engenharia of Bello Horizonte, 50 000 *milreis*; Istituto Electro Technico e Mecanico of Itajubá, 25 000 *milreis*; "Escola Agricola de Lavras" and "Escola D. Bosco" of Cachoeira do Campo, 10 000 *milreis* each; Aprendizado agricola" annexed to the "Gymnasio Leopoldinense" 5 000 *milreis*; "Escola Mineira de Agronomia e Veterinaria" of Bello Horizonte 4000 *milreis*; "Escola professional Delfim Moreira" of Porto Alegre 2500 *milreis*; "Escola do Commercio" of Bello Horizonte 2000 *milreis*; total amount of grants: 118 500 *milreis*.

6) *Travelling Instruction*. — This is almost at its beginning, and may therefore be said to be in the experimental stage. In 1920, the "mestres de cultura" visited 271 agricultural farms, and it is thanks to their propaganda, that so many agricultural machines have been used. One of these "mestres" has introduced a new type of tobacco drier which gives a better colour to the dried leaves. The use of this apparatus at once increased the market value of dried tobacco leaves which has risen from 4 to 6.5 *milreis* per kilogram.

AGRICULTURE. — The following data, which refer to 1920, bring out clearly the great importance of agriculture in the State of Minas Geraes

	Value of exports. Milreis	Returns of the export tax	
		Absolute value	% of total
Agricultural industry	195 196 702	13 175 723	55.21
Stock-breeding.	182 234 482	7 091 411	29.78
Manufacturing Industries	43 980 422	1 613 808	6.76
Extractive Industries	32 948 508	1 965 154	8.22

The increased value of the chief Brazilian products during the war induced a considerable rise in the exports, and hence a great influx of capital, which was used, by preference, in the development of agricultural production : enlarging plantations, the introduction of new crops, the purchase of machines, etc.

The traditional crops of *maize, haricot beans* and *yams* are continually developing, and motor-ploughing has already been introduced into certain zones.

Coffee is still the chief source of public and private wealth. *Rice* appears to have found conditions that suit it perfectly in the regions on either side of the Rio Grande, viz., in the municipalities of Sacramento, Conquista and Fructal, as well as at Uberabinia, Araguary, and other centres. The rice-fields on the banks of the Rio Grande already form one of the granaries of the country, and their importance will still further increase when transport is rendered easier by the works undertaken to ensure the navigability of the the Rio Pardo from its mouth as far as the Station of Jaguará. The states of Minas and of São Paolo as well as the Federal Government are interested in these works.

Rice-growing is a very favourite industry in other parts of the South and West of the State; for instance in Matta where in the municipalities of Leopoldina, Cataguazes, Ubá, São João Nepomuceno, Rio Branco, Viçosa, Ponte Nova, Abre Campo, and Rio Casca alone, the crop totalled 750 000 sacks.

Sugar-cane cultivation is constantly extending, and is very successful. New modern sugar factories are being built. As alcohol is very heavily taxed, the canes are more used for sugar-making than for distillation. In 1920, the export was 15 909 423 kg. of sugar, or 10 427 901 kg. more than in 1919.

The Government has engaged specialists for the purpose of restoring the *tobacco-growing* industry of the State which reached its height in the middle of the last century but has since declined because the cord tobacco of the State of Minas Geraes has been supplanted by the lighter-coloured and more delicate leaf-tobacco, produced in Bahia and Rio Grande do Sul.

The efforts made by the Government to develop *fruit-growing* have been crowned with success ; the fruits of Barbacena, Maria da Fé, Silvestre Ferraz, etc. are fully equal in colour and flavour to the European products ; the State already exports large quantities of plums, pears, apples, grapes, peaches, mangoes, and pine apples.

Everything makes it probable that *cotton* will become one of the State's permanent sources of revenue, as soon as proper methods of cultivating and preparing the crop are adopted. The Secretary of the Manchester (England) Cotton Association states that the cotton of Minas is generally of excellent quality, the fibre sometimes being 32 mm. long. The river district of San Francisco is especially suitable for this crop. The Government has drawn up a scheme for establishing a Cotton-Growing College in this region, and a Station for the selection and distribution of cotton seeds. Other crops worthy of mention are *potatoes* (chiefly in the

Southern part of the State); *cacao*, on the frontier of Bahia; *tea* in the neighbourhood of Ouro Preto; *onions, groundnuts, kitchen-garden plants*, etc.

MEASURES TO ENCOURAGE POWER-FARMING. — In order to encourage the use of agricultural machines, the State imports them, and allows the agriculturists to buy them at cost price with free transport by rail. In 1920, 1380 agricultural machines were imported, 281 apparatuses for destroying ants, 2168 diggers, etc. Seed sorting-machines were also purchased and are about to be set up. Depots for agricultural machines have been established in many municipalities, and entrusted to the "Cameras Municipaes" which keep, exhibit and sell the machines at the price paid for them by the State.

The Government occupies itself with the purchase within the State, and outside its frontiers, of sound selected seed, which it sells to the agriculturists at cost price. This work cannot, however, be thoroughly carried out, until a special Institute is founded for the purpose.

The "Horto florestal" of Boa Vista (6 km. from Bello Horizonte) does excellent service in re-afforestation. It supplied a large number of cuttings, especially of eucalyptus, to the Municipalities for planting along the roads, and to private individuals for afforestation. The State gives each agriculturist cuttings up to the number of 5000, carriage-free by rail; and will supply more, with the sole stipulation, that the "Secretaria da Agricultura" be informed of the results obtained.

STOCK-BREEDING. — Cattle represent one of the chief sources of wealth possessed by the State of Minas Geraes. In 1920, 1 278 444 kg. more meat were exported than in the preceding year. There are in the country over 60 factories for the preparation of "xarque" (dried beef), and the annual output is estimated at 9 million kg.

The "Instituto Oswaldo Cruz" has supplied a vaccine which has practically stamped out symptomatic anthrax (*manqueira*). At present, measures are being adopted for the prevention and control of foot-and mouth-disease, and a State Veterinary Service is in process of organisation. The serum for swine fever is prepared at Bello Horizonte by Messrs Aristides and Co.; in 1920 as many as 22 500 doses were sold. The Instituto Oswaldo Cruz prepares a serum for immunising calves against "pesta de manqueira" and distributed 419 800 doses in 1920, and 359 945 during the first 4 months of 1921. A branch of this Institute, at Bello Horizonte, has been entrusted with the Antiophidian Service. It has begun a careful systematic study of the snakes of Brazil, and published information, for the guidance of the country-folk, respecting the poisonous and non-poisonous species. The Institute also prepares and distributes a serum which is an antidote to snake-venom.

With a view to combating piroplasmosis, the Government offers prizes to the 2 first stock-breeders constructing tanks for dipping cattle, as arsenic dips are the best means of freeing animals from ticks (the carriers of trypanosomiasis).

The Government further encourages the breeding-industry by providing barbed-wire for enclosures. This is sold at cost price and carriage-free.

In order to promote the laying down of pastures, the Government gives gratuitously, on request, to all agriculturists, seeds of " Capim gordura " (*Panicum minutiflorus* = *Melinis minutiflora*) or " Capim jaraguée " (*Andropogon rufus*) (1) up to the weight of 10 kg., and supplies larger quantities at very low price.

The " postos zootechnicos " (stockbreeding observation Stations) attached to the State " fazendas " and " colonias " have greatly contributed to the more general rearing of good breeds of animals, especially of cattle, horses and pigs.

Owing to the establishment of lard factories, *pig-breeding* is steadily increasing.

Silkworm-rearing is practised to a small extent in the municipalities of Barbacena and São João Nepomucena : some timid attempts in the same direction have also been made elsewhere. The climatic conditions obtaining in the State are eminently suitable to this industry.

1079 - **The Purification of Sewage Water by Activated Sludge and the Bacterial Flora in Sewage thus Purified.** (2) I. I. — Thanks to the work of FOWLER, ARDERN, and LOCKETT, the chemical pheuomena produced during the purification of sewage with " activated sludge ' are well known. The great reduction in the number of micro-organisms present in sewage-water thus treated has been shown by ARDERN, HATTON, BARTOW (1915), and RUSSELL and BARTOW (1916). The biological nature and the nitrification process was determined by ARDERN and LOCKETT (1915) and RUSSELL and BARTOW (1916). Little trouble has, however, been taken to discover the part played by other micro-organisms, whether as regards the transformation or the destruction of ternary substances, or from the point of view of the breaking up of albuminoid matter, as preparation for action by the nitrifying bacteria present in the sludge.

The object of Messrs COURMONT and ROCHAIX's paper is to confirm the reduction in the number of micro-organisms in water that has been purified and decanted, and to give a preliminary account of the bacterial flora. The conclusions arrived at are as follows: —

---

(1) See *R.* Aug. 1921, No. 816. (*Ed.*)

(2) See *R.* Aug 1915, No. 793; May 1919, No 570. Sept. 1920, No. 843; Nov.-Dec. 1920, No 1051. (*Ed.*(

1) The number of micro-organisms in water purified by the activated-sludge method is greatly reduced. In one of the samples examined, the total number fell, after purification, from 202 500 000 per cc. to 67 587, whereas in another sample after treatment it was only 58 600 per cc.

2) All the bacteria in the purified sewage are aerobic forms, no true anaerobic forms being present so that the putrefactive bacteria appear to have been destroyed.

3) Chromogenetic species predominate over non-chromogenetic.

4) The bacterial flora of purified sewage shows little variation and is reduced to a few species.

5) The purified sewage appears to contain no *B. coli*, or any other typical pathogenic species.

II. — Sewage sludge, when alternately aerated, and then allowed to settle, gradually acquires the property of purifying the sewage with which it comes in contact, in the presence of air. It is generally supposed that this purifying action proceeds in a manner similar to nitric fermentation.

M. CAMBIER has investigated the rate of nitrification, and gives the results of some of his experiments. One drop of sewage-water containing 32 mgm. of ammoniacal nitrogen, and no nitric acid, after having been aerated for 18 hours in contact with activated sludge contained hardly any traces of ammoniacal nitrogen, and 23 mgm. per litre of nitric nitrogen. A similar result was obtained with 2 other muds.

The chief point is the disappearance of a large proportion of the ammonia from the sewage-water after it has been in contact with the sludge for a few minutes, although the amount of nitric acid produced is little or nothing.

This fact is especially noticeable in newly formed sludges and is less marked in old sludges, but in the case of the latter, however short the time of aeration may be, the amount of nitric acid that appears in the liquid is much larger than could be accounted for by the total nitrification of all the ammonia in the untreated water. This addition comes from the combustion of the sludge itself, which in the course of time has become rich in nitrogen compounds.

Even at 0° C. purification is complete and nitrification is only slowed down; at 5° C. the process is completed in 4 hours; it is most rapid at 20°-25° C. and goes on quite satisfactorily at 30° C. At 37° C. which is the optimum temperature for true nitric fermentation, nitric acid is not formed and the sewage-water does not undergo any further change in appearance. Nitric acid only occurs in appreciable quantities when the temperature is *above* 30° C.

Activated sludges can transform nitrites into nitrates at ordinary temperatures: in the presence of chloroform vapour, their activity as regards ammonia ceases.

The author has stated that, if decantation of the mixture of sludge and sewage is deferred for 3 hours, it begins to nitrify rapidly, and that if this purified water is carefully drawn off and the interstitial water removed from the residual sludge by whirling the centrifuge, this water is found to be very poor in nitrates, but to contain on the other hand 10 mgm. of ammonia per litre. Nevertheless if mixed with some fresh sewage, and again aerated, this mud will again purify and nitrify it energetically.

Finally, the colloids present in sewage water are to a large extent, like the ammonia, fixed after the first moments of contact. When after the purifying process was complete, a quantity of ammonia, similar to the amount it first contained, was added to the purified clear water floating on the surface of the mud it was found that colloids were once more present in suspension and the water again assumed the aspect of untreated sewage.

III. — Results obtained by M. DIÉNERT in researches extending, over several years, on the purification of sewage water by means of activated sludges. To obtain activated sludge finely-divided air is blown into the sewage, which is allowed to settle, and fresh sewage is introduced and aerated in the same manner. This process is continued for several days, until the moment arrives when by blowing in air for 5 consecutive hours, it is possible to transform 20 mgm. of ammoniacal nitrogen per litre into nitric or nitrous nitrogen. The time required to attain this result may be called the " activation period " ; its duration depends upon the sewage water used, the amount of air introduced, and the temperature of the water.

In the case of Paris sewage, if the air is blown in for 4 hours each time, this activation period lasted about 2 months; but the time can be shortened by increasing the length of the aeration process each time, or by the addition of carbonate of lime.

Activation is thus produced rather quickly in sewage sludge; it can however be attained in all waters containing similar deposits after a longer or shorter period of treatment.

The process takes place in the same manner as in the case of the introduction of yeast into a sugar, or in the adaptation of organisms to an antiseptic. For a few days the micro-organisms remain inactive and produce no changes in their nutrient medium, then suddenly they become very active and grow rapidly.

IV. — Messrs DIÉNERT and GIRAULT compared the effect of activated sludges from Colombes sewage-water, upon sewage water and ordinary water to which had been added the same amount of ammonia as was present in the sewage. The chief results of these experiments shewed: — 1) That ammonia disappears from sewage and from ordinary water after the same time; 2) That nitric nitrogen only appears after the activated sludge has been at work for some months.

V. — Messrs COURMONT and ROCHAIX have demonstrated, that the effluent from apparatus for purifying sewage by the activated-sludge process contains a much reduced bacterial flora. They could only obtain 7 species from this one effluent but they studied their action upon the albuminoid substances and the nitrogenous compounds that may follow the latter, viz. urea and nitrates.

The proteolytic properties of these micro-organisms are either much reduced or *nil.* All of them except two act upon peptones (indol), but not upon the other albuminoid matters studied. Only *Bacillus subtilis* possesses the power of energetically attacking albuminoid compounds, which it breaks up into simple degradation products.

Only three out of 7 bacteria fermented urea to any extent ; *B. subtilis* possesses this power to a certain degree, but the other 3 are completely inactive.

Five out of 7 of the bacteria present in the purified sewage behave as direct denitrifying organisms, and some of them appear to be very active, judging from their effect upon potassium nitrate.

VI. — Messrs COURMONT and ROCHAIX also studied the action upon carbohydrates of bacteria isolated from the flora of sewage purified by the activated sludge method.

They found that these micro-organisms have a fermenting action upon carbohydrates, which though it varies according to the species, shows that the destruction of ternary products during purification may be due to bacterial activity.

VII. — In order to purify sewage rapidly by means of activated sludge, experience teaches that a certain volume of sludge is necessary. The volume required is about one-third of that of the sewage when measured after standing for 2 hours.

When different amounts of activated sludge were employed, Messrs DIÉNERT, WANDENBULKE and LAUNCY discovered that the proportion between the amount of the ammonia that disappears and the weight of the supposed-dry sludge introduced decreased as the mud increased in quantity.

With the activated-sludge method of purifying sewage-water an ammonia-free, non-putrefactive effluent can be obtained, but owing to the great differences in the composition of sewage, the reduction of the number of bacteria by this process seems necessarily to be very variable.

VIII. — A slight trace of chloroform in the air passed through the mixture of sewage-water and activated sludge is sufficient to prevent the formation of nitrates.

In one of his experiments, M. CAMBIER exposed sewage for 1 hour to a current of air almost saturated with chloroform, and then for 4 hours to a strong current of pure air in order to free the water from all trace of chloroform, after which, it was mixed with very "active" sludge and aerated for 16 hours. The ammonia was fixed, but no nitrification took place.

The experiments made by the author for the purpose of isolating the nitric ferments from the activated sludge gave no positive results.

It thus appears that there are some serious objections to be opposed to the generally-received idea that nitric fermentation takes place during the course of the purification of sewage water by means of activated sludge. It is permissible to believe that the ammonia and other nitrogen compounds in sewage water, which are first fixed by the sludge during the early phase of purification, can later be oxidised and transformed into nitric acid by the oxygen of the air blown into the mass. In a subsequent paper (IX), M. Cambier has shown how this oxidisation is encouraged, if not determined, by the oxidisation of certain substances present in activated sludge, especially sulphide of iron.

IX. — Activated sludges contain a considerable proportion of iron in the form of sulphide, which helps to impart to them their dark colour. When for any reason, their activity begins to decrease or cease, these muds not infrequently assume a reddish hue due to the presence of ferric hydrate. Everything (acidity of surroundings, heat, coagulating agents, etc.), that tends to destroy the iron sulphide, or change its physical condition, also tends to destroy the activity of the mud.

M. Cambier has sought to find out whether the addition of iron sulphide to sludges with little "activity" would not restore their purifying properties or their nitrifying power. He found that the reactivation of the mud exactly coincided with the introduction of iron sulphide, both as regards the fixation of the ammonia and its subsequent nitrification.

He finally observed that sewage-water to which sulphide of iron had been added, in the absence of activated sludge was not purified in any way. Under these conditions, the ammonia is not oxidised by the current of air, although the small amount of sulphide of iron is entirely transformed into ferric hydrate.

X. — M. Cavel attempted to discover whether the transformation of ammonia into nitrous and nitric nitrogen is the work of bacteria. He states that the addition of sludge followed by activation by a current of air brings about the above-mentioned change, even in sewage-water that has been sterilised, either in an autoclave, or by passage through a Chamberland filter.

On sprinkling fresh sludge on slag moistened with "active" sludge, and blowing in air, the activation of the fresh sludge was brought about in 3 days

All these facts seem to show that disappearance of ammonia during the purification of sewage by the activated-sludge method is due to bacteria. The medium in which the preceding experiments were made was alkaline, which is the normal reaction of sewage. If the reaction is changed by the addition of a little acid, the results are no longer the same; no change takes place in the ammonia, the amount present remaining the same, which is in accordance with what we known from Christensen respecting the susceptibility of Nitrobacter to an acid medium.

XI. — Courmont, Rochaix and Laupin who studied from the hygienic standpoint the bacilli of the typhus and paratyphus groups, and the vibrion of cholera, have reached the following conclusions:—

1) At the termination of the chemical purification (which was always after 6 hours in their experiments), the pathogenic micro-organisms of the typhus-paratyphus groups were nearly always present in the effluent, but the cholera vibrion had disappeared.

2) The late disappearance of the typhus and paratyphus bacilli, and cholera vibrion, do not seem to depend on aeration in the presence of

activated sludge, but essentially upon the active competition of other micro-organisms.

XII. — Because town sewage is mixed with industrial waste water, which contains many antiseptic substances, M. DIÉNERT has studied the effect of certain antiseptics used in England and America for purifying the sewage of cities, upon the activated sludge.

If 3 parts of sewage-water containing 0.5 % carbolic acid are added to 1 part of activated sludge, and air is bubbled through the mixture, the ammonia and carbolic acid disappear slowly, but without any formation of either nitrous or nitric acid.

If instead of adding carbolic acid to the water in the first place, the antiseptic is introduced during the course of nitric fermentation, this is arrested and the ammonia continues to disappear but much more slowly, and without leaving any traces.

When carbolic acid is added to sewage-water that has been wholly freed from ammonia by nitrification, and nitrous acid is introduced, the latter is transformed into nitric acid with the same rapidity as if no carbolic acid were present. This antiseptic only prevents nitrous fermentation. As soon as the carbolic acid is removed by a current of air, the latter pro cess begins once more. Nitric fermentation is not affected by weak doses of carbolic acid.

The ammonia that disappears from the sewage-water owing to the action of activated sludge, in the presence of carbolic acid, vanishes, without leaving any traces, either in the water or the mud.

If carbolic acid is allowed to act upon activated mineral powders, expecially on pure manganese dioxide obtained from the nitrate, the same results are obtained as in the case of activated sewage mud. Should pure untreated $Mn O_2$ (whether sterilised or not) be substituted for the activated $Mn O_2$, air can be blown through it for 15 days without any of the ammonia disappearing.

These experiments prove that activated $Mn O_2$ oxidises the ammonia when under the influence of bacterial action. Since in the author's experiments, the bacterial action of activated $Mn O_2$ was precisely similar to that of the activated sludge of sewage water, he thinks he may safely state that the bacterial nature of nitric fermentation may be considered absolutely proved.

As regards the loss of the ammonia which is not found again in the form of nitrous, nitric, or ammoniacal nitrogen in the mud, or sewagewater, this is not an absorption phenomenon, but appears also to be due to bacterial action.

1080 - **Pellagra in Lombardy and Tridentine Venetia Since 1900.** — DEVOTO, L., in the *Rendiconti del Reale Istituto Lombardo di Scienze e Lettere*, Third series, Vol. LIV, Parts VI-X, pp. 239-242. Milan, 1921.

Cases of pellagra, which were still very numerous both in Lombardy and the Province of Trent during the last forty years of the past century, began to decrease with the beginning of the new century, and continued to become rarer, even during the war, so that it may now be stated that this disease, which has existed in Italy for over two hundred years, has at last completely disappeared, and its re-occurrence will be prevented by careful supervision

In 1899, there were still about 40 000 cases of pellagra in Lombardy, and 10 000 in the Province of Trent. In 1920, not a single case of the disease was to be found in either, so that the Hospitals for patients suffering from pellagra in Rovereto and Inzago, respectively, have altered their names, and are used for other purposes.

The Italian anti-pellagra legislation (which was immediately adopted and applied by Austria to the Province of Trent) was based on the work of CESARE LOMBROSO, who demonstrated that the disease was due to the use of spoiled, mouldy maize. Though there are still some points that remain obscure respecting the complicated connection between maize and pellagra, it is nevertheless true that the results of Italian legislation are the best confirmation of the truth of the discoveries of LOMBROSO, and his school, to which the author belongs.

LOMBROSO's work should, in the author's opinion, be completed at the present time in the following manner. — *Practically*, by observing whether the use of sound maize can cause a recrudescence of the malady in persons who have formerly suffered from pellagra, or aggravate it in the case of patients in whom it is clearly developing; *Theorically*, by determining whether the intense and prolonged use of sound maize can be the origin of the disease.

1081 - **The Institution of a Laboratory for Scientific Research in Galicia, Spain.** — *Fl Cultivador moderno*, Year XI, No. 8, p. 12. Barcelona, August 1921.

The *Junta por Ampliación de Estudios* (Commission for the Development of Study) has instituted a Laboratory of Scientific Research in Galicia. This Laboratory is intended to devote its attention to the study of matters relating to agriculture, horticulture, stock-breeding, fish-rearing, etc. The Institute is installed on the premises occupied by the Veterinary College of Santiago.

The same Commission has intrusted to M. CRUZ GALLÁSTEGUI (who has studied the methods adopted in the United States) the work connected with the selection of maize.

CROPS AND CULTIVATION

1082 - **Temperature Survey and Length of Growing Season in the Salt River Valley, Arizona, U. S.** — GORDON, J H., in *Monthly Weather Review*, Vol. 49, No. 5, pp. 271-274, graph 1, figs. 2. Washington, May 1921.

The completion of the Roosevelt Dam and distributing canals in the Salt River Valley early in 1911, marked the beginning of an era of rapid development of the section round Phoenix (Arizona).

Large plantations of citrus fruits, sugar cane and sugar beets were made, and decidedly important cultural tests were conducted, including the growing of figs, vines, olives, dates, cotton and several other crops.

The winters of 1911-12, and 1912-13 were unusually severe, putting to a serious test the experiments in hand. Need was felt for a more definite knowledge of atmospheric conditions in order to make it possible to take the necessary steps to arrive at a rational adaptation of crops to prevailing climatic conditions.

The work was started in the autumn of 1913 by R. R. BRIGGS " to determine the area and limits within which the highest money value crops could be grown. "

Upon the basis of records kept up till the end of the survey in 1919-20, it was found possible to prepare a map of the area showing the isotherms and the length of the growing season. There has already been a wide demand for this map which has helped the growers in the choice of the best locations for citrus plantations, etc.

Surveys were made with the use of ordinary thermometers and thermographs at 42 stations

TEMPERATURE RECORDS. — The average minimum temperatures for December and January were taken, owing to the fact that these were the coldest months of the year and also because for these months more complete figures were available. It has not been found possible to utilise the records from all the stations, as in some cases they were too short to give a fair mean; those utilised however included records made in areas covering periods of 16 to 25 years, which have given ample opportunity for the summing up and control of the data collected during the surveys from 1913-20.

The mean minimum temperatures do not however particularly interest the farmers; the most vital question is to become acquainted with the absolute low temperatures which may prove fatal to certain crops.

The relationship however between these temperatures and the mean minimum is very close, with a difference almost constant of about 11° F. This is shown in Table I.

TABLE I. — *Comparison of mean minimum and absolute minimum temperatures.*

Station	Record period	Mean minimum temperature	Mean absolute minimum temperature	Difference
	Years	°F	°F	
Granite Reef Dam	21	40.0	28.8	11.2
Phoenix weather Bureau	25	38.5	28.0	— 10.5
Phoenix nº 2	6	37.5	26.6	— 10.9
Gould's Ranch	5	37.0	25.8	— 11.2
Mesa	18	36.0	25.4	— 10.6
Higley	5	36.0	24,8	— 11.2
Tempe.	15	35.0	24.4	— 10.6
Phoenix nº 1	18	34.5	23.4	— 11.1
Chandler	6	33.0	23.1	— 9.9
Average difference	—			— 10.8

Not only will the temperature map enable the farmer to make a wise choice of locality the least liable to frost attack, but it may also be used, with the necessary alterations, in the forecasting of frost.

LENGTH OF THE GROWING SEASON. — The Phoenix Weather Bureau serves as a base with temperature of 38.5° F, and 288 days as the average length of the growing season.

TABLE II. — *Length of the growing season.*

Stations	Record period	Mean minimum temperature	Season as compared with Phœnix
	Years	°F	*Days*
Granite Reef Dam	16	40.0	+ 5.0
Phœnix weather Bureau	25	38.5	0.0
Phœnix n° 2.	5	37.5	— 1.2
Gould's Ranch	5	37.0	— 2.8
Mesa	11	36.0	— 17.5
Higley	5	36.0	— 18.5
Tempe	14	35.0	— 19.0
Phœnix n° 1	11	34.5	— 22.0
Chandler	5	33.0	— 31.0

Temperature maps such as those described in the present article may serve a very valuable purpose, not only for the grower, but also for the health seeker, as they contribute to a wider knowledge of the climatic conditions prevailing in various districts from the bio-geographical standpoint.

1083 - **Investigations Concerning the Critical Period of Wheat at College Park, Maryland, U. S.** — SANDO, W. I., in *Monthly Weather Review*, Vol. 49, No 5, p. 301. Washington, May 1921.

During the autumn of 1920, a careful study for the purpose of ascertaining the relation of climate to the yield of wheat was undertaken at the Maryland Agricultural Experiment Station at College Park. Four varieties of wheat were observed. The records cover a period of 12 years.

Correlation coefficients for temperature and rainfall for each month of the growing period were determined for each variety.

A significant negative correlation was found between rainfall and yield for March and May, but was not evident between temperature and yield.

Other factors were also investigated, but further study will be necessary before their actual relation to yield can be determined.

1084 - How to Forecast the Total Yield of Cotton from Weather Records in November.

— KINCER, J. B., in *Monthly Weather Review*, Vol. 49. No. 5, pp. 295-299. Washington. May 1921.

On the following dates, viz. :—

September 1 — September 25 — October 15 — November 1 — November 14 — December 1 — December 13 — January 1 — January 16 and March 21, the Bureau of the Census, Department of Commerce U. S., issues a succession of reports on the harvest or ginning of the cotton crop, followed by a final report showing the total production (1).

In the present case, the author gives the results of a study to establish: 1) the relation between the weather conditions and the amount of cotton ginned between November 1 and December 1 (the two earliest periods of the harvest season); 2) the relation between the cotton ginned up till the end of November and the total output.

The calculations are made with reference to the 15-year period 1905-19 and concern the 10 Cotton-belt States: North Carolina, South Carolina, Georgia, Alabama, Mississipi, Louisiana, Tennessee, Arkansas, Oklahoma and Texas.

The frequency of the rainfall and the amount of cloudy weather are very closely associated to a negative degree with the cotton harvested or ginned in a given period. In the course of his investigations, the author refers to the average number of cloudy and rainy days in November.

During the period in question, the average annual cotton production was, in round numbers, 12 340 000 running bales (2); the average number of bales ginned prior to November 1 was 7 788 000 (63 % of the total crop); the average amount unginned on November 1 was 4 553 000 bales, 57 % of which was ginned during November. This latter percentage varied greatly from year to year, depending on atmospheric conditions, either favourable or unfavourable for picking and ginning, and in very close relation, as previously mentioned, with the frequency of rain and clouds.

With a knowledge: —

A) Of the actual amount of cotton ginned during November (as indicated in the Bureau of Census reports for November 14 and December) ;

B) Of the percentage relation between this amount and the total remaining unginned on November 1 (as calculated from the weather records), the quotient obtained by dividing *A* by *B* gives an indication of the actual total remaining unginned By adding to this the amount ginned prior to November, the computation for the total yearly crop is established.

A study of the prevailing weather in November would permit the forecasting of the yield of cotton some months in advance of the harvest.

A series of tables is given for the 10 states in the Cotton belt.

In North Carolina the rainy days were in 1905, 4 and the number of cloudy days 8.

---

(1) See *R.* June 1918, No. 622. (*Ed.*)

(2) *Running bale* = bale of 500 lb. (*Ed.*)

In view of the fact that wide variations exist in the amount of cottons harvested in the respective States, the averages of meteorological data obviously could not logically be combined on an equal basis for the purpose of correlation with the ginning reports.

To establish a more reliable comparison ratio, the meteorological value of each State is multiplied by the amount of cotton ginned in November, expressed in % of the total quantity of ginned cotton in the 10 afore-mentioned States, and the value obtained is then divided by 10 (See Table I).

If the correlation coefficient between these percentages and the average number of rainy and cloudy days (as shown in the last right-hand column of Table II : 7.2 ; 6.3 ; 9.3 etc.) is calculated, using the generally recognised formula, the result will be − 0.91 ± 0.03, a distinctly high negative correlation coefficient. The percentage of cotton produced and ginned should therefore be all the less when the number ot rainy and cloudy days is high.

The letter r indicates the number of rainy days and y the quantity of cotton ginned in November and expressed in % of the total amount of unginned cotton on November 1.

The preparation of a dot chart to determine the relation existing between the 2 quantities, shews that the dots dispose themselves diagonally across the chart with a considerable uniformity of arrangement and that a very clearly definited straight line relation exists. (See annexed graph).

TABLE I. — *Computations of the Cotton ginned during November* 1905-1919, *in % of total amount of unginned cotton on November* 1.

1905	55.3%	1909	60.9%	1913	63.2%	1917	62.2%
1906	51.4	1910	66.2	1914	53.4	1918	43.4
1907	44.9	1911	51.0	1915	63.0	1919	50.6
1908	57.6	1912	64.6	1916	63.1		—

The dot chart, indicates that the constants of the oblique line in the figure (which fits bests to the data in hand) may be determined by the equation $y = a + br$ with only 2 unknown quantities.

Table III shows the constants of the equation (r, y, r^2, ry).

The following series of equations is forthcoming. (n = number of years, etc).

$$y = a + br \quad \ldots\ldots\ldots\ldots\ldots \quad \text{I}$$

$$b = \frac{n\ (\Sigma\ ry) - (\Sigma\ r)\ (\Sigma\ y)}{n\ (\Sigma\ r^2) - (\Sigma\ r)^2}$$

$$a = \frac{\Sigma\ y - b\ (\Sigma\ r)}{n}$$

TABLE II. — *Mean of cloudy and rainy days according to percentage ratio of cotton ginned during November.*

Year	orth Carolin	uth Carolin	Georgia	Alabama	Mississippi	Louisiana	Tennessee	Arkansas	Oklahoma	Texas	Total	Average for Cotton-belt
1905	4.8	5.0	8.4	8.0	10.2	3.8	3.0	7.0	4.0	18.0	72.2	7.2

1913	2.8	3.0	5.6	3.5	5.4	2.2	3.6	8.0	8.6	17.1	59.8	6.0
1914	5.2	6.5	9.1	7.5	9.6	3.6	4.0	6.5	3.2	16.2	71.4	7.1
1915	4.0	4.0	5.6	5.5	7.8	2.2	3.8	7.5	2.2	6.6	49.2	4.9
1916	4.8	5.5	7.7	5.5	6.0	1.4	2.6	5.5	4.0	7.6	50.6	5.1
1917	4.4	4.5	5.6	4.5	6.6	1.2	3.4	6.5	4.5	4.8	46.0	4.6
1918	4.8	8.0	11.9	8.0	9.6	3.6	4.0	8.5	6.8	18.0	83.2	8.3
1919	4.8	4.5	9.8	7.5	10.8	3.2	4.2	8.5	6.3	13.3	72.9	7.3
Average	202	254	355	243	299	104	92	236	223	484	2492	
Percentages . . .	8	10	14	10	12	—	4	10	9	19	100	

Substituting in equation 2 gives :

$$b = \frac{15\ (5\,276.0) - (95.6 \times 850.8)}{15\ (643.7) - (95.6)^2} = \frac{-21\,965}{516.1} = -\ 4.26.$$

Substituting in equation 3 gives :

$$a = \frac{850.8 - (-\,4.26 \times 95.6)}{15} = \frac{1258.1}{15} = 83.9.$$

The application of these constants to the weather data grouped under r in Table III permits the computations for y for each year.

Column 1 : Amount of cotton ginned during November :

Column 2 : Computed percentage of cotton remaining to be ginned on November 1, that was to be ginned during November (computed from equations in Table III applied to weather data).

Column 3 : Computed amount remaining unginned on November 1 (*Column* 1 divided by *Column* 2).

Column 4 : Amount ginned prior to November 1.

Column 5 : Computed total crop (Column 3 + Column 4).

Column 6 : Total crop as reported by the Bureau of Census.

Column 7 : percentage of error in computed amount.

Dot chart showing the relation between the number of rainy and cloudy days in November and the percentage of cotton remaining to be ginned in November, that was ginned during November.

TABLE IV. — *Computation of the total cotton production by the application of the constants of the equation of the straight line (shown in Table III) to the weather data and ginning reports for November.*

1905	2,232	53.2	4,195	6,458	10,653	10,495	+ 1.5
1906	3,122	57.1	5,468	6,906	12,374	12,983	— 4.7
1907	2,214	44.3	4,998	6,129	11,127	11,058	+ 0.6
1908	2,817	57.5	4,899	8,192	13,091	13,086	± 0.0
1909	1,859	60.9	3,053	7,018	10,071	10,073	± 0.0
1910	2,794	62.6	4,463	7,346	11,809	11,568	+ 2.1
1911	2,846	46.8	6,081	9,971	16,052	15,553	+ 3.2
1912	2,986	66.0	4,524	8,869	13,393	13,489	— 0.7
1913	3,258	58.3	5,588	8,830	14,418	13,983	+ 3.1
1914	3,246	53.7	6,045	9,827	15,872	15,906	+ 0.2
1915	2,325	63 0	3,690	7,349	11,069	11,068	± 0.0
1916	1,728	62.2	2,778	8,624	11,402	11,364	+ 0.3
1917	2,529	64.3	3,933	7,185	11,118	11,248	— 1.2
1918	1,794	48.5	3,699	7,777	11,474	11,906	— 3.6
1919	2,539	52.8	4,809	6,305	11,114	11,326	
Average	—	—	—	—	—	—	1,5

It is therefore clearly demonstrated that by means of data concerning the cotton yield in November and weather data for the same month, it is possible to calculate to a large extent the final output.

1085 - **Nicolaidi Sacks, a Protection Against White Frosts in Spring** (1). — I. PARESCHI in the *Giornale di Agricoltura della Domenica*, Vol. XXXI, No. 12, pp. 20. Piacenza, March 20, 1921. — II. CALZONI, A., in the *Rivista di Ampelografia*, Vol. II, No. 7, pp. 99-101. Alba-Livorno, July 1, 1921.

I and II. — NICOLAIDI sacks (Magia brand) are filled with thread ravellings, tar and fatty substances. In burning they produce columns of very thick smoke that hang above the ground for half an hour or longer. The smoke may extend over on area of 2-3 hectares, but it is quite innocuous. These sacks can be used in the open, if they are put upon a stand made of 4 branches in the form of a cross, and covered with tarred paper. They are lighted very rapidly and simply by a friction fuse with which each sack is provided. These sacks ought not to be expensive, for they are filled with the waste products of certain industries, and in any case, seeing that the injury wrought by a white frost may affect the harvest of 2 or 3 successive years, the money spent on this protective device is certainly of little importance.

---

(1) For the use of smoke-generating candles for the same purpose, see *R.* April 1921, No. 365. (*Ed.*)

1086 - **Colloidal Clay in Agricultural Soil.** — De Angelis D'Ossat, G., in the *Stazioni sperimentali agrarie italiane*, Vol. LIV, Parts 4-6, pp. 214-224. Modena, 1921.

The author gives an account of the experiments carried out on this subject by various investigators, and shows wherein he differs from some of their conclusions. He then describes his own researches, and states that, from the results of his work and that of others, he has arrived at the conclusion that clay may be regarded as a zeolitic substance or one of very similar nature which cannot by means of the swelling of its colloidal elements act upon the fundamental structural characters of the soil to the point of reducing the distance between the particles beyond the lowest limit (0.000,05 mm.) established by Quincke for molecular action. On the other hand, from the physical and chemical facts determined experimentally by several mineralogists (Zambonini, etc.), it seems reasonable to suppose that zeolites may have a micellar structure similar to that of colloids. Clay, being hydrated in the same way as zeolites, takes up water by capillarity and adsorption (molecular) which renders it impermeable to other water, as occurs in the case of crystalline substances of a similar nature.

The chief factors bringing about changes in clay are heat and pressure; the action of heat may be subdivided under the following heads:— Temperature, evaporation, insolation, congelation. In the case of rocks, it is necessary, as far as possible, to regard pressure as distinct from thermic action.

The author considers the effect of each of those factors separately, and concludes that the alterations they cause in the colloidal clay are responsible for the different properties of rocks and agricultural soils.

Colloidal clay takes up water by capillary and molecular imbibition, and may lose it again, wholly or in part, through evaporation and dehydration. In the first case, the colloidal clay becomes impermeable to external water and to gases, in the second, it once more becomes permeable to both. The two cases correspond to the two typical structures of Wollny and Hilgard, and as the author says, to explain them it is quite unnecessary to have recourse to hypotheses which are not supported by any of the current views respecting colloids.

The changes taking place in colloidal clay as a result of the combined action of heat and pressure, sufficiently account for all the physical properties of clay soils, and their relation to productivity.

1087 - **Ammonia-Absorbing Capacity of Soils.**— Petit, A., in the *Annales de la Science agronomique*, Year 38, Series 6, No. 1, pp. 20-35. Paris, January-February 1921,

It is often maintained that lime must be present for the soil to be able to fix alkaline bases combined with strong acids . Were this the case, acid soils like those of moors, would be incapable of retaining ammonia, or the potash from fertilisers containing mineral salts. A certain number of experiments have however shown that this assertion is somewhat too sweeping.

The question is one of great interest to horticulturists, who use moor-soil for so-called lime-shunning plants. The author has also begun to study the question, and has taken the opportunity of determining how far different factors affect the ammonia-absorbing capacity of soils.

In his experiments he used:— 1) Moorland soil composed of siliceous sand and decomposing vegetable matter, and having a distinctly acid reaction; 2) crude kaolin, only passed through a sieve with meshes of 1 mm., which when damp turned litmus red. Those substances were free from lime. At the beginning of the experiments, the moor soil contained some ammonia; the amount increasing with the course of time.

The results, which were not always in accordance with received opinions, were as follows:—

1) Moor soil readily yields up its ammonia to water, and the process is encouraged by the presence of different salts used as fertilisers, such as potassium chloride, sodium nitrate and lime.

2) Moor soil and kaolin, which are both lime-free, and have an acid reaction, are nevertheless capable of fixing ammonia combined with sulphuric acid, but this power is partly masked in the case of moor soil by the ammonia the latter gives up to water.

3) Treatment with hydrochloric acid does not deprive either moor soil or kaolin of their power of absorbing ammonia combined with sulphuric acid.

4) The addition of lime only slightly increases the capacity for absorbing ammonia combined with sulphuric acid in the case of the moor soil, and has no such effect for the kaolin.

5) The addition of lime decreases the free ammonia fixing capacity of both moor-soil and kaolin.

6) When the moor soil has no ammonia to give up to the water, weak ammoniacal salt solutions are more impoverished by its absorbent power than concentrated solutions.

7) The fraction of ammonia that is fixed decreases when the volume of the salt solution is increased, and diminishes when the weight of soil taken is augmented.

1088 - The Nature of Soil Acidity with Regard to Its Quantitative Determination. —

MACINTIRE, W. H. (University of Tennessee Agricultural Experiment Station, Knoxville, Tenn.), in *Journal of the American Society of Agronomy*, Vol. 13, No. 4, pp. 137-161, bibliography of 74 publications. Lancaster, Pa. April, 1921.

In recent years no one phase of soil chemistry has received more attention than the problem variously referred to as lime requirement, soil acidity or lime absorption coefficient. The problem can hardly be considered however as having solely a chemical or physico-chemical basis in its relation to soil fertility, for it is closely correlated with, if not inseparable from, both bacteriological and plant physiological considerations. Until very recently, if even now, little effort has been made or opportunity offered for concerted authentic action to clarify this intricate problem and to adopt terms or phrases which convey a definite and accepted meaning for the several possible causes and the possible differential intensities of the reactions responsible for the soil condition known most commonly as acid. In the past, the study of so-called "soil acidity" took direction largely from the isolated and academic viewpoint of the laboratory worker seeking to establish reactions and to determine their speed and extent. Nevertheless in much of the more recent work, special emphasis has been placed upon correlations with bacterial and plant-response factors. It is the purpose of this paper to offer briefly the chronological development of most of the viewpoints and hypotheses advanced and conclusions maintained, with or without subsequent modification, by those who have reported upon this topic.

As to mucks and peats poor in alkali and alkali-earth bases the acidity cannot be considered on the same basis as rock-derived soils. The organic contents of peats and mucks possess acid, or base fixing, properties. It is a moot point whether such acidity is caused by adsorption or by true acids.

Considering rock-derived soils it may be concluded:

1) Although salts of a number of organic acids have been isolated from soils, no one definite free organic acid has ever been extracted, If all of the organic carbon in many soils was considered as being a constituent of a definite organic acid, the hypothetical acid so calculated would be equivalent to only a fraction of the amount of acidity determined by different methods of procedure.

2) In practice, certain salts produce a decrease of soil acidity (sodium nitrate, potassium nitrate, etc.) though in the laboratory treatments during short periods followed by extractions, the reverse may be true, while the addition of certain other neutral salts produced an increase in acidity in both laboratory and field, due to removal of native bases or amphoteric elements.

3) Removal or adsorption of dissolved bases by soils appeared to be a chemical function of acid silicates, principally alumino-silicates, the extent of whose hydration is a controlling factor in initial intensity and continuity of reaction. The acidity of soils is, in the main, induced by the loss of calcic and magnesic inorganic salts, derived originally from the hydrolysis of the alkali-earth siliceous complexes, thereby increasing the acid properties or amount of acid silicates.

4) Where the base and its combined radical are added in water solutions to soils, and in equivalence, with reference both to mass and degree of dissociation, the adsorption of basic ions may be considered as of near equivalence. But when alkali-earth carbonates (calcium and magnesium carbonates) are subjected to moist and intimate contact with acid soils, the active masses will vary in amount and degree of dissociation, while the precipitated products of the reactions will vary in their solubility, or tendency toward reversion through hydrolysis and recarbonation; hence, the difference in attaining and maintaining equilibria and the disparity in the extent of the reactions, which will vary markedly from chemical equivalence in a given time.

5) Silicic acid in mass will progressively hydrolyse and continue to decompose calcium and magnesium carbonate when the liberated car-

bonic acid is removed from solution. This acid will pass from the solid to solution phase yielding hydrogen-ion concentration and is capable of effecting an inversion of cane sugar.

6) After intense alkali treatments and the removal of excess of hydrates and after intense heating, pure silica, silicates, and titanium oxide will, on the addition of water, hydrolyse and act as acids towards the alkali-earth bases.

7) Many acid soils will yield aqueous extracts, alkaline to some of the common indicators, but showing hydrogen-ion concentration by electrometric or colorimetric methods. The hydrogen-ion concentrations of acid soils are not generally considered as being of such intensity as to be of direct detriment to higher plant life, though they may affect the growth of bacteria and fungi.

8) The injurious effect of acidity may be attributed in some instances to aluminum and other toxic salts, but, in general, more particularly to the diminished supply of available calcium from the depleted lime content of the soil, as influencing the adaptability of the media for biological development and the meagreness of the lime as plant food, or as an essential regulatory component of the plant juice.

9) The formation of organic acids and the generation of mineral acids, such as nitric, in soils may be conceded; but their occurrence within the soil seems to be of but brief duration, because of neutralization by native or applied basic materials.

10) The reactions between soils and alkali-earth carbonates are characterized by a more intense initial activity, with a continued and lesser intensity extending over a long period of time. Such variations have been attributed to different acids, of active and less active " avidity ", or to the greater immediate solubility and the lesser progressive solubility of silicic acid and its acid salts. An excess of basic carbonates may occur in a soil possessing slow reacting but potential, acidity, in the form of slowly hydrolysing and ionizing silicic acids and their hydrogen salts.

11) Finally, though it is not unanimously agreed, it seems to be the view of the majority that the laboratory determination of a soil's tendency to absorb, fix or neutralize lime is an academic consideration, without any definitely established quantitative correlation with field practice.

1089 - **Researches upon the Protozoa found in the Water of the River Tessin (Italy)- and the Lands Watered by it.** — COPPA, A., in the *Stazioni sperimentali agrarie italiane*, Vol. LVI, parts 4-6, pp. 181-213, 5 figs., bibliography of 17 publications. Modena, 1921.

The author has studied the protozoas to be found in the rice and " marcita " fields in the neighbourhood of Pezzana and Gravellone (near Pavia), and also in soils growing strawberries, heather, zinnias and haricots (in the Botanical Garden at Pavia), specimens being taken each month from February 1919 to the end of March 1920. He has discovered a total of 62 species, the majority were encysted, but living cultures were made in the laboratory. Heat and food are the most important factors in bringing about the de-encysting of these protozoa.

The geological nature of the soil has a certain influence in unicellular life. Soils in which silicates predominate are far more favourable than calcareous soils, particularly as regards actual numbers. Different types of fertilisers have no particular influence on the protozoon fauna. Temperature and osmotic pressure, calculated experimentally for various conditions and for various solutions of fertilisers are not sufficiently potent influences to permit the establishment of a facies of protozoa with definite characteristics for their various habitats. It is only possible to attribute definite characteristics to the types found in the rice-fields. Water is the main determining factor; as a matter of fact the 17 varieties belonging exclusively to the rice-fields (*Amoeba beryllifera, Difflugia acuminata, D. lobostoma, D. coronata, D. fallax, Lequereusia modesta, Arcella vulgaris, Arcella costata, Centropyxis aculeata, Volvox globator, Coleps hirtus, Spirostomun teres, Opisthodon niemeccensis, Loxodes rostrum, Urostyla weissii*) were found by Madam COPPA or other workers in fresh water.

Protozoa are conveyed in soils by passive agencies, among which water is the most important, being at the same time particularly favourable to their development.

The number of species of protozoa in the waters about Pavia discovered by the author in a year is 63. Of these three presented particular characteristics, not hitherto recorded by previous writers on the subject.

The author ascertained that the maximum development of unicellular life takes place in the Summer (June) and the minimum in Autumn (October).

Of the classified species, 35 are common to water and soil. Among these the Rhizopods occupy the first place. The majority of the aquatic forms observed in the soil belong to lands irrigated or submerged during a great part of the years, that is to say, in the water-meadows and ricefields.

Speaking generally there cannot be said to be any difference in the time when the same species make their appearance in different localities.

The varieties of protozoa in the Pavia district are essentially cosmopolitan. Certain species (*Ceratium hirundinella, Peridinium tabulatum*) exhibit seasonal variations.

1090 – **The Plough as a Means of Making Gradually Sloping Terraces.** — GIANNOBI, I. in *Il Coltivatore*, year 67, No. 23, pp. 133-138, 6 figs. Casale Monferrato, Aug. 20, 1921.

The author has made a study of a method of terracing (starting with a plantation at the outside) devised to avoid as far as possible the difficulties of the system which consists in cutting the hills across by rows of vines and by ploughing transversely between the rows. With this method, since the soil is constantly being turned from above, there is a gradual terracing of the slope, leaving between each pair of terraces a smaller level in which the rows of vines will have to grow. The general conditions are not, however, favourable. If the slope faces north the soil raised against the row will keep it in continual shade ; if it faces south, the exposure below the row with increase the already high evaporation in the soil ; in clay or clay-loam soils, during the early years of the plantation, water will lodge in the trenched soil ; finally a somewhat extensive area will be unavailable for the usual herbaceous crops.

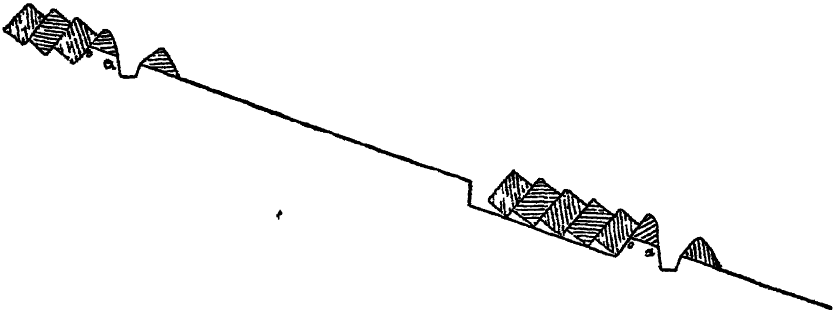

Fig. 1

The following method is suggested by the author to overcome these difficulties :

First, the surface of the hill, is divided transversely into sections of such breadth as will allow, when the terracing is complete, for a depth of slope not exceeding two metres.

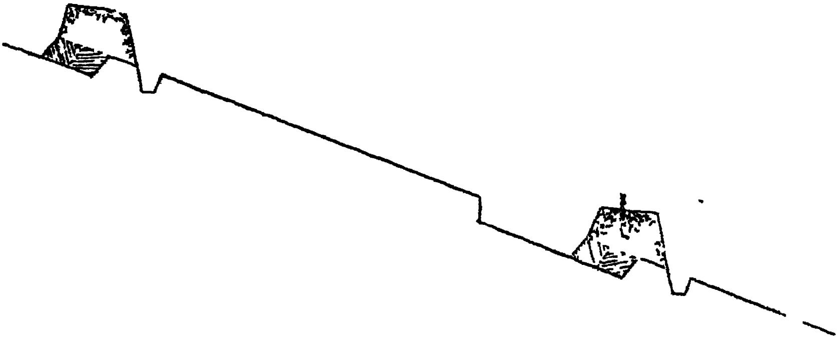

Fig. 2

The first furrow is cut by the plough immediately below the dividing line of each section (i. e. below point *a*, fig. 1). Other furrows follow the first above this line, leaving however intact the part *oa* (fig. 1) about 40 centimetres wide, to serve as a support for the slope of the turned soil. The number of these furrows should be such that the displaced soil, added to that from the first furrow below point *a* should be sufficient to form a more or less trapezoidal mound about 1.20 metres wide at the base and 60 cm. at the top, with a depth of about 30 cm. less than that which the terrace should have when finally established.

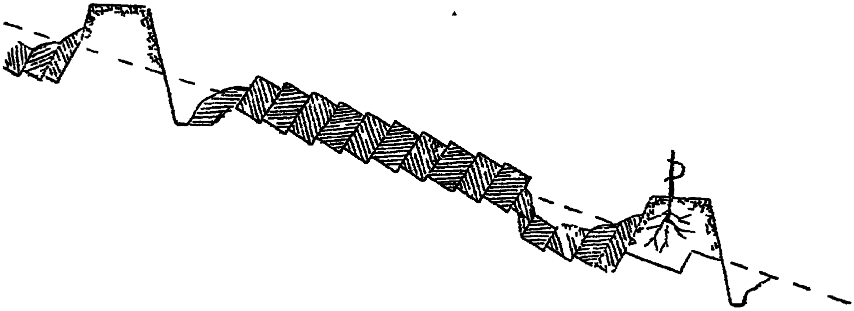

FIG. 3

The remainder of the ground, including that in which the furrows have been cut for the formation of the mound, will be worked in the ordinary way with a turnwrest plough as for the usual herbaceous crops. Afterwards, if time allows, cuttings or slips can be planted in the mound.

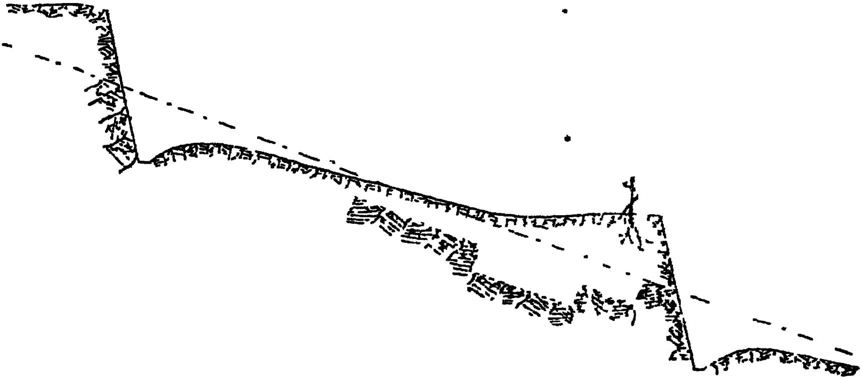

FIG. 4

The profile will then be as shewn in fig. 3. The work that follows will enable the horizontal profile to be gradually attained and in this way the terracing will be completed. At the final working the vines will be duly ridged up so as to give the mound its proper depth (figs. 4 and 5).

This method has the following advantages:

1) The construction of the mound is a simple matter of shovelling the earth already displaced by the plough and close to the mound. In the terracing of a 1:4 slope divided into sections 8 metres wide, a single workman was able to make 50 metres of mound in the day, while one workman by ordinary digging could not have done more than 5 or 6.

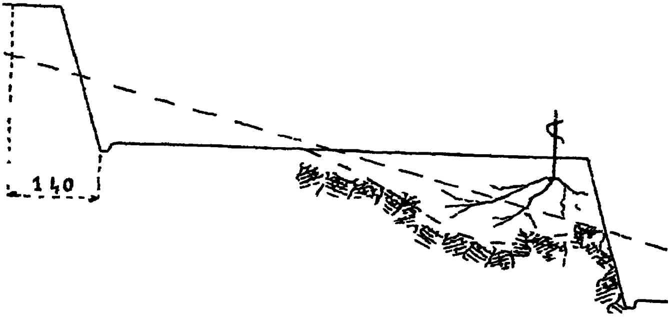

FIG. 5

FIG. 6

2) At the end of the working, the amount of displaced soil available for the planted row is twice as large as that obtained by digging a row in the ordinary way.

3) The amount of soil taken from the herbaceous crops is considerably less than that resulting from a form of terracing which is alternatively too wide for the herbaceous crops and too narrow for the rows of vines.

4) The first construction of several mounds across the slope ensures, beginning with the first year, against erosion or washing away by rain.

5) The grass border affords greater security for animals working close to the edge of the terrace and also for carts passing along the terrace.

6) Standing water is avoided in the built-up soil.

7) The soil which forms the mounds and is used by the roots of the vines all belongs to the cultivated layer.

This method is applicable to all exposures, except a southern. In this case, as in all other forms of terracing, the evaporating surface is unduly large, which is injurious in warm climates. In order that the young vines when first planted in the mounds may enjoy the most favourable conditions, the author recommends for the first two years the growing on the crossing sections such vegetables as admit of cropping towards the end of spring so that ploughing can immediately follow, providing fresh material for the mound and preventing it from becoming too dry.

1091 – **The Supply of Fertilisers and the Increase of Agricultural Production in Germany.** — HILTNER (Direktor der Landesanstalt für Pflanzenbau und Pflanzenschutz). in *Sonderabdruck aus dem* 6. *Sitzungsbericht des Bayer. Landwirtschaftsrates vom* 22 *Dezember* 1920. *IInd. Edition.* Munich, March 1921.

The author describes the present conditions of agricultural production from the point of view of the supply of fertilisers in Germany and particularly in Bavaria.

The fall in the cost of food stuffs, which is so much desired, can take place only when agricultural production shall not merely have reached but gone beyond the pre-war level. On the other hand despite all appeals for increased production there is in fact such a decrease from year to year, especially in cereal and potato crops that, if a remedy cannot be found, the results will be disastrous for the German people.

The causes of this situation which in the years to come will bring about grave difficulties in food supply are to be found in the various obstacles, which at present fetter agricultural production, e. g. shortage of labour, exceptional diminution of manure alike in quantity and quality, lack or insufficient application of fertilisers. These handicaps force the farmers more and more in the direction of extensive cultivation at a time when the food requirements of the German people, which can scarcely be met by the home production call, for a cultivation in its most intensive form.

During the last 6 years, land under cultivation in Germany received 1 500 000 tons of nitrogen and 1 600 000 tons of phosphoric anhydride less than the required amount and at best the deficit can only be made good gradually (1). To meet the extreme general need for nitrogen the whole German Empire had at its disposal for the season 1920-1921, 270 000 tons of nitrogen in the form of fertilisers, whereas the capacity for the production of synthetic nitrogen by the plants set up during the war would amount to 500 000 tons corresponding to the minimum annual requirements of German agriculture.

---

(1) According to MULLER LENHARTZ (Der Kreislauf des Stickstoffs pp. 29-32. Hanover, 1917) the average quantity of nitrogen consumed per hectare of land cultivated in the 30 chief crops would amount to 90 kg. annually which, multiplied by the 34 500 000 hectares under cultivation in Germany before the war, gave for the whole German Empire, a consump-

The lack of phosphoric anhydride is also particularly important because the production of basic slag has diminished in consequence of the loss of the iron-working aıeas in the west and the fact that superphosphates have to be prepared almost entirely with phosphate from overseas which are particularly expensive in consequence of the depreciated exchange. Basic slag is now 20 times dearer than before the war and superphosphates 33 times, taking into account the already high cost of pyrites which has to be imported. The total German consumption of phosphoric anhydride in fertilisers, which for the season 1913-1914 was 630 000 tons, was reduced in 1918-1919 to 230 000 tons and has latterly still further decreased. As the consumption of fertilisers had formerly been least in Bavaria, it is impossible in general to reckon on reserves of phosphate accumulated by previous heavy applications (2); in fact an examination of Bavarian soil, made in 1920, showed that more than half the soils which were tested were insufficiently supplied with phosphoric anhydride. In any case, if the Government is unable to co-operate in bringing down the cost of nitrogenous as well as of phosphatic fertilisers, some other mean of effecting a reduction must be devised or at least the payment of two-thirds of the cost must be allowed to stand over till after haıvest.

As regards the consumption of potassic salts however, there has been a marked increase lately in Germany: the increased price is only five or six times higher than before which is satisfactory provided there be no further augmentation. This result can be attained by increasing the

---

tion of nitrogen amounting to 30 050 000 quintals, in part constisting of the following items:

	Quintals		Quintals
Seed	862 500		
Atmospheric precipitation	414 000	By-products of gas industry	713 000
Bacteria from leguminous plants	9 500 000	Calcium cyanamide	150 000
Purin	1 275 000	Synthetic ammonia	63 636
Human urine	766 500	Imported nitrate of soda	100 000
Solid excrements	1 000 000		
Industrial waste products	1 000 000	*Total*	**16 744 636**

There is therefore, a deficit of 14 305 364 quintals of nitrogen which cannot be made good, unless there be in the soil other microbiological forces to supply the balance from the atmosphere.

(2) According to AEREBOE (Volksernährung, Stickstoffdünger and Stickstoffpreise, II. Deutsche Landw. Presse, XLVII, 101, pp. 688-689. Dec. 18, 1920) general conditions in Germany as regards phosphatic fertilisers are better than appears at first sight. He bases his argument on the conclusions drawn by GERLACH. According to these, if crops take out from the soil an average of 1 part of nitrogen, $^1/_2$ of phosphoric anhydride and $^1/_2$ of potash, it receives by way of compensation 1 part of nitrogen, 3 of phosphoric anhydride and 2.7 of potash and, as in practice phosphoric anhydride is not washed away by rain, a good reserve should have accumulated. (*Ed.*)

export which will of necessity increase production, due regard being paid at the same time to the loss of the Alsatian deposits. The first condition necessary for obtaining good results from potassic and nitrogenous fertilisers is an adequate reserve of lime in the soil. In Bavaria many tracts of cultivated or meadow land, as has been frequently demonstrated during the last few years, are poor in lime, a defect that should immediately be remedied by limeing and marling on an extensive scale. At the same time one must not lose light of the fact that a reduction in the price of nitrogenous and phosphatic fertilisers is not the only thing necessary, especially in countries where, as in Bavaria, small holdings predominate; the chief essential is an organisation ready to give technical assistance to every farmer.

1092 - **Italian Phosphate Mines in Egypt.** — CORTESE, E., in *La Minera italiana*, Year V, No. 1, pp. 14-24, figs. 14. Rome, Jan. 31, 1921.

Description of two phosphatic seams in Sebaieh, alongside the Nile, in Upper Egypt and in Kosseir near the Red Sea.

The content of tricalcic phosphate in the first mentioned is about 60 %; taken as a whole, however, the average may be limited to 58 and even to 45 %; occasionally it has been found to be as high as 70 or 73 %

All these phosphates contain however more than 2 % of sesquioxides of iron and aluminium, in some cases to the extent of 4 to 6 %. For sale purposes, 4 % has been taken as the mean, and it has been decided that a depreciation of 2 units of phosphate to 1 of sesqui-oxide should be applied only from 3 %.

At these places, a factory for the manufacture of tetraphosphate has been constructed in order to utilise the siliceous phosphates containing not more than 45-48 % of tricalcic phosphate, more than 1 million tons in the Nile districts. If the outlying districts are also considered, it is possible to count upon 2 million tons.

Other seams, showing very superior quality phosphate, have been noted in the *ouadi* (valleys) on the right bank of the Nile, and in the hills on the left bank of the Nile. Taking into account the difficulties of transport to the sea coast and the comparatively low phosphatic content, these seams have up till now not been exploied.

Along the Nile bank and at Djebel Agula, Djebel Hagarza and Djebel Gorn, there are very well marked seams, showing several phosphatic beds but in every case siliceous. Even along the caravan routes crossing the Arabian desert, inferior quality phosphates have been noted. Beyond the division of the river basin, in the direction of the Red Sea, the phosphatic zone reappears at Djebel Duai, where there is visible a large bank of grey phosphate at a distance of 30 km. from the sea coast. Then comes the seam at Djebel Narkeil, 12 km. from Kosseir, where the standard of phosphate varies to a large extent, but with regularity. It is stated that below this, there is a large layer of yellow phosphate varying round 53 % and other phosphates of the same type (6 in all), not exceeding 48 %, owing to the presence of silicate or other impurities. There is at least 1 million tons of this last type.

Following this come the grey siliceous phosphates in two beds, also to a limited extent, but the principal layer maintains a comparatively high content (64 to 69 %) with only very little silica, and only a 1 % average of sesqui-oxfdes of iron and aluminium; these may be considered therefore as very superior quality phosphates. As regards the white and grey phosphates, where these occur to a reasonable thickness, it is possible to count on 2 million tons, and even now the work executed has dealt with about 500 000 tons of phosphatic bed. The high quality and percentage of phospate compensates for the cost of transport from Kosseir to the Italian ports including the big tax levied at the Suez Canal.

1093 - **The Effects of Liming on the Availability of Soil Potassium, Phosphorus and Sulphur.** — PLUMMER, J. K. (North Carolina Agricultural Experiment Station, West Raleigh, N. C.), in *Journal of the American Society of Agronomy*, Vol. 13, No. 4, pp. 162-171, bibliography of 21 publications. Lancaster, Pa., Apr. 1921.

A discussion dealing with the important question of the effects of liming on the availability of soil potassium, phosphate, and sulphur.

The more recent research, embodying laboratory extractions with weak solvents, pot studies using a variety of plants as indicators of the concentration of the soil solution in potassium and the analyses of their ash, lysimeter experiments by which the production of potassium has been measured, and field tests, has failed to show that basic compounds of calcium and magnesium increase, by chemical action, to any practical extent, the availability of the soil store of native potassium.

More research needs to be carried out before we can say that additions of lime will reduce the necessity of applying soluble phosphates to the soil. As measured by yields, phosphates of iron and aluminum seem to be as available as calcium phosphates. It is very probably true that fixation of phosphatic fertilizers by colloidal absorption induced by iron and aluminium oxides is responsible for the failure of some crops to respond to phosphorus additions. Additions of lime to such soils undoubtedly flocculate some of these colloids, thus giving the soils a better physical condition for plant growth. Additions of lime before or after applications of soluble phosphates. have greatly increased the efficiency of the phosphatic fertilizer. When insoluble calcium phosphate has been applied, it seems that applications of lime have reduced the effectiveness of the phosphate in the majority of cases.

The scant data of lysimeter experiments only, which deal with the question of sulfate availability or conservation, seem to show that liming with small amounts of lime, both small and large amounts of magnesia, magnesium carbonate, limestone, dolomite, and magnesite, increases the solubility of native soil sulfate. Heavy applications of lime for a few years at least, apparently reduce this loss of sulphur from the soil.

1094 — **Leucite.** — GIANNOBI J., *La Leucite, Memoria premiata col Premio Cesare Zucchini della R. Università di Bologna*, pp. 56, bibliography of 74 works. Osimo, 1921.

Monograph upon: The Italian deposits of Leucite. (*La leucite in natura*); industrial utilisation of leucite (*La leucite nell'industria*); its utilisation by plants (*La leucite come fonte di potassa agricola*); its application to agriculture. (*La leucite nella sperimentazione agraria*).

In this last section, after quoting the results of the somewhat scanty previous researches (AMPOLA and DE GRAZIA, BERNARDINI, CARUSO, MONACO, GIGLIOLI, BANDINI, NAZARI, CECCHETTI, ANGELONI, BONOMI, FELCINI), the author describes his own investigations made on three plots in the years 1909, 1910 and 1911.

The following was the scheme of treatment per plot of 100 square metres:—

1) Control
2) Sulphate of ammonia, mineral superphosphate, potassium chloride
3) Nitrate of soda, mineral superphosphate, sulphate of potassium
4) Mineral superphosphate, leucite
5) Potassium sulphate
6) Sulphate of ammonia, nitrate of soda
7) Sulphate of ammonia, mineral superphosphate, leucite
8) Nitrate of soda, mineral superphosphate, leucite
9) Potassium chloride
10) Leucite.

Amounts per hectare: sulphate of ammonia Nos. 2 and 7, 200 kg.; No. 6, 100 kg.; nitrate of soda, Nos 3 and 8, 150 kg. No. 6,100 kg.: mineral superphosphate, 500 kg.; potassium chloride; No. 10, double application. The rotations were as follows: — On the first plot (sandy soil) Noé wheat, meadow clover and sainfoin combined (investigation abandoned); on the second plot (calcareous clay soil) Noé wheat, sulla and meadow clover combined, reproduced Rieti wheat; on the third plot (clay loam) Noé wheat, horsebeans, reproduced Rieti wheat.

The returns obtained, in grain for the wheat, in dry fodder for the grasses and in seeds for the beans justify the following conclusions:

1) Leucite is a powerful potash fertiliser comparable in its effects to Stassfurt salts (manure salts).

2) Its beneficial action is most pronounced in soil that is rich in lime, less in sandy soil and still less in clay soils.

3) Its effects begin to be shown after the first year and tend to increase with subsequent years.

4) In complete mixtures a combination of leucite with ammonium sulphate is preferable to one with ammonium nitrate.

In fact leucite either alone, or associated with other fertilisers has always held its own with other potash salts and has occasionally given better results. The varying action of leucite on the different soils that have been tested depends upon their physical, chemical and biological variations which are very difficult to analyse. The effect of leucite as a fertiliser tends to increase after the first year, and if it is found that the results in the second year are less satisfactory than in the first, there are cases in which the best results are given in the third year. It is possible therefore to ascribe the unfavourable results in the second year not so much to any weakening in its action as to the change of crop (leguminosae), for which Stassfurt salts would have been better than leucitic potash. The fact that leucite has a preference for sulphate of ammonia supports the theory of the comparative inefficacy of basic substances in lieu of leucitic potash, since it is more effective in conjunction with a salt that is physiologically acid such as ammonium sulphate than with a salt that is physiologically basic such as sodium nitrate which in the absence of leucite is not found in a complete mixture.

1095 - **Radioactivity Experiments in Spain.** — *Estación central de Ensayos de Semillas, La Moncloa, Madrid, Boletín trimestrial*, Year I, No. 2, pp. 7-8. Madrid, June 1921.

Experiments carried out by Prof. MUÑOZ DEL CASTILLO, of the University of Madrid, at the " Instituto agrícola de Alfonso XII " on 8 plots 4 sq. metres in area with maize; the height of the stalks, weight of the ears, and weight of 1000 kernels being the subjects of comparison. Radioactivity was produced by watering with water containing the chloride of the radioactive substance. The results are given in Table I.

TABLE I. — *Effect of Radioactivity on the Growth of Maize.*

Plot N°	Treatment	Average height of stem in metres	Number of plants per plot
1	Complete fertiliser	2.18	24
2	Complete fertiliser + rhodium	2.20	23
3	Complete fertiliser + thorium (50 gm. per hectare) .	2.16	23
4	Complete fertiliser + thorium (50 gm. per hectare) + rhodium	2.11	22
5	Complete fertiliser + thorium (48 gm. per hectare) + rhodium	2.28	24
6	Complete fertiliser + thorium (30 gm. per hectare) + thorium	2.40	22
7	Complete fertiliser + thorium (20 gm. per hectare) + rhodium	2.35	25
8	Complete fertiliser + thorium (18 gm. per hectare) + thorium	2.22	22

RESULTS OF THE EXPERIMENT. — 1) Plot No. 6, with 30 gm. of thorium per hectare, and plots 7 and 5 with 20 and 40 gm. of thorium, respectively per hectare showed the maximum effect of radioactivity as regards growth in height.

2) Plots 4 and 3 showed that quantities above 30 gm. of thorium per hectare have a toxic effect.

3) In plot No. 8 (10 gm. of thorium per hectare), the effect was negligible and the dose insufficient.

4) Comparison of plots 2 and 8 shows that if thorium is added to rhodium, even in small quantities, the effect of the latter is increased.

5) The result obtained from plot 1 can only be attributed to the

influence of the 1210.6 volts of gaseous radioactivity observed in this plot, the same influence made itself felt also in plot No. 5; on the other hand, no such effects were noticed in plots 4 and 8, where the radioactivity only amounted to 636 volts.

Table II gives the effect of radioactivity upon the ears; this being to some extent masked by that of hybridisation.

TABLE II. — *Effect of Radioactivity Upon Maize Production.*

Plot No	Weight of 6 white ears in gm.	Weight of 6 red ears in gm.	Weight of 100 white kernels in gm.	Weight of 100 red kernels in gm.
1	937	927	298	283
4	1866	1273	315	400
5	966	911	287	281
6	1107	1389	275	469
7	994	930	283	367
8	961	1110	236	256

1096 - **The Condition of Chlorophyll in Plants.** — LUBIMENKO, V., in the *Comptes rendus de l'Academie des Sciences*, Vol. 173, No. 6, pp. 365-367. Paris, August 8, 1921.

From the experiments described in this paper, the author draws the conclusion that chlorophyll is intimately connected with the protein substances of the plant and that this connection is probably of a chemical nature. It is also most likely that the chloroplasts of normal green colour only contain a single green pigment that is easily decomposed through the action of all those agents that coagulate protein substances by merely producing some alteration in them. This decomposition of the natural pigment is shown by a greater or less change in its optical qualities and its absorption spectrum. Chlorophyll *a* and *b*, as well as a series of variable yellow pigments, are probably only derivatives of a single original green substance which, judging from the absorption spectra, would seem not to be the same in all green plants. The author's researches on the absorption spectrum of living leaves have shown that the spectrum varies greatly in the leaves of different species of plants, and in all likelihood, these optical variations are due to chemical variations in the protein substances with which the green pigment is connected.

1097 - **The General Presence of Manganese in Plant Tissues.** — BERTRAND, G., and ROSENBLATT, M., in the *Comptes rendus de l'Academie des Sciences*, Vol. 173, No. 5, pp. 333-336. Paris, August 1, 1921.

According to MAUMENÉ (*Bull. Soc. Chim.* Series 4, Vol. 9, p. 361, 1911), there are some plants in which no manganese is found. Some of these plants are of quite ordinary chemical composition such as orange and lemon trees, whereas others like garlic and onion, etc., contain sulphohydric, or sulphocyanhydric compounds. Bran, the receptacle of the strawberry, and the leaf-tissue of the cabbage are also free from manganese according to MAUMENÉ.

In view of the importance of these exceptions (if they actually exist) from the standpoint of the biochemical action of manganese and further, that MAUMENÉ determined the presence of this element merely by observing the green colouration of ash heated to melting point (so that probably he had failed to detect its presence in ash that was not sufficiently alkaline, or was fused with difficulty), the authors made a further study of the question, and found manganese in all the plants analysed, amongst which were those mentioned by MAUMENÉ as not containing it.

" It may therefore be affirmed as a result of all the work hitherto published on the subject that manganese is of general occurrence in plants, being present, not only in all the various species, but also in all their organs. "

1098 – **The Nature and Extraction of a Substance that Generates Hydrogen Sulphide in the Seeds of Certain Papilionaceae** (1). — MIRANDE, M., in the *Comptes rendus de l'Académie des Sciences*, Vol. 173, No. 4, pp. 252-255. Paris, July 25, 1921

The substance occurring in the seeds of certain *Papilionaceae*, and especially in those of vetches (*Lathyrus sativus* and *L. Cicera*), which when it comes in contact with water, spontaneously liberates hydrogen sulphide, appears to be a special protein that gives off its free sulphur in the form of the above.

The author has isolated this substance by grinding ; extraction with ether and then with alcohol at 96° C ; soaking the extracted material in distilled water ; filtering on glass-wool : allowing it to take up a little water ; pressing ; mixing the two liquids ; precipitation with neutral lead acetate ; filtration ; precipitation of the excess lead in the filtrate by a current of sulphuretted hydrogen ; filtration ; precipitation with concentrated ammonium sulphate, or with alcohol or by heating to 55° C.

The white, amorphous substance thus obtained liberates sulphuretted hydrogen at 35°-40° C, and gives all the chief reactions characteristic of proteins.

1099 – **The Relation of Certain Nutritive Elements to the Composition of the Oat Plant with Special Reference to the Calcium and Phosphorus Content.** — DICKSON, J. G., in *American Journal of Botany*, Vol. VIII, No. 5, pp. 256-271, figs. 2, tables 10, bibliogr. of 41 works. Lancaster, Pa., May 1921.

From 1871 onwards a quantity of literature has been devoted to the study of the relation of various environmental factors to the composition of plants, but the work has never been satisfactorily concluded. The author started experiments with a view to studying the effect of limiting certain essential nutrient elements upon the composition of the grain and straw of well matured plants when other environmental factors were as far as possible controlled.

The culture work from May to August in 1915 and 1916 respectively was carried on under climatic conditions different from those that prevailed during the latter part of the work, which may in some cases explain the differences between the data recorded for the two respective periods. A brief comparison of the meteorological data for the 2 periods has been included in the present paper. From September 1916 until 1917 the work was continued in the laboratory of plant physiology at the University of Wisconsin.

---

(1) See *R.* June 1921, No. 641 ; *R.* July 1921, No. 706. (*Ed.*)

The normal solution employed consisted in KNOPS solution modified by the addition of 0.1 gm. of sodium chloride per litre of solution, and diluted to $^1/_{10}$ the concentration usually employed; and of 5 further modified culture solutions in each of which one of the elements, magnesium, calcium, potassium, phosphorus, and nitrogen was reduced to $^1/_{10}$ of the quantity present in the normal solution.

Pedigree Swedish select oats, *Avena sativa aristata* were used in all the experiments. In most cases the quantity of the plant material produced was too small to permit the analysis of the grain and straw for all the essential nutrient elements and determinations were therefore confined to total phosphorus and calcium content.

It was found that the calcium content of both grain and straw was reduced to about 10 % of that of the plants from the controls, by reducing the calcium in the culture solution according to the above mentioned method. The average calcium content of the straw from the calcium deficient solutions was only 13 % of that produced in normal cultures. It was greatly reduced in both grain and straw by a similar deficiency in phosphorus or in nitrogen.

As regards the relation between nutrients and content of the oat grain, the total phosphorus content of the grain was reduced to 46 % and of the straw to 10 % of that in the plants from the controls by reducing the phosphate on the $^1/_{10}$ system in the culture solution. It was slightly reduced in both grain and straw by a similar deficiency in potassium, and increased by a similar reduction of calcium or nitrogen.

The following table shows the average composition of plants grown in the normal solution and in solution with one nutrient element in each case reduced to $^1/_{10}$ the normal amount.

Solution Deficient element given	Percent. Calcium Oxide (CaO)		Percent. Phosphoric Pentoxide P_2O_5	
	Grain	Straw	Grain	Straw
Normal	0.697	3.114	1.206	0.628
Calcium 0.1	0.097	0.408	1.364	0.667
Magnesium 0.1.	0.729	2.589	1.092	0.673
Potassium 0.1	0.734	2.763	1.084	0.427
Phosphorus 0.1.	0.366	1.727	0.552	0.068
Nitrogen 0.1	0.451	1.519	1.336	1.463

The relation of climate to the composition of the oat plant, showed that variations in composition were more pronounced in the straw, but were more or less analogous in both grain and straw. The combination of temperature, humidity and other climatic conditions greatly influenced the composition of the plants except when the reduction of certain essential nutritive elements became the predominant factor in controlling plant development. Under these conditions variations due to the environmental factors were outweighed by the deficient nutritive element.

With a few exceptions the phosphorus content was highest in the 1917 samples and lowest in the 1915 samples. The average of all the grain analysed each year from 1915-1917 was 0.679 % in 1915, 0.976 % in 1916 and 1.570 % in 1917. The increases in phosphorus content of the straw were equally high. This fact stands out conspicuously when compared with the contents of both grain and straw of plants grown in phosphorus deficient solutions which showed no influence of climate on composition.

The calcium content of grain including the calcium deficient solutions, was highest in 1917 and lowest in 1915. The calcium content of the straw did not appear however to be greatly influenced by seasonal differences.

No attempt is made to correlate the variation in composition with any given factor, as it is only a case of speculation until controlled experiments have determined the relation of such factors as light intensity, air and soil temperature and humidity on the development and composition of plants.

1100 - **The Effects of Senility in Plants.** — MONTEMARTINI, F. (Istituto botanico della R. Università di Pavia), Extract from the *Atti del R. Istituto botanico dell'Università di Pavia*, pp. 133-135, 1921

According to M. B. HARRIS (1) the effect of senility in plants is to give rise to a denser growth of the vein system with a reduction of the portions bounded by the veins.

The author has made a new contribution to our knowledge of the phenomenon of senility by determining the proportion of ash, on a dry-weight basis, in the leaves of old and of young individuals of the same species of tree. He obtained the following percentages:— Leaves of *Platanus occidentalis*: over 120 years old, 11.20 ; 15 years old, 10.32. Leaves of *Aescolus Hippocastrum*: 40 years old, 8.78 ; 4 years old, 7.43. Leaves of *Aesculus Hippocastrum:* over 100 years old, 9.64 ; 3 years old, 8.41. Last leaves, of *Abies pectinata:* about 100 years old, 4.62 ; 15 years old, 3.16.

It will thus be seen that the leaves of old trees have a greater ash content on a dry basis, than the leaves of young trees. A series of quantitative analyses, which have already been begun, will show whether this difference is connected with the fact that in the leaves of old trees, the vein system is denser, and the veins themselves contain more ash than the mesophyll, or whether it depends upon special senile changes taking place actually in the cells of the mesophyll.

(1) See *R.* Feb. 1921, No. 208. (*Ed.*)

1101 - **The Intensity of the Green Colour As a New Factor to be Taken into Account in Wheat Selection.** — WESTERMEIER, KURT, in the *Zeitschrift für Pflanzenzüchtung*, Vol. VIII, Part I, pp. 14-25. Berlin, March 1921.

Chlorophyll is a fundamental factor in all the physiological processes leading to increase of substance, and since the chief aim of all breeding work connected with agriculture is to increase the yield, the study of chlorophyll from the genetic standpoint is of paramount importance.

The author's experiments were carried out on the following varieties and kinds of wheat :—

WINTER WHEAT. — *Triticum vulgare* : — Nassauer Milchweizen, Klädener Altmärkischer Braunweizen, Crievener 104, Siebenbürger gefleckt, Strubes Squarehead.

Triticum turgidum : Wohltmanns Schwarzer Bartweizen, Wohltmanns Weisser Bartweizen, Kirsches fruher Grannenweizen.

Triticum capitatum : Cimbals Geheimrat Wohltmann.

SPRING WHEATS. — *Triticum monococcum vulgare, T. dicoccum seringeanum album, T. Spelta Arduini, Triticum polonicum, T. durum* (Durum wheat and Portuguese Lobeiro), *T. vulgare* (Bielokoloska, Svalöfs Perl ; Rapado de espica blanca, Rimpaus Roter Schlanstedter, etc.), *Triticum compactum* (Mocho de espica quadrata, Igel and Binked), *T. turgidum* (Ontario, Utah, Branco).

The author studies the connection between the different metabolic processes and the development of chlorophyll as shown by a scale of colours based on two fundamental colour schemes : 96 green mottled with yellow, and 92 (decided green).

The following results have been obtained :—

A. *Effect on the Plant of Chlorophyll Development.*

I. — The plants of the *vulgare* form, colour 96 ;

(*a*) In the first stages, grow more slowly the deeper the colour.

(*b*) The reverse occurs at the time of heading, the darker plants developing more rapidly.

(*c*) The dark types head earlier than the light.

(*d*) The total growth period of the dark types is longer than that of the light.

II. — The plants of the *vulgare* form colour 92, have, as has been said, a shorter growth period, they develop slowly until the heading stage, but from that time, the process is accelerated (until the stage when growth ceases), as if the chromatic type 92 was able to turn the solar energy to better account.

III. — The same occurs both with the *compactum* and *vulgare* forms.

IV. — The dark *turgidum* forms first grow quicker than the light forms, and it is only at the flowering season that they are out-distanced by the latter, which have altogether a longer growth period (thus differing from *vulgare*).

---

(1) See *R.* Sept. 1916, No. 96[illegible]. (*Ed.*)

V. — The light types flower later.

VI. — The darker the colour, the less is the foliage in proportion to the length of the culm. There is thus, economy of leaf-surface.

VII. — The development and tone of the leaves influence the culm length, which increases with the intensity of the colour. The same applies to the thickness of the culms.

B. *Effect of Chlorophyll on the Grain*: I. — The weight of kernels per ear, the content of nitrogenous substances, of dry matter and ash increase as the green of the vegetative parts becomes deeper.

II. — With greater intensity of colour, the proportion of nitrogenous substances to dry matter increases with growing rapidity, though the dry matter content itself tends to rise.

III. — The proportion of nitrogen free substances to gluten decreases with the intensity of the colour.

IV. — The same colour shade may have different effects upon different varieties of wheat.

1102 - **Concerning the Inheritance of Green and Yellow Pigments in Maize Seedlings and the Interesting Phenomena of "Linkage" and "Crossing Over."** — LINDSTROM, E. W, in *Genetics*, Vol. 6, No 1, pp 91-110. Baltimore, M. D, Jan. 1921.

INTRODUCTION. — There are 3 quite distinct types of abnormal maize seedlings: the albino or pure white, the virescent or greenish-white and the yellow. These 3 types are inherited as simple Mendelian recessives to normal and dominant green, and are governed by the 3 following factors:

1) **W**: when homozygous, this entirely prevents the development of chlorophyll, the result being a pure white plant.

2) **V**: when homozygous, this may repress partially or delay the formation of green pigment; the result being greenish-white. Directly after germination, the seedlings are white, but under optimum conditions of light and temperature sufficient chlorophyll may develop to mature and set the seed.

When a green plant, heterozygous for both factor-pairs (**Vv Ww**) is self-pollinated, 9 : 3 : 4 ratio is obtained as follows:

9 **V W** green
3 **v W** greenish white
3 **V w** white
1 **v w** white

Sufficient data are available to establish the conclusion that these factors are inherited independently.

3) **L**: the determinant for yellow. When a green plant heterozygous for both greenish-white and yellow seedlings is self-pollinated, a 12 : 3 : 1 ratio results as follows:

9 **L V** green
3 **l V** green
3 **L v** greenish white
1 **l v** yellow slightly virescent)

TRIHYBRID RELATIONS. — From the cross L l Vv WW × L L V V W w, where 3 factor pairs are concerned in the development of green chlorophyll and yellow pigment, the F_1 plants were completely green both in the seedling and fully-developed stages. In F_1, 8 different genotypes should be produced, according to the gametical constitution, but only 5 of the 8 appeared.

1-2) Two kinds of green.

3) One type segregating into 3 greens to 1 white

4) One type segregating into green, greenish white and white in the ratio 9 : 3 : 4.

5) One new type segregating into green, greenish white, yellow and white, giving a peculiar ratio of these characters, 36 . 9 : 7 : 12, which is explained as follows :

27	**L V W**	green seedlings	3	**L v w**	white seedlings
9	**l V W**	» ›	3	**l V w**	yellow ›
9	**L v W**	greenish white seedlings	3	**l v W**	›
3	**L V w**	white seedlings	1	**l v w**	› ›

Among the F_1 genotypes of the original cross, the gametic composition should be LlVvWw. An analysis of F_2 confirms the trihybrid relations and presents material relative to the discovery of the independence of the 3 factors L, W and W, which it may be assumed are located on separate chromosomes

RELATION OF LINKAGE BETWEEN COLOUR FACTORS OF SEEDLINGS AND THE COLOUR OF THE R ALEURONE FACTOR. — With the material employed during these experiments, the segregation of characters does not only concern the aleurone, but also the colour of the pericarps, and it is difficult to determine with exactitude the chromatic constitu-

Seedling progeny from ears with colourless pericarp.

Pedigree Number	From coloured aleurone			From colourless aleurone		
	Green	Greenish white	Yellow	Green	Greenish white	Yellow
2343–10	156	50	1	59	1	22
2343–19 . .	157	53	0	60	1	19
2343–24	186	52	1	60	1	18
2343–25 .	67	23	0	22	1	10
2343–30 . .	229	75	0	72	0	27
2343–31	179	50	0	66	1	25
Total .	**974**	**303**	**2**	**339**	**5**	**121**
Total theoretical (independent inheritance)	959	240	80	349	87	29

tion of the former. Certain ears, however, with colourless pericarps have been found, which permitted an accurate separation into coloured and colourless aleurone (See Table).

If the factors R and L were independently inherited, we should expect a 12 : 3 : 1 ratio of green, greenish white and yellow seedlings from both coloured and colourless seed. But according to the Table the results are contrary to expectation : from the coloured aleurone instead of 80 yellow seedlings, only 2 actually occurred, and from the colourless aleurone, instead of 87 greenish-whites, only 5 appeared. Evidently therefore the gametes **R l** and **r l** are produced far in excess of the cross over gametes **r l** and **R l**, and the latter formation is practically never produced.

According to the data given, the percentage of crossing over is estimated at 1.6.

1103 - **Sterile Male Anthers of Maize as Heritable Characteristics.** — EYSTER, L. A., in *The Journal of Heredity*, Vol. XII, No. 3, pp. 138-141, figs. 3. Washington, D. C., March, 1921

Male sterile plants are distinguishable from the normal by the fact that no pollen forms in the anther sacs and they remain undeveloped. The sterile spikelets are almost empty and usually remain flattened against the rachis, giving a characteristic appearance to the whole rachis.

This appearance is regulated by the genetic factor **m. s.** In progenies grown from self-pollinated heterozygous plants **Ms ms** the number of *normal* and male *sterile* plants appeared to be in the ratio of 3 : 1.

Pedigree	Normal	Male sterile
A 133—12	48	17
S 11— 1	33	11
Total . . .	81	28
Estimated total (3 : 1) . .	82	27

From the crosses **ms ms** × **Ms ms**, the ratio between the number of normal and male sterile plants appeared to be 1 :1.

1104 - **Studies in the Heredity of the Colour of Rice Glumes.** — YAMAGUCHI, Y., in *The Botanical Magazine*, Vol. XXXV, No. 414, pp. 106-112. Tokio, June 1921.

The rice variety " Karasumoti " has violet-black glumes and variety " Sinriki ", whitish-yellow. By crossing these two varieties, in F_1, individuals with violet black glumes have been obtained, but of a somewhat paler tint than that of the parent Karasumoti.

In F_2, the segregation phenomena are evidently very complicated, producing 5 distinct types :—

I) N = violet black.

II) B = glumes tinged with violet-black only at the two extremities of each glume.

III) C = reddish-brown.

IV) D = reddish-brown at the tips only.

V) E = whitish-yellow.

The examination of other shoots up to F_3 and F_4 brought to the forefront the following facts : —

I) 7 different types may be picked out in the A progeny.
1) Constant, i. e. breeding true from A.
2) Segregated — 328 A : 109 E, approximate ratio 3 : 1.
3) Segregated — 36 A : 10 B : 18 E. approximate ratio 9 : 3 : 4.
4) Segregated — 249 A : 89 C ; approximate ratio 3 : 1.
5) Segregated — 27 A : 12 B : 7 C : 3 D ; approximate ratio 9 : 3 : 3 : 1.
6) Segregated — 162 A : 47 C : 88 E : approximate ratio 9 : 3 : 4.
7) This type corresponds to F_1, and has the same gametic composition, i. e. heterozygote relatively to 3 factors and segregating into 5 forms : 23 A : 7 B : 12 C : 4 D : 19 E ; approximate ratio 27 : 9 : 9 : 3 : 16.

II) 4 types may be distinguished in B progeny.
1) Constant, reproduction of B.
2) Segregated — 339 B : 124 E ; approximate ratio 3 : 1.
3) Segregated — 307 B : 94 D, ratio 3 : 1.
4) Segregated — 156 B : 45 D : 59 E, ratio 9 : 3 : 4.

III) 4 types may be distinguished in C progeny :
1) Constant, reproduction of C.
2) Segregated 88 C: 27 D, ratio 3 : 1.
3) Segregated 173 C : 79 E, ratio 3 : 1.
4) Segregated 126 C : 47 D : 48 E, ratio 9 : 3 : 4.

IV) 2 types in D progeny.
1) Constant, reproduction of D.
2) Segregated, 265 D : 102 E, ratio 3 : 1.

V) The E progeny, although they show different genetic combinations, are all constant as regards colour.

From these facts it may be concluded that the colour is formed in a tri-hybrid mendelian manner. B may be taken as the violet determinant, R as the red determinant and S the factor which limits the red to the two extremities of the glume. If it is supposed that B and R are not able to manifest themselves in the absence of S, the following formulae may be indicated: for Karasumoti, **BB RR SS**, for Sinriki, **bb rr ss**: for F_1, hybrid **Bb Rr SS**; and for F_2, the 5 types **A, B, C, D, E,** quite distinctive and in the ratio 27 : 9 : 9 : 3 : 16 that is to say:—

Type A: **BBRRSS** (1) **BBRrSS** (2) **BBRRSs** (2) **BBRrSs** (4)
BbRRSS (2) **BbRrSS** (4) **BbRRSs** (4) **BbRrSs** (8)
Type B **BBrrSS** (1) **BbrrSS** (2) **BBrrSs** (2) **BbrrSs** (4)
Type C· **bbRRSS** (1) **bbRrSS** (2) **bbRRSs** (2) **bbRrSs** (1)
Type D **bbrrSS** (1) **bbrrSs** (2)
Type E **BBRRss** (1) **BBRrss** (2) **BBrrss** (1)
BbRRss (2) **BbRrss** (4) **Bbrrss** 2)
bbRRss (1 **bbRrss** (2) **bbrrss** (1)

According to this hypothesis, it appears evident that each of the members included in each type should show its genetic constitution according to the method of segregation in *F*, except the elements in group E, not coloured, which should remain constant.

Individuals	Method of segregation	Individuals	Method of segregation
	Type A		*Type C*
BBRRSS	Constant	**bbRRSS**	Constant
BBRr SS	3 A : 1 B	**bbRrSS**	3 C : 1 D
BBRRSs	3 A : 1 E	**bbRRSs**	3 C : 1 E
BBRr Ss	9 A : 3 B : 4 E	**bbRrSs**	9 C : 3 D : 4 E
Bb RRSS	3 A : 1 C		
Bb Rr SS	9 A : 3 B : 3 C : 1 D		*Type D*
Bb RRSs	9 A : 3 C : 4 E		
Bb Rr Ss	27 A : 9 B : 9 C : 3 D : 16 E	**bb rr SS**	Constant
		bb rr Ss	3 D : 1 E
	Type E		
BB rr SS	Constant		*Type E*
Bb rr SS	3 B : 1 D		All constant
BB rr Ss	3 B : 1 E		
Bb rr Sr	9 B : 3 D : 4 E		

This theory clearly explains the above mentioned facts: the absence in type A of a sub-type to which the formule **BB Rr SS** should correspond, existed in comparatively limited numbers in the individuals examined. An interesting fact has been brought out during these experiments: it is due to the probable existence of "repulsion" between the colour factors and those of the character of the endosperm. Out of 59 individuals with violet-black glumes none possessed an *amylaceous* endosperm whilst 31 (i. e. 53 %) had a *dextrinose* type of endosperm. On the other hand, out of 107 individuals with whitish-yellow glumes, 4 only were *dextrinose*, whilst 65 (i. e. about 60 %), possessed an *amylaceous* endosperm. Similarly, out of 61 individuals with reddishbrown glumes, 2 only (3 %) showed an *amylaceous* endosperm.

[1104]

Repulsion is therefore almost complete as regards colour and *amylaceous* content of the endosperm, and partial as regards a non-coloured glume and a *dextrinose* content. It is certainly very interesting to trace this relation between the formation of a violet-black pigment and a *dextrinose* endosperm. The pigment evidently belongs to a group of anthocyanines which are merely glucosides. The chromogene from which the anthocyanine originates is probably a product resulting from sugar synthesis, whilst amylo-dextrine and erythro-dextrine as found in the rice endosperm, are products only of the decomposition of the amide in the living cells, in other words a changeable substance which is formed at the expense of the sugar during the synthetic formation of the amide.

The author intends to continue his investigations with reference to genetics and physiology.

1105 - **Utility of Further Selection with a View to the Improvement of the Cotton Variety "Pima" in the United States.** — KEARNEY, T H., in *Journal of Agricultural Research*, Vol. XXI, No 4, pp. 227-242, tables 10, fig. 1, pl. 7. Washington, D. C., May 1921.

The Pima variety of cotton which originated with a single plant selection in 1910 covered an area in 1920, in California and Arizona, of 250 000 acres. So great is the apparent uniformity of this variety of cotton that the utility of further selection has been considered doubtful.

The author, however, reports the results of a series of investigations which show that the variety possesses frequently, heritable variations which not only justify, but render even necessary the continuance of selection and line breeding, etc.

Some of the seed collected from the parent plant in 1910 had been successfully preserved, and it was therefore possible to compare the present commercial stock and the line bred strain (32 plants in 1919).

In order to measure the degree of change which might have occurred after several years of selection, the progeny of the parent plant was compared with an equal number of plants, taken at random in the commercial stock, of strain 5-3 and of 2 progenies ($Y_1 A$ and $Y_2 A$) derived from the same strain, but self-fertilised for 5 successive generations.

Three populations therefore exist : *a* = parent progeny, *b* = 5-3 bulk and *c* = 5-3 selfed.

Twelve characters were examined : —

1) *leaf length* (cm.), measured from base of midrib to tip of central lobe ;
2) *leaf width* (cm.), measured from tip to tip of the principal lateral lobes ;
3) *leaf index*, width as % of length ;
4) *leaf vein angle* ; in degrees ;
5) *leaf lobe index* ; leaf length as % of distance from the base of the midrib to the bottom of the upper right hand sinus. The index is still higher for a deeply-lobed leaf;

6) *leaf extension index*; length of basal extension of the blade, below a line bisecting the base of the midrib at a right-angle to the latter as a % of the leaf length;
7) *boll length* (mm.);
8) *boll diameter* (mm.),
9) *boll index* = maximum diameter as % of length;
10) *fibre length* (mm);
11) *lint index* (gm.) = weight per 100 seeds;
12) *seed fuzziness*.

The fibre length, lint index and seed fuzziness are of chief practical importance. Table I shows the means and coefficients of variations; Table II shows the frequency distributions.

Comparison between the commercial stock and the Pima variety proves that there has been a significant improvement in the length and abundance of fibre.

TABLE I — *Means and coefficients of variations for 3 important characters.*

Character	Means			Coefficients of variation		
	Parent	Bulk	Selfed	Parent	Bulk	Selfed
Fibre length (mm)	40.8±0.19	44.6±0.12	42.9±0.12	3.8±0.32	2.2±0.19	2.4±0.20

Parent progeny . . .	4	10	13	2	3	—	—	—	—
5–3 line. .	—	—	—	1	18	10	2	—	1
5–3 selfed	—	4	14	10	3	—	1	—	—

Seed fuzziness.

	Grade 1	Grade 2	Grade 3	Grade 4	Grade 5	Grade 6	Grade 7
Parent progeny	1	5	7	8	8	3	—
5-3 line	—	—	13	23	5	1	—
5-3 selfed	—	—	11	13	13	13	2

As regards quality of fibre, this seemed to differ more with the parent progeny than in the two other populations.

The abundance of fibre, as expressed by the mean weight of fibre borne by 100 seeds, averaged 36.5 % greater than in the "bulk" or commercial stock (5-3 strain).

In the earlier years of breeding work, no special attention was given to the fuzziness of seeds; consequently it is not possible to establish the difference between the commercial stock as compared with the parent progeny. On the other hand, the frequency distribution of the parent progeny indicates that selection of a strain having smoother seeds than the present commercial stock is quite possible.

The question has been raised whether any new developments are possible. The reply is positive: there have been observed on "Pima" plantations certain heritable variations which, although rare and comparatively unimportant, certainly justify the continuation of selection work. Some examples will illustrate this fact. The boll of Pima cotton has usually 3 locks or carpels, although 4-lock bolls are borne by nearly all plants of this variety. As regards the proportion of 3-lock and 4-lock bolls there is much individual variation. The author conducted a series of investigations in order to ascertain whether such differences are heritable, and selected as a start several plants which had more or fewer 4-lock bolls than the average. Table III shows the percentages in the progenies of 3 of these plants (1918).

The differences appear to continue. Work was renewed in 1919 with selfed seed of one plant in progeny No. 3 and of 2 plants of progeny No. 1 (both with 4-lock bolls).

TABLE III. — *Percentages of 4-lock bolls in the progenies of individual plants selected in* 1917.

Progeny	Number of plants	Percentage of 4-lock bolls
No. 1 (from parent with few 4-lock bolls)	19	4.6 ± 0.031
No. 2 (from parent with many lock bolls)	22	5.9 ± 0.33
No. 3 (from parent with many lock bolls)	8	10.5 ± 0.67

TABLE IV. — *Percentages of 4-lock bolls in progenies of plants selected for a high percentage of 4-lock bolls.*

	1919			1920	
	Number of plants	Percentage of 4-lock bolls		Number of plants	Percentage of 4-lock bolls
1-3	13	8.5 ± 0.65	1-3-12.	45	9.2 ± 0.36
1-5	20	8.7 ± 0.54	3-2- 4.	39	22.0 ± 0.62
3-2	5	10.9 ± 0.87	3-2- 5.	42	23.3 ± 0.60
Total	38	9.1 ± 0.37	*Total*	126	17.2 ± 0.30
Commercial	38	4.2 ± 0.27	*Commercial*	50	5.3 ± 0.29

The results are therefore positive; it is evidently possible to obtain by selection an increased percentage of 4-lock bolls. These types would in all probability give a yield of fibre and seed 10 % superior to the ordinary stock.

Similar facts exist concerning the seed fuzziness, the development of the branches and flower stems, etc.

A very striking variation consists in the complete or nearly complete absence of the dark red spot near the base of the petals, which is normally characteristic of the Pima variety. An examination in 1919 of the 4-lock progenies (see Table IV, left) bears out this statement and was evident in 3 progenies.

The 38 plants inspected in 1919 were graded with respect to degree of development of the petal spot, grade 8 indicating the extreme development in typical Pima cotton and grade 0 indicating complete absence of the spot, as is the case in most varieties of American Upland Cotton (*Gossypium hirsutum* L.). Two or three flowers were separately graded on each plant; the total averages for the 38 plants is estimated at 1 ± 0.04 and for 13 typical Pima plants 7.5 ± 0.19.

The absence or weak development of the spot, in association with the 4-lock bolls, is clearly hereditary, and suggests the possibility that Upland cotton (*Gossypium hirsutum*) or Hinde cotton (*G. punctatum* Schum. and Thonn.) may have been involved in the remote ancestry of the Pima variety.

The fact that heritable variations are found in this apparently uniform variety is considered as justifying the continuance of selection and line breeding and the elimination of inferior individuals.

1106 - **Experiments on Flax Hybrids.** — BLARINGHEM, L., in the *Comptes rendus de l'Académie des Sciences*, Vol. 173, No. 5, pp. 329-331. Paris, August 1, 1921.

Varieties of flax grown for seed are much more homogeneous than those cultivated for their fibre and shew little degeneration In a genetic study of flax it is necessary to bring out the stability of the first type of plant, in order better to explain the irregularities and degeneracy of the second The author had the good fortune to obtain a line of " white seeded flax " characterised by ivory-coloured seeds and fruits with non-ciliate septa As it is very productive and homogeneous, this variety forms an excellent standard of comparison for the hereditary qualities of other types. The author gives the results of his experiment with " Morocco flax," which he believed to be homogeneous, but found, on crossing it with the white-seeded flax, that the hybrids formed a heterogeneous population possessing dominant characters.

The two types are distinct as regards all their most noticeable characters : —

	White seed flax	Morocco
Plant . . .	Slender, ramified from base, small (25 cm.)	Strong, unbranched, tall 40 (cm.)
Flowers	Light blue small (12 mm.)	Blue, large (25 mm.)
Fruits.	Small, depressed, white non-ciliate septa	Large, globular with ciliate septa
Seeds . .	Small (2-3 mm.), virgate, white	Large (5-6 mm.), oval, brown

Crosses are difficult to make ; of the 5 emasculated flowers on each stalk, the youngest always prove abortive ; one or two may set seed, but are often empty.

As regards the 1919 crop, 5 out of 12 *Moroccan* female parent plants (P_1 to P_5) bore respectively 6, 7, 5, 2 and 3 seeds, and 1 in 6 (P_6) of the *white seeded* variety produced 4 seeds.

The *White seeded* × *Moroccan* cross is more difficult to effect than the reciprocal cross, as the author also found in 1920 and 1921, the two types behaving from this point of view like distinct species (NAUDIN).

In the first generation the *Moroccan* characters are predominant. The progeny of a Moroccan female parent plant are all similar, tall (40 cm.), ramified at the base, bearing light-blue flowers (15 to 20 mm.), and oval, average sized fruits with ciliate septa. Seeds are rare, some are wrinkled, and germinate badly. P_2 which had produced 7 seeds was still the most fertile in F_1, bearing 125 good seeds; P_4 which had borne 2 seeds, produced 52 in the F_1 but half of them did not germinate. The cross P_6 (*White-seeded* × *Moroccan*) gave in the F_1, 2 low plants (22 cm. and 31 cm.) with a stalk which was much ramified throughout its whole length and this peculiarity persisted in the F_2. Examination of the second generation (1921) confirmed the theory that the *Moroccan* type was heterogeneous. The following Table shows some of the results of the segregation.

Line	Plants with White seeds	Plants with Grey seeds	Plants with Brown seeds	Fruits with non-ciliate septa	Fruits with ciliate septa
P1	3	13	14	12	18
P2	20	42	12	17	57
P3	20	27	14	13	48
P4	3	21	5	6	23
P5	8	17	9	12	22
P6	3	21	35	4	55

If the columns are added up, the figures do not give the mendelian ratio. Instead of postulating multiple factors, the author leaves on one side, as standards of comparison, the lines P_1, P_4 and P_6, only taking into account the results furnished by P_2, P_3 and P_5. These taken together, give a total of 121 plants with coloured seeds, as against 48 with white seeds, that is to say, 3 brown to 1 white. The individual deviations, which are still considerable, are of the type observed by TINE TAMMES in crosses between white-flowered and blue-flowered varieties of flax. The author states that they are due to the partial abortion of the seeds, which is a constant and very marked peculiarity of flax plants.

Limiting the investigation to the 3 lines in question, it was found, as regards the second group of characters, that there were 127 plants with ciliate septa, as against 42 with non-ciliate septa (ratio 3 : 1). It results from these data :— 1) That the brown colour of the *Moroccan* flax is dominant as regards the white of the white-seeded variety; (2) that ciliate septa in fruits are dominant as regards non-ciliate septa.

The author, however, deduces another important fact connected with the Moroccan type, which is in appearance vigorous and homogeneous, viz, some of the lines, when crossed with a clearly defined reactive type, behave as bearers of simple Mendelian characters, whereas others behave as bearers of complex characters.

Crossing with a selected reactive type therefore makes it possible to separate regular lines from an assembly in which all differences appears to have been lost, and the individuals seem precisely similar. This method, combined with the choice of lines producing ordinary pollen, forms the basis of the technique adopted by the author for flax selection.

1107 – **Association of Characters of Flax Varieties Selected at Verrières, France.** — See No. 1120 of this *Review*

1108 – **The Selection of *Hevea brasiliensis* in the Dutch East Indies.** — HEUSSER, C., in the *Archief voor de Rubbercultuur*, Year 5, No 6, p 332. Buitenzorg, June 1921

A nursery of *Hevea brasiliensis* was established in 1915 at the Bijawak farm with seed from 4 vigorous and highly productive female parent stocks. In September, 1918, a selection was made of a hundred female descendants :— 34 from parent I, 20 from parent II, 23 from parent III and 23 from parent IV. The following tests were made up to September, 1920 :—

1) Five tapping tests each lasting for a months.

2) Three determinations of the number of latex vessels.

3) Three determinations of the trunk circumference and the thickness of the bark at 1 metre from the ground.

The tapping experiments (on six year-old plants) showed, after eliminating all possible errors by calculation, an increase in yield, compared with the original plantations, of 16.8 % (reckoned on equal areas). On the other hand, in the case of individuals among the selected plants, the increase was as high as 75 %.

The descendants show a wide range of variation as regards productivity, and the genetic value of the females also varies considerably. In making choice of the latter it seems desirable to lay special stress upon a conjunction of vigorous growth with high productive power

It is also better in apportioning the descendants to have regard to the actual yield from the incisions than to the number of latex vessels. The degree of correlation between this value and the yield is not high, especially in the case of young plants.

1109 - **Commercial Production of Seed According to the Swedish Improved Method, and the Progress Already made in Canada and New South Wales.** — I. BREAKWELL, E., The Production of Better Seed in other Countries. *The Agricultural Gazette of New South Wales*, Vol. XXXII, Pt. 4, pp. 245-248. Sydney April, 1921. — II. NEWMAN L. H. (Secretary, Canadian Seed Grower's Association), Seed Centres in Canada. *The Agricultural Gazette of Canada*, Vol. VIII, No. 2, pp. 212-214. — III. CUTLER, G. H., The Beginning of an Important Movement for Supplying Pure Seed, *Ibid.* p. 151. Ottawa, March-April, 1921.

The improvement of cultivated plants and the commercial production of seed therefrom have been for some time vigorously undertaken by European countries, and also by America. The two nations outstanding in this respect are Sweden and Canada. The methods adopted in Sweden have served as a model for other nations and the author gives an account of the methods employed in that country.

I. SWEDEN. — The General Swedish Seed Company, a private commercial body for growing, treating and selling farm seeds in bulk, buys all the improved seed from the Swedish Institute at Svalöf for further commercial production. It extends further production on its own land, and also enters into contracts with private growers. The terms of contract are briefly as follows :—

1) The grower undertakes to grow the seed for the General Swedish Seed Company ; 2) The grower is bound to deliver to the seed company without remuneration the same weight quantity as received with an addition of 25 % ; 3) the grower is bound to deliver the entire balance of the crop to the seed company for a fixed remuneration ; 4) should the company be unable to accept the average quality sample which the grower is bound to send to the company the growers' obligation shall cease ; 5) the grower shall deliver the crop in clean condition ;

6) the grower binds himself to allow the seed company's representative to inspect at any time, and at the company's expense, the growing crop at any place ; 7) should the crop not be approved as seed goods by the seed company on account of faulty harvesting, bad smell, low germination, mixing with foreign sorts, disease, or other causes, and providing this is caused in any way by neglect or improper handling by the grower, he shall be bound, if so claimed, to pay for the seed he received at the price quoted for the goods in question in the year's catalogue ; 8) should the goods delivered be found not up to sample, or should they show upon closer examination that they do not reach the standard mark on the measure, and the goods thus be in any case unfit for seed, they will then be valued according to the mutual agreement of the grower and the seed company.

I. II. *Canada* (1). — It seems practically certain that this method served as a model for Canada. A Canadian Seed Growers' Association was founded in 1900.

The Association appoints provincial officers for field inspections, and its own officers for the final inspection in the sack. The method adopted is as follows : —

1) Membership is open and free to any *bona fide* farmer who has shown himself capable of producing improved pure seed ; 2) the farmer who undertakes to grow pure seed obtains his foundation stock from the association. Such seed is either " first generation registered seed " (*i. e.* F_1, F_2 or F_3 progeny of an improved selected strain) or *élite stock seed* (*i. e.* pure stock of seed originating from a single plant, or obtained from a hand selected seed plot) ; 3) any seed of any kind of crop produced or selected by a member during the succeeding years is entitled to registration by the association ; 4) certificates are given : (*a*) for seed grown according to regulations and recovered from élite stock seed, such seed being marked *registered seed* and (*b*) for pure élite stock seed ; 5) no certificates are issued unless the seed be (*a*) pure as to variety and true to type ; (*b*) free from seeds of other cultivated plants ; (*c*) free from seeds of weeds coming within the meaning of the term " noxious weeds " as applied to the Seed Control Act ; *d*) free from or containing not more than a total of one seed of other weeds of minor importance ; (*e*) well-matured, clean, sound, plump, of good size and colour, and free from disease ; *f*) up to the percentage standard of vitality recognised for good seed of the kind under the Seed Control Act.

II. The methods thus outlined are extremely successful and are well supported, and at present the demand for " registered seed " is greater than the supply. For example the Canadian Seed Growers' Association is endeavouring to assemble in Ontario a number of carloards of registered Banner oats, but the supply to meet the ordinary demands of the trade is inadequate : the author considers that at least one good seed producing centre should be established in each district where high class seed of the kind most in demand may be produced to a high degree of perfection and in considerable quantity.

---

(1) See *R.* March 1921, No. 280. (*Ed.*)

Prof. CUTLER states that during the past 3 years the Department of Field Husbandry of the University of Alberta has been putting forth every effort to standardise and purify old varieties and breed new varieties of the diverse farm crops. During that time there has been an insistent and steady demand for pure seed representing suitable varieties, and for information as to how " registered seed " can be obtained or produced. In answer to these applications, samples have in nearly every case been sent out; the size varying from a few ounces for testing to 3 bus. or more for multiplication. During the past 2 seasons, over 1500 samples of seeds were placed in the hands of interested seed growers who are undertaking to test and multiply given improved and purified strains of the different farm crops. This is the beginning of a very important movement in seed production in Alberta, but necessitates special organisation. In meeting adequately therefore the needs of the farmers' demands, the University of Edmonton is prepared to coordinate all co-operative seed testing, seed distribution, and multiplication work under one organisation to be known as the " Alberta Crop Improvement Association ".

I. NEW SOUTH WALES. — The Department of Agriculture has already taken the initial steps for the production of better seed. The method adopted differs from those in Canada and Sweden in the fact that the Department deals directly with the farmers. It is interesting to note that a list of growers of pure seed of good quality of wheat, oats, maize, sorghum, Sudan grass, potatoes and other crops is published in the *Agricultural Gazette of New South Wales* monthly, in order to enable farmers to get into direct touch with reliable sources of supply of such seeds. The list is compiled after inspection of the seed and report by a field officer (preferably during the growth of the crop), and farmers who have pure high-class seed of good quality of any variety of farm crop are invited to communicate with the Department of Agriculture, Sydney.

1110 - **Comparison Studies of the Resistance to Lodging of Several Pure Bred Wheat Varieties.** — DRAGHETTI, A. (R. Laboratorio autonomo di chimica agraria, Forlì), in *Le Stazioni sperimentali agrarie italiane*, Vol. LIV, Pts. 4-6, pp. 145-180, fig. 1, bibliography of 21 works. Modena, 1921.

For general purposes it is possible to distinguish at least 3 characteristic forms of lodging, to be attributed: 1) to excess of nitrogen; 2) to weather conditions; 3) to a lack of uniformity of the stem.

Practical experience has led to the classification of the varieties most liable to lodging, even under normal conditions; it is therefore possible to make a distinct classification of wheat varieties. This may be attributed to the fact that different types present marked and constant differences as regards the equilibrium of the stem. For this reason it is possible to make investigations with a view to the discovery of the weak side of their morphological structure.

The author was not content to rely on empirical observations for the investigations described in minute detail in the present article, but rather on the statistical biometric method by which means he aimed at the solution of the following problems.

1) To find a positive or negative value attributable to different varieties, under fixed biological cultural conditions in order to facilitate the establishment of a rational gradation with respect to lodging;

2) To find and evaluate the positive and negative characters which should serve as a guide in selection work;

3) To trace the outline, from the statistical standpoint, of a typical plant free from the inferior qualities associated with the breed.

A selection of varieties of cultivated wheats was made with a view to conducting comparative adaptation trials at the Experiment Farm at the Forlì Agricultural Station, on clay loam, following on beets; the ordinary fertilisers and cultural operations being in every case employed.

For each stem the author determined (from May 10 to 20): 1) weight; 2) height to top of ear; 3) height from centre of gravity, taking into account the influence exercised by the varying lengths and thickness of the upper leaves; 4) length, weight, diameter and thickness of the epidermis of each internode; 5) weight, in grammes, determining the break due to bending of the lower portion of each internode and for a bract of 10 cm.; 6) submission to bend up to limit of breakage in cm., and angle of inflexion in degrees. For determinations 5) and 6), the author has invented an apparatus which is described and illustrated.

The biometrical data obtained serve as a basis to estimate the mean and to deduct the coefficients of variability by applying the GAUSS formula.

In this way a marked positive correlation has been established between the unit weight of the internode and its resistance to bending.

The data obtained concerning the average degree of bending of 10 varieties studied, permit the conclusion that a characteristic elasticity exists for each and this factor is a point of considerable importance. As a matter of fact, their progressive value is in perfect correlation with the gravity of lodging observed in the plots concerned, for example:

Inflexion. 1st Internode	Cultural observations
4.8 a 5.9 cm.	Stems completely resistant
7.3 a 8.6 »	» partly liable to lodging
8.8 a 9.0 »	» completely beaten down.

Flexibility of stems is therefore a character which should be taken into consideration as much from the practical (comparatively thick sowing) as from the experimental point of view.

[1110]

Formulae have here been established, criticised and developed, relative to the calculation of moments of inactivity, of resistance and of unit coefficients of breakage ; this is followed by observations with reference to the extrinsic or local mechanical factors : *a*) pressure due to the force of wind ; *b*) pressure due to the displacement of the centre of gravity from the vertical ; *c*) pressure due to adhesive raindrops. Determinations are made as to the statistical equilibrium and the balance between positive and negative pressure of the stem and an examination of the differential mechanical characteristics attached to the varieties studied.

Taking the " index of resistance of lodging," to indicate the relationship between the pressure of resistance and the pressure of flexion for each variety, in such a manner that the equilibrium be represented by unity, the positive resistance by a number superior to 2 and the negative resistance by a value inferior to unity, the following values will be obtained: Rieti fam. 11 : 1.026 — Gentil rosso fam. 48 : 1.002 — Cologna fam. 12 : 0.881 — Inalletabile fam. 38 : 1.232 — Carosello fam. 91 : 1.052 — Masolino fam. 33 : 0.981 — Coronation : 1.309 — Apulia : 0.818 — Luigia Strampelli : 0.950 — Dauno : 0.877.

Supposing that the more forcible pressures of total resistance or total deflec-tion be taken as equal to 100, the author calculates that this may be sub-divided into 3 part time pressures due to wind, to displacement of centre of gravity and adhering raindrops. The results are shown in tabular form, and permit the following conclusions :—

1) That the force which is the chief cause of distorted development even for varieties with a very flexible stem, is in all cases the wind, which possesses an influence coefficient varying from 64.3 to 83.7 % for total deflection.

2) That the sum of the coefficients of wind effect and displacement of centre of gravity is very nearly constant, *i. e.* the coefficient of wind effect is inversely proportional to stem flexibility, whilst the coefficient of effect of deviation from the centre of gravity is directly proportional to it.

But these relations have only an approximate value ; the only one having any absolute and specific value is that arising from the results of comparison of the index numbers concerning moments of resistance and total deflection.

The statistical ratio of the stem is given by the formula

$$\pm M = \frac{KI}{z} \overset{<}{\underset{>}{=}} \left(0.57 \frac{A+a}{z} p.\, h\right) + [(P + P_1)\ h_1 \text{ tang } \alpha)]$$

when K indicates the unit effect of the elements chiefly concerned with the section of the stem ; $\frac{I}{z}$ the moment of resistance of the joint of node ; *A* and *a* the portion of the stem and sheath affected by the wind ; *p* the unit of wind force ; *h* the height of the vertical projection of the stem ; P the weight of the stem and P_1 the increase in weight owing to the rain , h_1 the height of the centre of gravity and the angle described by the new position of the abnormal stem in conjunction with its original position.

In this case, the values K, $\frac{I}{z}$ and h represent characteristics of particular types, upon which depends the degree of resistance to lodging of different varieties of wheat. The means available in order to procure the most advantageous combination of the 3 above-mentioned factors are of both a practical and biological nature. Belonging to the first group may be mentioned the earthing up of wheat which causes a decrease in h and which, if somewhat thickly sown or in well spaced lines, increases K and $\frac{I}{z}$; in the second case, the only methods which can hope to solve the problem definitely are associated with pure line selection and hybridisation. The results obtained recently are very encouraging as to the possibilities of arriving at the solution of the problem of lodging and increase in yield.

1111 – **Experimental Cultivation of Foreign Wheat and Oats in Italy.** — POGGI, G. in *Il Coltivatore*, Vol. 67, No. 24, pp. 177-181, 4 figs. Casale Monferrato, August 30, 1921. — ROSSI, G., in the *Rivista di Agricoltura*, Vol. XXIV, No. 34, pp. 181-182. Piacenza, August 26, 1921.

I. — M. POGGI describes the good results he obtained with foreign wheats and oats sown broadcast in March in very stiff, clay-loam, hill soil with an average amount of fertiliser. The year being a wet one greatly contributed to his success. Among the wheats, the best results were given by Marquis and April Bearded Wheat, both proving resistant to lodging.

The oats sown were as follows :—

GARTON'S " Record," an English variety with erect, stiff straw, and panicles containing 220-250 white, full, heavy kernels. It ripened somewhat late (perhaps because it was sown in the spring) ; it is rust resistant.

Prolific Black Tartarian, which gave the maximum unit yield. Its straw is of average length ; the panicles are very large ; kernels black with white tips. " Green Mountain," a variety from the United States, proved resistant to drought. Its straw is very stiff, the panicles attain the length of 40 cm., and the kernels are inflated and very white.

" The Hero " is another of the GARTON varieties, its straw is very stiff and its panicles enormous ; the kernels are white and heavy. " The Yielder," another GARTON product, ripens a little earlier.

The " Great Lizo, " originally a Canadian variety, proved to have very strong straw, large compact panicles, and large inflated kernels. The Swedish varieties " Suédoise selectionnée," and " Iowa 105," although sown in the spring, ripen at the same time as the autumn-sown native oats, which makes them much prized in districts which are usually dry. Their straw is strong, the panicles are very lax, and the kernels somewhat small.

II. — Dr. Rossi has introduced into Italy many varieties of wheat including the " Reliable," bred in the United States by A. Read. In the north of that country, it is a winter wheat; in Italy it does best when sown as early as possible in the autumn.

In the district of Sienna, this wheat has grown well on estates at an altitude of 400 metres. In the experiments made in 1920-1921 by the " Cattedra ambulante d'Agricoltura di Pisa " at Cecina, this variety gave the maxima unit yields. The author suggests that it should be tried in the different regions of Italy.

1112 – **Experiments in Cereals Cultivation Carried out by the " Istituto agrario provinciale di San Michele ", Trent.** — Springhetti, in the *Bollettino del Consiglio provinciale d'Agricoltura*, etc., Year XXXIV, No. 16, pp. 229-230. Trent, August 31, 1921.

During the agricultural year 1920-1921, the Provincial Agricultural Institute of San Michele all'Adige (Trent) tested the three varieties of wheat " Gentil rosso," " Carlotta Strampelli," and " Conte Piatti," by growing them under the most suitable conditions as regards situation, quality and richness of soil, preparation of the ground, and choice of fertilisers. " Conte Piatti " is an awned wheat especially suited to hilly country and is resistant to drought and frost.

The seed was sown in the first fortnight of October, in soil dressed with 6 quintals per hectare of superphosphate + 2 quintals per hectare of potash salt. The wheat followed potatoes or maize, preceded by red clover or lucerne; " Carlotta Strampelli," however was sown directly after the clover. " Gentil Rosso " was sown on three plots, and " Carlotta Strampelli " and " Conte Piatti " on a plot each. The respective yields of the plots were 35, 29.4, 34.32, 28, and 31.37 quintals per hectare, the general average being 31.61 quintals per hectare.

As the local farmers never succeeded in obtaining more than 15 quintals per hectare, the above crops, which were the result of the careful following of known rules, show that it is possible to increase the agricultural production of a region simply by means of a suitable rotation, proper preparation of the ground, sowing seed of good quality, and the systematic application of a fertiliser.

1113 – **The Transplanting of Rice, and the Production of Seed Rice in Italy.** — Chiappelli (Relatore, R. Stazione sperimentale di Risicoltura e delle Coltivazioni irrigue, Vercelli), in the *Giornale di Risicoltura*, Vol. XI., No. 7, I, pp. 105-109; II. pp. 110 112. Vercelli, July 31, 1921.

I. — Report of the Prize Competition, opened in 1920, by the " R. Stazione Sperimentale di Risicoltura " of Vercelli, with the object of encouraging the transplanting of rice, and the production of two crops in the year. The following facts are deduced from the results obtained by the rice-growers who took part in the competition.

The increased unit return, and the yield of the preceding crop, after deducting the transplanting expenses, gave a large margin of profit. Mechanical ploughing, by leaving the teams free at the critical moment when they were needed for other crops, has greatly contributed to the development of transplanting, so that, on some farms, it was practised on ½ of the area under rice.

Most of the transplanting is effected in new rice-fields which allows of a good hay crop being obtained the same year, but it is also practised after rye, or rape grown for seed, or after wheat harvested at the, beginning of July, the early Dellarole variety of rice being transplanted towards the middle of the month. An interesting experiment was made at Morimondo (Abbiategrasso district, Province of Milan) by M. TAGLIABUE, who transplanted rice after having obtained a good crop of grass, and bred mirror carp in the rice-field (1).

The average increase in the return obtained by transplanting the rice, as compared with the ordinary method, was from 7 to 8 quintals per hectare. In addition, the kernels were heavier, and the panicles ripened more uniformly. Therefore transplanting is much to be recommended, especially for seed-rice.

II. — Report of the Prize Competition opened in 1920 by the "R. Stazione sperimentale di Risicoltura" of Vercelli for the rice-growers who were most sedulous in the field selection of seed-rice.

The keenest farmers carry out 3 successive selection operations in the field, removing any panicles that are mal-formed, or belong to other varieties, and thus prevent all chance of degeneration. The seed used for these fields of selected rice is usually hand-picked in the selected fields by expert workers, who choose, panicle by panicle, the kernels that are finest and largest, and borne by vigorous plants that give good yields.

The CABRINI method of cultivation (2) gives good results in producing seed-rice, plants thus obtained being vigorous and productive, with well-shaped and well developed panicles and large heavy kernels; in addition they were more resistant to lodging.

The crops obtained from transplanted rice were also most satisfactory.

1114 - **Experiments in Lentil-Growing in Upper Italy.** — BONASERA, G. (R. Istituto tecnico di Novara) in *Giornale di Agricoltura della Domenica*), Vol. XXXI, No. 36, p. 286. Piacenza, September 4, 1921.

The author, having noticed for some years that lentils were not much used as an article of human food in Upper Italy, and hence little grown in fact, attempted to find out whether this neglect was due to unfavourable conditions of soil and climate. He found that the conditions obtaining were in fact most suitable to the lentil.

By sowing lentils in the experimental kitchen-garden attached to the "Scuola di Agraria e Estimo" of the Royal Technical Institute

(1) See *R.* April 1921, No. 422. (*Ed.*)

(2) See *R.* April 1921, No. 457; *R.* June 1921, No. 624. (*Ed.*)

at Novara, at the rate of 1.18 hectolitres per hectare, and cultivating it in the usual way (which he describes), the author obtained 20 times the seed used, that is to say, 24.62 hectolitres of seed, and 18 quintals of straw per hectare, which at present prices, leaves a considerable margin of profit. From an investigation of the data furnished by several workers (A. FELCINI, *Lezioni di agraria*, Vol. II, Jesi, 1918; C. LUMIA, *Estimo rurale* 3rd edition. Catania, 1919), the author discovered that the ratio of the money value of the gross return, to production cost is as 1 : 0.73 for pulse crops.

In order to protect .lentils against *Bruchus signaticornis*, they should be sterilised by heating to about 100° C. They must be placed in thin layers, and carefully turned over.

Some investigators object to this treatment, alleging that it makes the lentils difficult to cook, but the author shows from the results of his own experiments, that there is no foundation for this statement.

1115 - **Cultivation of "Dolic" in the Open Field.** — MANVILLI, V., (Istituto Agricolo Bonafous di Lucento, Turin), in the *Giornale di Agricoltura della Domenica*, Vol. XXXI, No. 19, pp 147, 2 figs. Piacenza, May 1921.

The general name of " dolic " is applied to 3 species, each containing several subspecies, viz., 1) *Dolichos sesquipedalis* (asparagus Dolichos); 2) *Dolichos Catjang*, or *Vigna Catjang*; 3) *Dolichos unguiculatus* or *Vigna sinensis*, known as the cow pea, unguiculate Dolichos, or Blackeye. The last group is the one most cultivated in the United States and in South Europe (Greece, Italy, Provence, Spain and Portugal). In the United States, it has spread rapidly throughout the wheat belt. The best *forage* varieties grown there are:— Whip poor Will, Iron, New Era, and their hybrids Brobham, and Groit, and those most suited for *human consumption*, are, Couch, Cream, California Blackeye, Extra Early Blackeye, etc.

When cultivated for seed, the cow-pea is grown like the French bean with the same rotation, fertiliser, and treatment, and like it is sown from 4-6 cm. apart, with a space of 80-90 cm. between the rows. If intended for forage, it is grown as a catch-crop, and broadcast at the rate of 80 to 120 pounds per hectare, the seed being covered by means of a cultivator, or harrow. In order to obtain a large amount of forage for silage, the cow-pea is associated with Caragua maize, millet, or amber sugar-sorghum, being sown broadcast between the rows of the cereal.

An excellent combination for hay production, or pasture is cow-pea grown with soja (*Soja hispida*), as was discovered by the author in his experiments at the Agricultural Institute of Lucento (Turin). Twice as much seed is needed for the latter crop as for the former, and a variety of soja with strong stems must be chosen, in order that it may act as a support for the cow-pea. The hay thus obtained is very nourishing.

1116 - **Pearl Millet (*Pennisetum spicatum*) in Brazil.** — GABBATO, C. (Experiment Station of Viamão, Brazil), in *L'Agricoltura coloniale*, Vol. XV, No. 7, pp. 372-373, 1 table. Florence, July 1921.

The author has grown pearl millet (*Pennisetum spicatum*) at the Experiment station of Viamão (Porto Alegre, Rio Grande do Sul, Brazil), from seed obtained from the United States. This forage Graminea, although of African origin, did very well in Brazil.

It grows rapidly and attains a height of 2 to 5 metres. Cattle and horses eat it readily both when fresh and made into hay. The hay takes rather long to make, as the culms of pearl millet contain a great deal of water (75 to 80 %).

The highest yields are obtained on rich, alluvial soils, but it will grow on most soils. The seed-bed is prepared in the same way as for maize, and the millet is sown in the spring, from 80-90 cm. apart, the distance between the rows being 15 cm. About 4 kg. of seed is thus used per hectare. Should the pearl millet be intended for hay, it must be sown closer or broadcast, in order to prevent the culms becoming too thick. From 2 to 5 cuttings a year can be obtained, according to the dampness of the soil. In order to encourage the millet to throw up fresh stems, it must be cut to within 10 to 15 cm. above the collar.

A plot sown on Nov. 17, 1920 at Viamão, was ready for cutting the first time on February 23 (although the season had been somewhat dry), and yielded 49 285 kg. of green forage per hectare.

1117 - ***Bromus brachyantheca*, a Brasilian Winter Forage Plant.** — De Arruenda, J. M., in *Chacaras e Quintaes*, Vol. XXIV, No. 2, pp. 97-98. São Paulo, August 15, 1921.

For the last 5 years, the author has been growing in the State of Santa Caterina, Brazil. a *Graminea* for winter forage at an altitude of 4000 feet. The plant, which he found wild in his fields has been indentified by Dr. Kuhlmann (Agrostologist), as *Bromus brachyantheca* Doell. The author states that this grass is resistant to cold, ànd that he is well satisfied with the good crops he has obtained.

1118 - **Experiments in Growing Lucerne on Dry Soils in Italy.** — *Il Coltivatore*, Vol. 56, No. 21, pp. 81-83, fig. 1. Casale Monferrato, July 30, 1921.

It is generally believed that Gramineae are the best forage plants for cultivation on dry soils. Dr. A. Mannarini, Director of the Cattedra ambulante di Agricoltura di Lecce, has, however, demonstrated that certain varieties of lucerne, such as the Peruvian and Arab varieties which have been widely tested in the United States Agricultural Experiment Stations, succeed very well in the district of Lecce. Of the other Leguminosae which he tried, *Trifolium alexandrinum*, and the kidney vetch (*Anthyllis vulneraria*) gave a negative result. The substitution of Leguminosae for Gramineae as forage plants is a very important matter, for the former enrich the soil, whereas the latter impoverish it. Further, the nutritive value of Leguminosae as a fodder is much higher than that of Gramineae.

On January 10, 1920, Mannarini sowed the Peruvian, Arab and ordinary varieties of lucerne for purposes of comparison. The first cuttings, on May 30, amounted to 155, 102 and 49 quintals per hectare, respectively. From that date, until the beginning of September, there was a persistent drought; nevertheless, the two first varieties were ready for cutting a second time, whereas the growth made by the latter was entirely negligible.

1119 - **Dolic as a Forage Crop.** — See No. 1115 of this *Review*.

1120 - **Experiments in Flax-Growing in France.** — De Vilmorin, J., in the *Comptes rendus de l'Académie d'Agriculture*, Vol. VII, No. 6, pp. 397-403. Paris, April 27, 1921.

With a view to intensifying flax cultivation in France, the Interministerial Flax Commission appointed by the decree of January 24, 1918, decided in conjunction with an Agricultural Sub-Commission of which the author is a member, to plant experiment fields with the flaxes grown in 1918 in the collection of Messrs Vilmorin.

In 1920, three types of flax were sown at Verrières in plots of 1 sq. m. on Apiil 1, 2 kg. of seed being used per are (100 sq. metres). The collection consisted of 63 varieties.

Subsequently, the Agricultural Office for the Northern Region decided to establish an Experiment Station at Vattetot-sous-Beaumont near Goderville for the improvement of flax in the Seine-Inférieure. To this Station, which was under the direction of M. Thierry, the author sent 100 gm. of the seed of each of the varieties of flax that were considered the best at Verrières.

The straw of these different kinds was sent to the Manager of Messrs. Feuillette's factory at Goderville, who reported upon it as follows :—

Tensile strength. — This was high, and nearly equal in all the samples of tow; No. 269 (common variety with white flowers) was however a little inferior in this respect to the others.

Length. — Almost all the varieties were of good commercial length, 70 to 90 cm., only a few being too short and therefore excluded. Other qualities being equal, a flax of 60 cm. is worth about 25 % less than one of 80 cm. On the other hand, Nos. 228 (Pskoff flax, Verrières line) and 241 (selection 1803, Washington), which are over a metre in length, are a litt.e too long.

Quality and commercial value. — The tow is usually coarse, and harsh to the touch. If we class a 1914 sample of flax from Caux at 20, as representing the best Courtrai quality, the following varieties may be placed in the first class :— Nos. 228 (Pskoff, Verrières line), 241 (Selection 1803, Washington), 270 (with yellow seeds, Verrières line), and 232 (Japanese D. D. Leitch) as having sufficiently flexible straw to make fairly fine warp threads, probably No. 60, which on account of their textile strength, should comb well. This quality would certainly be much appreciated at the spinning-mill, and such flaxes would have a ready sale, and are marked 15. Nos. 228 and 241 have yielded respectively 231 and 209 gm. per square metre, which would mean a large return per hectare.

The second class includes the fairly good qualities marked 12 to 9; they are in order of merit, Nos. 223. 229, 238, (Dakota No. 52), 240 (Dakota No 114), 231, 242, 243, 245 (Irish flaxes, Feuillette group). In the third class, there follow in descending order, Nos. 293 (Dutch with white flowers), 253, 224 227, 247, 248, 267 (Royal with white flower), 268, 244 (No. 5 Irish, Hunter's Selection) and 225; all these flaxes are marked 8 to 7 as their fibres are strong and coarse. The fourth and last class consists of the "too short" groups with the exception of No. 235 (Canadian, Crawford), which is second to none in quality, and would be ranked among the best flaxes, if it were 75 cm. in length

Flaxes No. 228 (Pskoff Verrières line), and No. 241 (selection 1803) belong to the most approved industrial type as they strip and ret well. The Manager of the Goderville factory considers them superior to all the other kinds from the point of view of tow production.

The winter and spring flaxes from the district of Cremona, Italy, which are very short but of fine quality, proved unable to withstand the cold of the Parisian climate. They were tested in the south-west of France by the Director of the Agricultural Services at Mont-de-Marsan, but only one escaped injury by frost, resisting a temperature of −10° C; this survivor presented a flourishing aspect in April.

The collection being a large one, the author was able to make some genetic observations

Correlation does not always exist between the colour of the seeds, flowers, and pollen.

Most brown-seeded varieties have blue flowers and pollen, but there are also plants with brown seeds, white flowers, and blue pollen, while others have brown seeds, blue flowers, and yellow pollen. On the other hand, plants with yellow seeds and yellow pollen invariably bear white or pink flowers, or else flowers tinged or veined with blue.

In reply to M. HITIER's questions, the author states, that as a rule, the seed-yield is not correlated with the value of the tow. The Goderville hot-water retting process is used. Flax is grown at Verrières for its fibre and not for seed to supply the oil factories. Nevertheless, the author is of opinion that France, and Western Europe in general could grow flax yielding as good a linseed oil as any produced in Russia.

1121 - **Hemp Stalks As a Raw Material For Paper Manufacture.** — RASSOW, B., and ZSCHENDERLEIN, A., in the *Zeitschrift für angewandte Chemie*, Year XXXIV, No. 41, pp. 204-206. Leipzig, May 24, 1921.

A chemical study dealing with the use of hemp-stalks as a cellulosic raw material.

According to SCHWALBE and BECKER, the bast fibres of hemp contain 51.7 % of cellulose; the authors show that this figure is too high, probably because what the former investigators call "pure cellulose" is in reality mixed with lignin.

The authors have analysed two different samples of hemp fibre (the first obtained by ordinary retting and the second by retting in a 10 % solution of sodium carbonate. Carrying out the process used by SCHWALBE, but adopting more accurate methods of analysis, they found the percentage composition of the dry matter to be as follows:— Ash 1.25, 1.51; fats and resins 2.85, 4.26; furfurol 14.18, 14.37; pentosans (including those of the crude fibre) 40.57, 40.43; lignin 23.33, 22.08.

In order to obtain a cellulose free from lignin and oxycellulose, the crude fibre must be treated with chlorine (1 or 2 bubbles passed through per second for periods of half an hour), the product being washed each time with a 1 % solution of caustic soda, which is preferable to sodium sulphite.

Hemp bast, when heated for 12-13 hours at 140° C.-150° C with 4 % sulphite yields a paper pulp, which bleaches well, is of good appearance and contains 93 to 94 % of crude cellulose, with 10 % of pentosans. The results obtained with more concentrated solutions of sulphite were less satisfactory.

A product richer in pentosans can be obtained by other methods.

The composition of the stalks of flax and of hemp is very similar, but the first have a smaller pure cellulose content (37.05 as against 40.57 %). Hemp stalks are thus more suited than flax as raw material for making paper paste.

Coniferous timber contains much lignin and few pentosans, thus being just the opposite of the wood of dicotyledons. The authors suggest that perhaps pentosans are intermediate products in the natural synthesis of lignin.

1122 - **The Aromatic Plants of Algeria.** — BATTANDIER, J. A., in *La Parfumerie Moderne* Year XIV, No. 6, pp. 109-111. Lyons, June 1921.

Climatic conditions in Algeria are particularly suited to the cultivation of aromatic plants though up till now the industry has made very little progress. Many of the plants which abound in Morocco (1) are also found in large quantities in Algeria, but in addition to these, others are here enumerated and the list as it stands includes the following :—

RANUNCULACEAE. — *Clematis vitalba* and *Ranunculus bullatus.*

CRUCIFERAE. — *Matthiola* spp. and *Cheiranthus* spp. etc.

VIOLACEAE. — *Viola odorata.*

GERANIACEAE. — *Pelargonium* spp.

RUTACEAE — *Ruta montana, R. Chalepensis* amd *R. bracteosa* (high methylheptylic and methylnonylic cetone content), *Haplophyllum* (*Aplophyllum*) *tuberculatum.*

AURANTIACEAE. — These are more utilised for their fruits than for aromatics but exception is made in the case of Citron and Bergamotte.

ANACARDIACEAE. — *Pistacia Lentiscus* L. and *P. Terebinthus* L.

LEGUMINOSAE. — *Retama Bovei,* abundant in Ain Tédélès near Mostaganem, easily cultivated and forms well developed bushes, *Spartium junceum, Melilotus macrocarpa* DR., *Acacia Farnesiana* and other *Acacia* spp.

ROSACEAE. — Roses are grown only for their flowers, *Prunus Laurocerasus* (= *Cerasus Laurocerasus*), for distillation, apricots, plums, Japanese medlar, etc. for benzoic aldehyde.

MYRTACEAE. — *Myrtus* spp., *Melaleuca* spp., *Eucalyptus globulus.* Some years ago several tons per annum of Eucalyptus essential oil were produced but the industry has gradually died down and the old *E. globulus* trees have been utilised during the war as wood fuel for railway trains.

---

(1) " Aromatic Plants in Morocco ". See *R.* Nov.-Dec. 1920, No. 1115. (*Ed.*)

CUCURBITACEAE. — *Cucumis* spp

UMBELLIFERAE. — *Ptychotis ammoides,* abundant on the plains, *Pt. atlantica,* — rare. *Coriandrum* spp. *Daucus Rebondii* Cosson, rare (odour of aniseed), *Ammodaucus leucotrichus,* abundant in the Sahara.

RUBIACEAE. — *Asperula odorata* — forests of Babors.

COMPOSITAE. — *Artemisia Herba-alba,* abundant on the Hauts-Plateaux, *A. atlantica* Cosson, on the mountains in the South. *A. arborescens, A. absinthium,* var *atlantica, Warionia Saharae* Cosson and Beutham, *Pulicaria Mauritanica* Cosson, *Periderea fuscata, Rhaponticum acaule.*

OLEACEAE. — *Jasminum* spp.

ELAEAGNACEAE. — *Elaeagnus angustifolia.*

LABIATAE. — *Lavandula Stoechas, L. dentata,* and *L. multifida, Mentha* spp., *Thymus* spp. *T. Fontanasii,* abundant in the Dahra and elsewhere, *T. capitatus, Origanum floribundum, Rosmarinus officinalis, Melissa* spp., *Calamintha* spp., *Salvia officinalis, Zizyphora hispanica, Saccocalyx* spp., *Satureia* spp.

VERBENACEAE, *Vitex agnus-castus, Lippia Citrodora* (cultivated on a large scale at Boufarick).

LAURACEAE — *Laurus nobilis, Cinnamomum Camphora.* Camphor promises to be a rising industry in Algeria. M. TRABUT has grown camphor from seeds obtained from Formosa with complete success, the camphor being of equally good quality as that produced in Formosa.

CONIFERAE. — *Cedrus* spp., *Pinus halepensis, Juniperus nana, J. thurifera.*

AMARYLLIDEAE. — *Narcissus* spp., *Polianthes tubcrosa.*

IRIDEAE. — *Iris stylosa, I. palescens, Freesia* spp.

LILIACEAE. — *Asphodelus acaulis, Lilium Candidum, Smilax* spp.

ORCHIDACEAE. — *Aceras anthropophora, Spiranthes autumnalis, Orchis fragrans.*

The author admits that this list is doubtless incomplete, but considers that it includes practically all the plants at present utilised for aromatics in Algeria.

1123 - **Improvement in the Cultivation and Yield of the Walnut Tree in France.** — I. FAUCHEON C., in *L'Alimentation moderne et les Industries annexes*, Year XIX, New Series, No. 16, pp. 233-238, 1 diagram Paris, July 1921. — II. RIGOTARD, L. (Agricultural Engineer, Agriculturist at Chantesse Isère), Préparation des noix pour le commerce, in the *Annales de la Science Agronomique*, Year 38, Series 6, No. 1, pp 1-9. Paris, January-February 1921.

On the average, the annual walnut crops of the chief producing departments (Charente, Corrèze, Dordogne, Isère, Lot) may be estimated at 350 000-360 000 metric quintals. The so-called " Grenoble " and " Cerneau du Dauphiné " varieties are especially celebrated.

Table walnuts are grown on both banks of the Isère, in the Saint-Marcellin district; the " Mayette " variety from Moirans to Vinay; the " Parisienne " from Vinay to Saint-Marcellin, in the plain on the left bank of the river; the " Franquette " on the slopes of the right bank, and the " Chaberte ", or " commune ", on the Bizoir plateau from Voiron to

Lyons. The selected kernels (*cerneaux secs*) of the ordinary variety are sold, packed in cases of 25 kg., to confectioners. The Department of Corrèze (and chiefly the Cantons of Messac and Beaulieu, Brive district) produce dessert walnuts and oil-yielding walnuts.

In normal times, the consignments are dispatched chiefly from the Stations of Brive, Objat, Agyen-Juillac, Turenne, Quatre-Routes, Vayrac, Bretenoux and Tulle.

In the Dordogne, the nuts are gathered, when semi-hard and quite hard. The first are sent to the oil factories, the favourite varieties being "Nogarelle", large well-shaped nuts, "Redon de Montignac", and Noix de Brantôme, which are of average size and first quality. Of the hard-shelled varieties, only one "Conturas", or "Conduras", known also as "Corne de mouton", is exported. This is an excellent dessert walnut, coming principally from the Sarlat and Périgueux districts.

The chief walnut-growing centre in the Department of Lot is around Gourdon, which produces about 140 000 quintals.

TREATMENT OF THE WALNUTS WHEN GATHERED. — In order to free the nuts from the fleshy mesocarp, they should be piled up in a sheltered damp place. Here the walnuts finish ripening, and the mesocarp rots, so that it is easily removed, and the nuts are spread out in a thin layer, or dried in a current of air. They must be turned over several times a day, especially when they are damp.

The machines sometimes used to extricate the nuts are often defective and work too roughly.

When the mesocarp has not rotted off, it is removed to some extent by hand, and the nuts are then plunged into a corrosive solution, which removes the last traces of their green covering ; and are subsequently carefully washed to free them from all trace of acids (1).

When hulled, the nuts are washed and brushed, but are not kept long in water for fear of spoiling the kernel ; they are subsequently dried on screens, being often turned over

At Saint-Quentin-la-Rivière (Isère), a hot-air rotary drier has been installed, which makes the drying operation more rapid and regular. Nuts thus treated remain fresh, heavy, and very clean, and have a good colour.

In the Dauphiné region, walnuts are not usually treated with sulphur, through they are in the Bordeaux district. The operation must be carried out before the walnuts are perfectly dry, but is omitted in dry seasons, when there is no fear of mould. It is perfectly innocuous. At Bordeaux, the nuts are treated with sulphur at once after they are gathered, so as to take advantage of their rather damp condition which makes it unnecessary to wet them further. As soon as the sacks of walnuts arrive, they are placed in a good sized tank, which is completely covered, no opening being left. In the centre of the tank, sulphur-candles are lighted, the number depending upon the quantity of sacks to be fumigated.

---

(1) At the Second International Congress for the Suppression of Adulteration held in Paris in 1909, a vote was passed prohibiting the use of acids for this purpose.

In order to remove the particles of mesocarp, the walnuts can be brushed under water, or else, which is preferable, exposed to the action of steam for 1 or 2 minutes, then rapidly brushed under very hot water to which has been added 1 to 2 % of carbonate of soda.

Experiments made of recent years have proved that Eau de Javel bleaches the nuts better than sulphur fumes. In order to prepare Eau de Javel, 20 gm. of dry chloride of lime at 90° C are mixed with 600 gm. of water. Then 40 gm. of crystalline potassium carbonate are dissolved in 300 gm. of water and the two solutions are well mixed, and filtered after settling. The Eau de Javel is sprayed over the spread out nuts, which are afterwards washed very quickly in carbonated water, and finally, taken to the drier. The dry walnuts are kept in boxes or sacks in a cool place, and protected from drought or damp.

In order to prevent the origin of the nuts being wrongly stated, syndicates of growers have been formed in the Isère, especially in the arrondissement of Saint-Marcellin.

II. — The walnut-tree occupies an important place in French agriculture, a large number of nuts being exported, especially to the United States. From 1885-1916, the total walnut production of France varied from 210 000 to 1 590 000 quintals, being usually between 500 000 and 800 000. In 1916, the export of walnuts rose to 172 432 quintals, worth nearly 30 million francs, as against the total value of some 22 million francs for all the other exported dried or fresh fruits and fruit products.

Since 1885, walnut production in France has steadily decreased, falling to one half in 25 years.

As the walnut is a very important article of export, the author suggests that walnut-trees should be specially protected in France, and studies the following questions :— How can these trees be protected, and their cultivation improved ? What measures could be adopted by the State for safe-guarding the trees, increasing their returns, extending the area planted, and retaining the foreign market ?

PROTECTION OF WALNUT TREES. — This does not mean preventing the voluntary destruction of the trees, for since the value of the annual crop is practically equal to the sum which the wood would fetch, no owner of good walnut trees dreams of cutting them down. The State, however, might improve and facilitate the cultivation of the walnut.

The increase of the yield, the improvement of the varieties, the adoption of rapid methods of cultivating the soil of the plantations, the selection of suitable fertilisers, instruction in grafting, and the search for good stocks, are all matters requiring scientific study in order to effect any real improvement, but the research work can be carried out as well on the land as in the laboratory.

Little is yet known as to the conditions of climate and of soil moisture most adapted to the walnut, the stocks to be chosen for grafting, the method of transplanting, the spacing of trees when planted out, and the amount the trees should be pruned.

THE MAINTENANCE OF THE SOIL IN WALNUT PLANTATIONS. — A fairly large number of cultural operations is needed to keep the soil in a relatively friable condition and destroy the weeds.

In the regions of small holdings, which are the chief centres of walnut production, the labour crisis calls for an adaptation of motorculture, and the study of special tilling machines, for with an ordinary plough or tractor there would be a great risk of cutting the roots of the trees. The preparation of the soil for the crop (superficial cleaning), can be done by means of tractors. Further, it is necessary that the large amount of labour necessary for the short picking season, which is very difficult to procure, should be better organised and supervised.

COMBATING ANIMAL AND PLANT PARASITES. — Nearly every thing in this direction still remains to be done. Insects make the nuts " maggot ty ", fungi, of which the most dangerous would appear to be *Armillaria mellea*, attack the roots and the living portion of the trunks, or destroy the wood, so that they soon become hollow. Little is known of these parasites and still less of the way of combating them. When trees are removed that have died from the attacks of fungi, the soil in which they have been growing is never disinfected, and yet growers state that young trees planted to fill up gaps in the walnut woods rarely survive.

PREPARATION OF WALNUTS FOR SALE. WALNUT KERNELS AND OIL. — It is necessary to study the machines used for the different operations to which the nuts are subjected after being gathered : washing, sorting, sulphuring, drying. The apparatus devised for the treatment of colonial fruits might be adapted to breaking and shelling the walnuts. The manufacture of oil, and especially of oil that does not soon turn rancid, are subjects for careful study. The commercial side of the question (growers syndicates, the sale and transport of nuts) is also worthy of attention.

Perhaps wood industries could be started on the spot, so as to turn to good account the large quantities of walnut wood that is now actually lost, or used for fuel.

The author advises the formation of a special organisation for the study of the walnut-tree, the founding of a " Station for the study of the walnut tree ", equipped with chemical and pathological laboratories, an observation field, and an experiment field.

1124 - **The "Fuciletta" Cherry in Italy.** — PRIGANTI, G., in *L'Italia agricola*, Year 58, No. 8, pp 231-242. 1 plate. Piacenza, August 15, 1921.

The export season for fresh Italian fruit opens with the consignment of cherries. These are not only sent in their natural condition, but also after having been bleached with sulphur dioxide.

Bleached cherries are a special industry in Campania and the province of Bari (1).

It may be said, that each region of Italy has its special varieties of cherry ; some of these are of excellent quality, for instance " Imbriani ", which Messrs CIRIO have made well-known of recent years in Campania.

---

(1) See *R.* Feb. 1921, No. 208. (*Ed.*)

The fruits of this variety, are firm, of average size, and have pink pulp and small stones; they are well adapted to bleaching.

The most common of the varieties grown in the Province of Bari is "Fuciletta". The tree is remarkable for its very vigorous growth, which it long retains, and its constant crop whenever it is able to root well, as it does in the district of Bari, where the soil consists of the "terra rossa" (red earth), and the calcareous subsoil is traversed by many cracks. The chief characters of this variety are as follows:

Branches strong, oblique, only growing horizontal in old trees.

Leaves elliptical, 6.5 cm., broad, and 18 cm. long (the petiole representing 5.5 cm.). Edges with small pointed teeth, the apical tooth being much the longest and sharpest. Vein distinct on lower surface. Blades glossy, deep green on upper surface, of a lighter shade on lower surface; smooth. Petiole slender, cylindrical, present on both sides; at the beginning of the blade are two elongated, deep-red glands. Petiole slightly grooved.

Flowers many in number, white, open the first fortnight in March.

Fruits subspherical, depressed on the upper portion, bright ruby red and glossy when quite ripe. Average diameter 2.7 cm.; average weight 9 gm.; borne on a peduncle 3.5 cm. long on an average. Stone small; pulp very fleshy and white. Taste sweet, slightly acidulate.

Ripening in May after the 10th of the month; exact date depends on the exposure and altitude.

1125 - **The Mango Tree in Costa Rica.** — *Boletin de la Cámara de Agricultura de Costa Rica*, No. 1, pp. 9-11. San José de Costa Rica, April 1921.

The mango-tree was imported into Brazil from India in the eighteenth century, and spread from the former country over all tropical America. It grows very well at Costa Rica; sometimes attaining the height of 20 m., though usually it is from 8 to 10 m. high. The tree requires no special attention, and continues to bear fruit regularly for many years. It seems subject to no disease.

The mango adapts itself to the most different climates, but a really dry season is necessary for the ripening of its fruit. For this reason, the best Costa-Rican fruit is produced in the Departments of Alajuela, Guanacaste, and Puntarenas, where the altitude is always below 1000 metres.

The tree is grown from seed, the only selection practised being the choice of the seed from the finest fruits.

Shield-grafting is common, but does not give entirely satisfactory results; it would be better to replace it by in-arching combined with the progressive removal of the portion of the scion that remains below the graft-callus.

Good crops of excellent fruit are produced, especially in the western areas of the country.

1126 - **The "Marañón" (*Spondias dulcis*) in Costa Rica.** — *Boletin de la Cámara de Agricultura de Costa Rica*, No. 1, pp. 14-16. San José de Costa Rica, April 1921.

The *marañon* (*Spondias dulcis*) is one of the most highly-prized and valuable fruit-trees of Costa Rica. It grows to the height of 4 metres, and is unexacting and very hardy, doing well even on stony slopes, and not harmed by the presence of weeds or the grazing and treading of animals that crop the grass beneath the shadow of its leaves. The fruit is however, more plentiful when the orchard is carefully tended, that is to say if it is ploughed 2 or 3 times a year, lime and ashes being applied to the soil, the trunks limewashed, and the ground irrigated several times, if possible.

The tree is raised from seed. The seeds are sown 4 metres apart in a square; should the quincunx arrangement be adopted, 1 hectare can bear 700 trees; fruiting begins in the fourth year.

Old trees cut down to a little above the root-collar throw up fresh shoots, and produce a good crop for some years. The fruit is a drupe of lemon-yellow colour and may attain the size of a lemon. Part of the crop is exported, the rest is either consumed locally or used for making a delicious liqueur. The seeds are used in the manufacture of preserves.

1127 – **New Vine Stocks in Italy.** — ZANOTTI, L., in the *Giornale vinicolo italiano*, Year 47, No. 33, pp. 323-325, 2 figs. Casale Monferrato, August 14, 1921.

Among the vine-stocks created of recent years, the author mentions, as having apparently given good results, No. 5, BB Kober (Berlandieri × Riparia), and the two hybrids obtained by M. PIROVANO, of Vaprio d'Adda (Province of Milan), viz. 2-59 P., and 1-37 P.

The first is the best of the Austrian vine-stocks; it was selected by Prof. KOBER, Chief Inspector at the Ministry of Agriculture at Vienna. It has been widely used in the reconstruction of vineyards in Austria, where it is as popular with the vine-growers as Telechi No. 8 B. It does best on very calcareous (7 %), and on damp soils, but has also grown well for 20 years on clays. It has much grafting affinity with a large number of vines, causing them to produce an earlier and larger crop.

The Pirovano hybrids described by the author are distinguished by their vigour, and their resistance to lime, drought, phylloxera and fungoid diseases.

1128 – **Notes on the Exploitation of the Forests of the Equatorial Regions.** — TOUTÉE, in the *Comptes rendus de l'Académie d'Agriculture de France* Vol. VII. No. 24 pp. 545-554. Paris, June 22, 1921.

The author gives practical data showing that though a given region may be rich in forests, it does not always follows that the exploitation well be as remunerative as might be expected. This is generally the case when the forests are difficult of access, and without roads, and especially in those of the Equatorial regions where the many different species growing in a confused mass (as many as 150 may be counted on an average in an ordinary felling zone) differ greatly in quality and value. In such places, felling, classification and removal are very costly, even in forests traversed by a railway, since the belt to be worked may be as much as 200 m. in width on either side of the line. The freightage, increased by the cost of conveying the timber from the forest to the train, and thence to the port, becomes prohibitive.

The author draws attention to the clearing methods adopted by the natives, who after felling the trees on a given area, pile up all the wood thus obtained and allow it to dry, subsequently setting fire to it, in order to burn the trees which they are unable to cut down. All the clearing so made they cultivate, until the ground is entirely exhausted, when they and the whole village migrate to another freshly cleared space. This exhausted ground become over-run by the "parasolier" (umbrella-tree) a tree which prevents the growth of more valuable species. Its wood is so light as to be useless for ordinary purposes, but as it consists almost entirely of pure cellulose it is very suitable for paper-making The pulp could be prepared on the spot, for in the centre of the area covered by these trees, there are large streams with water-falls providing many thousands of H.P. together with all the water necessary for the treatment of the fibre. Thus everything required for starting a paper factory is at hand.

A second species of tree mentioned by the author is the mangrove (*Rhizophora racemosa = R. Mangle*). This is exceedingly easy to fell and remove, for it occupies areas which are much more accessible than those covered by the "parasolier"; they are of vast extent, and form the deltas of rivers flowing into the Atlantic.

Excellent railroad sleepers could be made from mangrove wood, for its weight would give solidity to the line. It offers great resistance to flexion, being twice as rigid as oak, and it is said to be almost, if not entirely, rot-resistant. This wood is also very suitable for making casks.

1129 - **Preparation and Use of Danish Timber.** — OPPERMANN, A. Tilvirkning og Anvendelse of Dansk Gaontree in *Det Forstlige Forsøgsvaesen i Danmark* Vol I, Pt. 2, pp 135-211, figs. 8, Vol. II, Pt 3, pp 331-361, figs 7 Vol V, Pt 4 pp 301-337, figs. 2. Copenhagen, 1906, 1911, 1920.

Forestry tries to ascertain the amount and quality of the yield obtainable with a view to finding out the most practical mode of working. The tests undertaken to this end are apart from a rough estimate, maintly based on measurements of the trees and technological experiments, although certain authors from a more practical, mercantile point of view have made investigations into the timber products. Technological and analytical research give information as to the mechanical, physical, and chemical qualities of the wood. In the terminology of foresters the idea of "quality" was once nearly synonymous with strength and durability as far as timber was concerned and heating power in the case of fire-wood. As all these qualities depend to some extent on the specific gravity of dry wood, the next step was to consider this — or rather the ligneous substance contained in a piece of wood — the standard of quality (ROBERT HARTIG). In more recent times the tendency has been to refer to the anatomical structure; a comparison between spring-wood and summer-wood, the proportion of cavity to thickness of fibre; that is to say the magnifying glass and the microscope take the place of the scale and the xylometer.

Increment measurements together with an estimate of the age of the trees, show the amount of production of wood as well as dimensions, and trees are classified according to size, shape, and structure, the line often being drawn mainly with a view to the requirements of practical working. While the trees are in growth, it is generally the surface only that the forester is able to examine and when they have been felled and worked, it is but a few cuts and lengths which can be examined. Experience and practice, however, together with knowledge of the structure of the wood, enable the forester to judge of the inner qualities from the outer shape and configuration, and in this respect he is assisted by his customers, who at least emphasize flaws and defects, while their approval results in greater demand and better prices.

The manufacturer, to whom wood is his raw material, must above all make sure to get the most out of it in the form of manufactured articles; in his estimation technical qualities will usually be of only secondary importance. The strict classification into specifie groups according to dimensions of the wood and the strong prominence given to the mere bulk of each class offered for sale have tempted the forester to lay the chief stress on formal compliance with regulations for classification, and not on the more essential consideration of what is in demand. It is the consumption now and in the future that is to direct felling, cutting and classification of the trees as well as cultivation and tending of woods; the prices made will show the character of the consumption, but practical forestry cannot be guided by it.

The experiments and tests discussed in the papers above quoted, are to show how dimensions, shape and structure — or possibly defects in structure — affect the amount and quality of the yield. To this end the raw material — trunks and piled timber — is examined much more closely than hitherto, and the yield obtained is divided into its various categories In practical forestry as also in the timber trade, stands and even regular forests often ought to be classified according to what characterizes the wood for some large area, indicating its particular use, the present state of the market always being taken into consideration.

In the long run it will be best for all parties concerned that each seller seeks a market for his goods where their good qualities are duly appreciated and the inferior ones tolerated; on the other hand, saw-mill and woodworking factories ought to be set up in districts that can deliver a constant supply of suitable raw materials.

The trunks examined are not classified according to length and diameter only. As the size of the knots, the decrease of diameter and several other characters change from root to top, a classification according to sections of height is also often made so as to distinguish the butt from a series of consecutive sections each at a certain distance from the ground. In this way we learn to understand how distance between the plants as well as cutting and pruning affect the amount and quality of the yield. It is obvious that these tests may to some extent be of assistance to the owners of saw-mills and similar factories, especially through particulars as to quantity of saw-dust, chips, etc. But this is not the principal object but rather the construction of a more solid basis for the production of timber, ranging from the very start of the work — selection of species and choice of seed — to the final preparation in the forest. Of the many experiments and tests the following may be mentioned (1).

1) *Staves made of beech-wood.* — The yield increases in proportion to diameter up to 10 Danish inches (1 Dan. inch. = 1.0297 Eng. inches.; 1 Dan. foot = 1,07 Eng. feet), after that decreases, but reaches a new maximum at 16 D. in. Even wood of 5-6 D. in. diameter may yield a considerable supply of staves, but these are always narrow (2 $^1/_4$ D. in.). At only 8 — 10 D. in. nearly the same amount of first class staves is obtained as from the class of 14 — 16 in. Classifications according to shape and purity of the three qualities *a*, *b*, and *c*, prove that the amount of interior staves increases from *a* to *c*, this last quality giving 30 per cent. less than of good wide staves. How the amount of stave-wood decreases in proportion to the distance from the ground may be learned from a special investigation on height sections in beech stands. As to saw dust, varying from 10 to 11 %, a good quality of wood gives more than an inferior kind, and thin wood more than thick.

2) *Shovel-handles made of beech-wood planks.* — Two trunks, 12 D. feet long, were divided into 3 sections, each of which gave 9 planks. From root to top the number of handles decreased as follows: 51, 43, 43 per cent., while for the inferior turner's wood 4, 8, and 4 per cent. was the result. The total amount of partly manufactured articles was 55, 51 and 47 per cent. Plank No 5 being next to the pith, 1 and 9 to the outer parts, the yield would be as follows:

		For planks				
		Nos 5	Nos 4 + 6	Nos 3 + 7	Nos 2 + 8	Nos 1 + 9
	%	40	41	54	41	0
Turner's wood	%	3	6	4	7	22
In all	%	43	47	58	48	22

The maximum of yield is thus far from the pith, planks 3 + 7, although narrow and sloping at the sides, but knotless and of regular structure.

3) *Bottoms for shoes made of beech-wood butts.* — 18 trunks, diameter 24-40 cm., were divided into 3 sections according to diameter, and each of these into 3 classes according to quality. The number of bottoms is 8-12 per cent., leaving some inferior timber. The loss on the small butts consists mainly in bottoms for small foot-wear. The bigger the butt, the greater amount of large bottoms for grown-up people.

4) *Spokes made of oak butts* — 16 trunks, averaging 18 D. feet in length, were cut into spokes, 2 D. feet long, after having been divided into 3 sections: root trundle, trundles nos. 2-5 and trundles nos. 6 and upwards. In each section trundles of more and less than 25 cm. were kept apart, and the two upper ones were divided into 3 qualities: *a*, *b*, and *c*. The yield was as follows:

(1) Cf. A. OPPERMANN. Trae og andre Skovprodukter, chap XVI, København, 1911, 16. (*Ed.*)

	Spokes, per cent., in the trundles		Spokes, per cent., quality	
	under 25 cm.	over 25 cm.	firsts	seconds
I. Root Trundle	34	48	78	22
II. Trundles 1-5 . . . . . . a)	44	50	63	37
b)	40	47		
c)	0	37		
III. Trundles 6 & upwards. a)	40	40	42	58
b)	38	44		
c)	29	37		

The top section gave a number of seconds, and they were mostly small. The proportion between firsts and seconds does not vary much in the same class divided according to width and quality; the loss in section III is due to the fact that it contains a proportionately large amount of inferior wood. The knotless part of the heart-wood of the trunk forms a shell, the thickness of which decreases greatly towards the top; the knotty part has the shape of an inverted cone.

5. *Handles for implements, made of ash butts.* — 62 small butts 86-180 cm. long, were sorted into 3 classes according to diameter, and these again according to quality into classes *a*, *b*, and *c*. The butts were cut into square poles, 1 5/8 × 1 5/8 D. in., to be turned into handles for implements. The yield in metres per m³ was as follows:

Yield of poles, m. per m³	Diameter and quality of the butt							
	under 30 cm.			30-35 cm.			over 35 cm.	
	a	*b*	*c*	*a*	*b*	*c*	*a*	*b*
Firsts	192	77	32	202	109	106	226	216
Seconds	36	133	79	31	83	69	19	51
In all . . .	228	210	111	233	192	175	245	216

It is evident that the quality of the butts is fully as important as the dimensions; first class butts of less than 30 cm. yield better results than seconds of more than 35 cm., and first class butts yield a much larger amount of first class poles, but fewer second class than butts of an inferior quality.

6) *Boards made of spruce butts.* — 80 butts, 12 D. ft. long, 12-26 cm. in diameter, were cut into boards, after having been divided into 7 classes according to diameter. The yield of unassorted boards increased but little in proportion to the diameter of the butts, but the thick butts yielded fewer boards of an inferior quality and many more good squar-

ed ones. The butts of each class according to diameter were subdivided into classes *a* and *b* according to quality, with the following average results:

a) Squared boards 49.0 per cent., inferior boards 10.4 per cent., in all 59.4 per cent.
b) » » 44.6 » » » » 10.4 » » » » 55.0 » »

Of the entire lot of butts the results were: 54.2 per cent. boards, 31.1 per cent. waste products, 14.7 per cent. saw-dust.

7) *Height sections of spruce trunks.* — 15 spruce trunks 48 D. feet long were divided into 4 height sections so as to yield 15 butts of each. The amount of unassorted boards decreases but little in proportion to height, but the amount of squared boards from the 2nd section was twice that of the 4th. By sorting the squared boards according to quality, the inferior goods from the four sections were found in the following proportion: 35, 82, 78, 87 per cent. The value of the boards produced shows the following distribution according to the four sections: 36.1, 28.8, 22.2, 12.9 per cent.

8) *Straight and crooked butts from spruce.* — In square plantations the trees that attain dimensions for timber will often have a curve at the bottom: the curvature observed being 6.5 cm. The aggregate amount of boards is not reduced by this defect, but in the squared boards the proportion between crooked and straight butts is 3 : 4, and of these there were 73 and 10 per cent. respectively of an inferior quality. The loss sustained by this form of cultivation may thus be very considerable.

9) *Wood-wool from spruce.* — A quantity of barked spruce was sorted according to dimensions yielding the following amount of wood-wool:

Diameter . . . . . cm.	6.5 to 8.5	8.5 to 10.5	10.5 to 12.5	12.5 to 14.5	14.5 to 16.5	16.5 to 18.5	18.5 to 20.5	20.5 to 22.5
Wood-wool. kg. per m.^{3}	356	393	411	426	423	413	423	405

Cheap and thin wood accordingly yields the same amount as the thick, which may thus more profitably be used for boards and similar material. The Danish export of eggs demands a large consumption of wood-wool, and thus earlier thinnings may be profitably utilized.

10) *Cellulose from spruce.* — A parcel of spruce was sorted according to dimensions yielding the following quantities of air-dried cellulose:

	Wood from stem			Wood from top	
Diameter . . . . cm.	10–15	15–20	20–25	10–15	15–25
Cellulose . . . . . kg per m.^{3}	170.6	177.5	185.6	163.2	170.5

As with the previous experiment the advantage of using the thin, cheap wood is evident.

A comparison between points nos. 1-5 on the one hand and nos. 6 10 on the other shows that a rational sorting of wood of broad-leaved trees is far more complex than the sorting of spruce.

11) *Production of planed, tongued and grooved boards.* — By the process of planing on all four sides, spruce boards, 1 1/4 D. in. thick, lost 22-23 per cent. in weight and bulk being more than is generally supposed.

[1129]

12) *Thickness of blade and amount of saw-dust.* — By cutting laths from spruce butts, using three different circular saws, the following amount of saw-dust was obtained :

Thickness of blade . . . . mm.	3.6	2.7	2.0
Amount of saw-dust . . . . %	22.3	18.4	12.3

Experiments like those mentioned above are quite simple; they are neither applied natural science nor applied economics. But they demand considerable circumspection, perseverance and exactness on the part of the person in charge of the work; when this work is to be kept within reasonable bounds, it must be planned in such a way that the experiment may settle the question asked without demanding more attention than absolutely necessary; and in formulating the problem to be solved in each case some knowledge as to how timber is to be worked and utilized, is requisite together with an understanding of the growth of trees and how they should be classified.

1130 - **Experimental Researches on the Electrical Treatment of Wood in Italy.** — PETRI, L., Extract from the *Annali del R. Istituto superiore forestale nazionale*, Vol. VII, pp. 3-118, 28 figs., 1 plate. Florence, 1921.

The author gives an exhaustive summary of all that is known respecting electro-capillary phenomena, and describes the experimental attempts hitherto made to dry and preserve wood by electrical treatment. He then describes his own experiments (so far limited to laboratory work), made chiefly for the purposes of determining :— 1) How far electro-osmosis, can be used industrially to impregnate different kinds of wood with antiseptic fluids, and what are the advantages and disadvantages of this process; 2) the practical value that can be attributed in electric impregnation to the displacement which takes place, within the ligneous tissue, of the ions of the solution when the electric current is passed through it ; 3) whether it is possible to fix the preservative substance in the wood by means of any reactions taking place between the products of electrolysis and the chemical constituents of the cell membrane or cell contents.

The application of electricity to the preservation of wood, by inducing the rapid penetration of antiseptic substances into the tissues, or to hasten its drying, has not yet been attempted industrially, although different investigators have repeatedly tried to discover practical methods for carrying it out.

It is a question whether this neglect of the subject is due merely to the inconstant or negative results obtained, and to the unpractical nature of the schemes suggested or whether there are economic and technical difficulties that prevent the industrial adoption of the electrical process.

In this article the subject is examined objectively, and, by giving the results of the first series of experimental researches, an attempt is made to throw some light on the principal questions that arise in studying the problem.

In the first place, it must be recognised that experiments on the impregnation of wood by means of solutions of electrolytes and the passage of the electric current, are justified by two classes of phenomena, viz., electro-osmosis, and the movement of the ions during the passage of the current

As regards the first of these phenomena, the author's experiments have proved that when wood is subjected to a continuous electric current, the realisation of the conditions which favour the passage of the maximum amount of liquid into the wood by electro-osmosis is of importance only when it is desired to obtain an appreciable exosmosis of wood sap, since when antiseptic substances are injected, they penetrate equally well into the cells, even if electro-osmotic transport of the liquid is at its lowest.

The amount of liquid carried through the wood in a unit of time varies according to the species under treatment, the concentration and conductivity of the solution used, and the current tension.

The electric impregnation of wood is easily attained with liquids having a relatively high dielectric constant, that is to say, with substances which show considerable dissociation of the molecules on going into solution. Nevertheless, provided the treatment is much prolonged, it is also possible to carry out the impregnation with substances that are bad conductors of electricity, but this is not satisfactory from the economic standpoint.

As a rule alternating current is preferable to continuous, because it enables the resistance of the wood to be overcome more quickly and induction resistances can be introduced into the circuit instead of chemical resistances. There are however some cases in which a continuous current gives better impregnation results, e. g., when corrosive sublimate is the substance to be used.

Complete impregnation of wood by the electric process can be obtained if the ligneous tissue is *still fresh*, that is to say, if the tree has been lately felled, and the wood cells are still well-supplied with water (40-50 %).

Dry wood that has been swollen by immersion in water, does not regain the electrical conductivity of green wood and is difficult to impregnate. The rapidity with which the same salt solution penetrates into wood when transported by the electric current is much greater than when simple imbibition takes place.

It is not possible to dry wood by the electric process in the same manner as by the natural process. The slowness of the natural process is due to the predominance of oxidation, whereas in the artificial treatment, the indirect action of the current causes reduction and hydrolytic phenomena to have the ascendancy.

It is thus possible by using a continuous current to impregnate wood with a weak solution of sulphate, or even very dilute sulphuric acid, to obtain the hydrolysis of the starch and most-easily hydrolysable compounds while exosmosis of all the other solutions contained in the ligneous tissue is taking place towards the cathode. This treatment may well be termed an *electric leaching* of the wood, and can be compared, as regards some of its effects, with *steaming*.

[1136]

With electric impregnation unlike ordinary processes, the toxic substance is fixed in the tissues, so that the preservative action of the former cannot be lessened by the action of water. This, however, only applies to certain metallic salts.

Wood injected electrically with zinc chloride, if subsequently immersed for a long time in water, does not lose any of the immunity to fungus attacks conferred by this salt, and is free from the increased hygroscopicity which is such a serious trouble when ordinary methods are adopted.

As regards the physical properties of wood, electric treatment causes a diminution in the changes of volume caused by variations in humidity, but for this result to be attained the current density must be high, 2 ampères per square decimetre. Under such conditions there is also a perceptible decrease in the resistance to flexion and shock. With less current density (0.10-0.20 ampères per square decimetre), the injurious effect is almost negligible.

Since wood that has undergone electric treatment loses a little of its hygroscopicity, it dries more quickly than untreated wood, but the difference is so slight that it is not worth while applying electricity in order to hasten drying Drying can however be effected by using a 150-volt current, but this frequently lessens the mechanical strength of wood

Experiments have shown that sleepers or beams for electric treatment should be placed on a layer of powdered gas carbon (lower electrode) put at the bottom of a wide but shallow basin containing the solution to be injected . Another layer of gas carbon is placed upon the wood (upper electrode), and well pressed down.

The two electrodes are connected by carbon rods to the cables of the dynamo. The water in the basin is raised continually by a pump and allowed to fall in showers upon the upper electrode.

One difficulty arising during the process is due to the different conductivity of each piece of wood. Some pieces allow an excessive amount of the current to pass, whereas others show great resistance. This trouble can, however, be overcome by gradually substituting untreated beams for impregnated ones, or by making two layers of beams placed at right angles to one another.

In order not to injure the physical properties of the wood by causing successive processes of hydrolysis, the limit of 0.80 amperes per square decimetre ought not to be exceeded.

As regards the practical application of the electrical treatment of wood, it should be regarded as suitable only for the impregnation or leaching of pieces with rectangular section, such as railway-sleepers, beams, joists, and paving-blocks. The preservative substances likely to give good results are zinc chloride, bichloride of mercury, and perhaps sulphate of copper, especially with beech-wood, if a low-frequency alternating current of not more than 0.5 ampères per square decimetre is used.

It would be premature to draw from these laboratory experiments any definite conclusions regarding the possible practical use that may be made of the facts just stated.

[1130]

Further experiments carried out on a larger scale should be undertaken to determine many points that the author has purposely neglected, such as for instance the amount of electric energy necessary for the impregnation of a cubic metre of wood with electrolyte solutions found most suitable for the purpose.

The work so far done inspires the author with the conviction that the application of the electric current to the preservation of wood will give good results (although only under given conditions), contrary to the pessimistic opinions expressed by certain other investigators.

LIVESTOCK. AND BREEDING

1131 - **Study of the Trypanosomiasis of Stock in Venezuela.** — TEJERA, E, in the *Bulletin de la Société de Pathologie Exotique,* Vol. XIII, No. 4 (meeting on April 4, 1920), pp 207-305. Paris, 1920

A) EQUINE TRYPANOSOMIASIS. — This disease is met with almost throughout Venezuela. It usually attacks horses, but is not infrequently found affecting mules and donkeys. It is an epizootic disease occurring under two rather different forms, which were long believed to be caused by separate pathogenetic agents, whereas they are now known to be merely two clinical types of the same disease. Both are caused by a trypanosome of the *evansi* species; it was discovered by RANGEL (1) and described by MESNIL under the name of *Trypanosoma venezuelense.* A detailed account is given of both forms, the chief characters of which are as follows: —

(a) *" Peste boba ", " hermosura ", or " tristeza "* — Characterised by loss of flesh accompanied by oedema in certain regions of the body; and depression. Breeders state that the first symptom is the dullness of the coat, which latter loses its gloss, becomes shaggy and dry, comes out easily and as the attack progresses, bald patches appear. Until this moment, the animals appear in their usual health, and it is very difficult to identify the cases: if their temperature is taken it is found to be high.

Soon after the first symptoms appear, the animal becomes listless and goes off its feed; this condition lasts only a short time, however, sometimes only 1 on 2 days. Afterwards the patient recovers its spirits and appetite, and seems quite well, but a few hours of work render it depressed and disinclined for exertion. The trypanosomiasis continues to develop, oedema of the face is noticeable, the eyelids swell so as more or less to conceal the eye-ball. Details respecting the appearance of the oedema are given. The animal rapidly becomes anaemic. The nasal and buccal mucous membranes are white and bloodless. Often signs of conjunctivitis accompanied by watering of the eyes are seen. A yellowish matter exudes from the nostrils. The temperature rises from time to time. During the last period, the fever is generally continuous and is accompanied by dyspnoea and tachycardia. The disease lasts 1 or 2 months, and over 80 % of the infected animals die.

---

(1) R. RANGEL, *Laboratorio del Hospital Vargas* (Boletín), No. 2, 1906, p. 11. (*Ed.*)

b) "*Desrengadera*". — Characterised by progressive loss of flesh and very pronounced anaemia. The animal becomes easily tired, and shows symptoms of tachycardia accompained by dyspnoea.

Very soon after these symptoms manifest themselves, disturbances of the nervous system are observed, viz., inco-ordination of movements, symmetrical paresia of the hind limbs, rarely complete paralysis. At first, the animal only stumbles occasionally, later it moves its hind legs with difficulty, dragging the tips of its hoofs along, and walks with stiff legs held very far apart. Every moment its difficulty in balancing itself increases, and often the animal has to lean against something, in order to keep on its legs. Nevertheless, it is a curious fact that at this stage of the disease it can run fairly well. Gradually, the symptoms of paresia increase, until the patient can no longer stand. Finally, it falls to the ground, but if given nourishment, it may live for some days in this condition. The mortality in cases of "*desrengadera*" is about 100 %. The animals that regain their health are few in number, and as the paresia of the hind-quarters persists, they are useless. In acute forms, the animal dies almost instantly before the first symptoms of the disease have fairly developed.

From the clinical standpoint, Venezuelan trypanosomiasis much resembles, in its complex of symptoms, Argentine trypanosomiasis (*mal de caderas*), except that in the former, haemoglobinuria which frequently occurs in the latter, is never present. Nevertheless, it is impossible to confuse the pathogenetic agents, for the two trypanosomes differ morphologically. *Trypanosoma venezuelense* appears to be far more virulent. The disease produced by *Trypanosoma equinum* generally lasts from 2 to 5 months, whereas the duration of Venezuelan trypanosomiasis, is only from a fortnight to 2 months. The latter disease usually appears at the beginning and end of the rainy season, most of the cases occurring in March and April. The carrier of this form is so far unknown.

In cases of natural infection *Trypanosoma venezuelense* has proved very virulent in horses, many thousands having died from the disease. It is of frequent occurrence among horses kept by breeders in "corrals", but is very rare among wild horses. Mules and donkeys are also subject to "*desrengadera*", but to a far less extent. Specimens of the capibara (*Hydrochoerus capibara*), suffering from paresia of the hindquarters, and infested with *Trypanosoma venezuelense* are frequently met with on the plains of Venezuela.

R. RANGEL has found dogs and monkeys attacked by the same trypanosome. Dr. A. I. FERNANDEZ says that he has discovered, in the blood of many monkeys, trypanosomes morphologically the same as *Tryp. venezuelense.*

In order to study the virulence of the *T. venezuelense*, the author inoculated some guinea-pigs, rats, mice, a horse, two monkeys, a cat, and a heifer. All the animals, except the heifer died after the disease had run a shorter or longer course. The heifer was inoculated with 1 cc. of guinea-pig blood; on the 7 th day, the animal had 40° C of fever, and this temperature did not change until the 10th day after inoculation. Then the trypanosomes in the peripheral circulatory system became much reduced in numbers, and disappeared entirely 4 days later. The heifer was infectious for 5 months after inoculation, but subsequently showed no signs of disease.

B) CATTLE TRYPANOSOMIASIS. — All the infected animals examined by the author were extremely emaciated and their skin showed may alopecic patches. The colourless mucous membranes pointed to a very advanced stage of anaemia. At the level of the neck, an especially hard swelling was to be seen This swelling, which sometimes is located in the dewlap, goes by the name of " papera " (goitre), among the breeders. The sick animals stand apart from the rest and are depressed, but their appetite is about normal.

The pathogenic agent, which had no effect when inoculated into adult guinea-pigs and a cat, seems from its characters, as described by LEGER and VIENNE, to be identical with *Trypanosoma guayanense*, which attacks cattle in French Guiana. This supposition is strengthened, by the fact that the latter does not attack dogs or guinea-pigs.

The author is inclined to believe, with F. MESNIL (1), that *Tryp. guayanense* is a variety of *Trip. cazalboui*, if it is not actually the same micro-organism for, as is well-known, these two trypanosomes are alike in not attacking rats, mice, guinea-pigs, dogs, cats, and monkeys, and in infecting only ruminants and equidae.

The cattle disease having the characters described by LEGER and VIENNE, and which was observed by the author in Venezuela, appears not to have existed long in the country, so that the author suggests that perhaps the zebu, an animal introduced into Venezuela some years ago, may have brought with it the form of trypanosomiasis known as " souma ", which is produced by *Tryp. cazalboui*.

1132 – **Current Ideas Respecting the Licking Habit in Cattle and Its Causes. Results of Practical Experiments with Drugs in Prussia.** — ZUNTZ, N., in the *Mitteilungen des Vereins zur Förderung der Moorkultur im Deutschen Reiche*, Year XXXVII, pp. 437-440 Summarised in *Biedermann's Zentralblatt*, Year I, Part 1, pp. 33-34. Leipzig, 1921 (2).

The analogy between the symptoms of the licking disease and those induced by depriving young growing animals of certain constituents of protein, such as tyrosin or tryptophane is, according to the author, so striking, that we are compelled to suppose that the habit of excessive licking in cattle is due to the absence of one or more of the substances necessary for the development of the organism. Further, the grazing experiments made by the author, the success of applying a dressing of sodium nitrate to the pastures, and the fact that the after math suited the animals better than the first cutting of hay, all suggested that the trouble was due to a deficiency of protein.

---

(1) MESNIL, F, Analyse du travail de MM. LEGER et VIENNE, in the *Bulletin de l'Institute Pasteur*, Vol. XIV, 1919, p. 076. (*Ed.*)

(2) See *R.* Aug. 1914, No 708 (*Ed.*)

As is well-known, only a portion of the plant protein consumed enters into the formation of animal protein.

The richer the forage in protein, the easier becomes the elimination of the constituents which are not used in metabolism. Further, in many cases, the real remedy for the licking disease may consist, on the one hand, of increasing the absolute amount of protein, and on the other, of giving protein of a different composition by altering the botanical constituents of the forage, or the fertiliser, or using forage of a different quality, viz., at different stages of growth. The drying of the forage may also have some effect, seeing that under natural conditions certain components are washed out by the rain, and that the action of the sun produces chemical changes affecting some important substances present in fresh grass.

The author, after a consideration of all the data referring to the licking disease, and the conclusions that may be drawn from them, recommends the following prophylactic measures:—

1) Care should be taken that sodium should not be lacking in the forage. The rest of the mineral constituents should form a basic mixture containing 600 to 750 mgm. of alkali equivalents.

2) The protein content of the ration ought to be increased by the addition of concentrates rich in protein (linseed cake, palm-oil cake) suitable for ruminants.

3) Hay must be made of the youngest grass possible; this has recently been advised by NEUBAUER, as the best means of remedying the lack of protein in forage intended for growing stock.

4) In conclusion, the author lays great stress on the necessity of further experiment to determine whether the good effect of sodium nitrate observed by him is to be attributed to the sodium, or the nitrogen. In order to do this, one plot must be manured either with sodium chloride, or with sodium sulphate, at the rate of 780 to 1170 kg. per hectare, whilst another plot is manured with ammoniacal salts. During the execution of his experiments, the author still believed in the efficacy of the sodium in the sodium nitrate, but he is now inclined to ascribe the favourable effect to the nitrogen content of the forage.

The author considers that ordinary drying causes the loss of certain indispensable substances; the truth of this opinion should be tested by comparing the products of the usual drying methods and those obtained by ensilage, or a modern drying process entailing the minimum loss of nutrient substances.

1133 - **Experiments in the Treatment of "Debab"** (1). — SERGENT, EDM, SERGENT, ÉT and FOLEY, H., in the *Annales de l'Institut Pasteur*, Vol. XXXV, No 3, pp. 204-211. Paris, 1921.

The authors tried the following remedies for the treatment of "debab" (trypanosomiasis of dromedaries) at the Pasteur Institute of Algeria:—

---

(1) See *R* Nov-Dec 1920, No 1130 (*Ed.*)

(1) 15 gm. afridol Cl. (o-dichloro-benzidine + H. acid) injected in 5 doses in 4 months; (2) trypano-blue in 3 injections of 4 gm. at an interval of 2 days; (3) emetic and atoxyl for 3 weeks, in intravenous injections of 2 gm. of emetic each week; 3 days later, a subcutaneous injection of 3 gm. of atoxyl; (4) a 0.5 % solution of emetic in tepid distilled water injected into the jugular vein.

In the doses used, afridol Cl. cured the animal 1 time out of 2; the amount of trypano-blue was insufficient; the emetic-atoxyl combination proved active; indeed emetic which has the advantages of being cheap and easily used for intravenous injections into camels, is capable of rendering signal service in the treatment of debab; if given in doses that are non-toxic to the dromedary, it however sometimes fails to act upon the trypanosome. It is thus necessary in such cases to try the effect of adding some other drug to the emetic. Quantities above 1.50 gm. are capable of killing a dromedary weighing 300 kg., but 1.50 gm. and less are well tolerated; 0.50 gm. is not sufficient; therefore the best amount is 1. gm.

1134 - **Critical Study of *Davainea* spp., Fowl Parasites in the District of Granada, Spain.** — RODRIGUEZ LOPEZ NEYRA C. (Laboratorio de zoologia de la Facultad de Farmacia en Granada), in the *Revista de la Real Academia de Ciencias exactas fisicas y naturales de Madrid*, Vol. XVIII, Nos. 7, 8 and 9, pp. 322-349, 3 figs., 3 pl., Bibliography of 26 works. Madrid, Jan. Feb. Mar., 1921.

The author gives the synonymy, morphological characters, life history, list of animal hosts, geographical distribution, and pathogenic action of the following species of intestinal worms found in fowls in the district of Granada: *Davainea tetragona, D. certicillus, D. proglottina*, and *D. enchinobothrida*.

1135 - **The Chemical Composition and Forage Value of the Straw of Different Varieties of Wheat Grown under the Same Conditions, in Italy.** — ALBERTONI F. and ROSINELLI, G. (Laboratorio di Chimica agraria della R. Università di Bologna). in *Le Stazioni sperimentali italiane*, Vol. LIV, Parts 4-6. pp. 129-144. Bibliography of 6 works. Modena, 1921.

The authors used the progeny obtained from selection experiments directed by Prof. TODARO, in order to answer the following questions.

1) Whether there is any chemical difference in the fully ripe straw of different varieties of wheat that have been grown under similar conditions. 3) The possible correlation between the composition and characters of the variety. 3) The forage value of straws thus grown.

1) *Chemical Composition.* — The straws investigated belonged to pure lines; they had grown in the same soil in a good year (1913-1914) with sufficient rainfall, and had not suffered from rust or lodging. The straw was cut at one third of its height. The analytical results are compared with the data furnished by other authors respecting the composition of wheats cultivated in higher latitudes.

This comparison shows that the soft wheats of the Province of Bologna are richer in ash, and hence poorer in organic matter; they contain more crude protein and are less lignified.

There was little difference in the amount of ash in the various Bolognese wheats (7.2 to 7.5 % of dry matter at 105° C except in the case of 2 families, when it was below 7 %), and also in the fats (from 0.9 to 1.75 % of crude fat, usually about 1 %). The investigation was thus confined to determining the amount of crude protein, cellulose, and phosphoric acid. The 13 families examined can be divided into the following groups :

(*a*) Straw containing over 3 4 % crude protein, less than 43 % cellulose, and 0.3 % phosphoric acid. Varieties :— Cimone, Normale, Rieti 1, Rieti 11, Gentil Rosso fam. 43, and Dur de Portonovo

(*b*) Straw containing over 3 % crude protein, less than 45 % cellulose, and. 25 % phosphoric acid. Varieties :— Cologna fam. 12, Nasolino, Bordelais, and Poulard d'Australie.

(*c*) Straw poorer than the preceding varieties :— Awnless Gentil Rosso, Inallettabile, and Turgido nero (Pétanielle noire).

2) *Correlation Between Chemical Composition and Variety.* — This grouping shows that the straw of different varieties of wheat grown un-

(1) Energy equivalents of the digestible part of the forage, not reckoning all energy, that is to say substance, expended for their utilisation by the organism.

(2) Energy values of the forage in the production ration. The calculation has been made from the amount of meat and fat produced, according to Kellner's researches on adult cattle that were resting, by each group of food principles when these are added *separately* to a good maintenance ration. From the total thus obtained have been deducted the calories equivalent to the work of digesting the cellulose which, in straw, accompanies these groups of simple nutritive substances.

der the same conditions, present when perfectly ripe, small differences of composition, which appear without exception to be in harmony with the type to which the variety belong.

On an average, the wheats most resistant to lodging have a more ligneous straw (culms and leaves), but this correlation is not always found.

3) *Forage Value for Feeding Cattle.* — The nutritive values of the straws examined are given in the annexed Table; the straws contain no digestible albumen, this result is obtained because the digestibility coefficient of the crude proteins is so low (4 %) that there remains of their total, which is ½ or ⅓ that of meadow-hay (11 %), only non-albuminoid nitrogenous substances.

When straw is fed as forage, the authors recommend that it should be chopped into small pieces of about 2 cm., and not ground; otherwise it would not be sufficiently penetrated by the saliva, and might produce constipation. They advise feeding it 3 times a day, and that the cattle should be gradually accustomed to this very fibrous diet.

With the exception of the Dur de Portonovo wheat (which, because the climate of Bologna is damper than that to which it is accustomed has an abnormal composition, being poor in cellulose, but also in protein and phosphoric acid), the Rieti straws of the Cologna and awnless Gentil Rosso types are the best and least fibrous. The differences are, however, so slight that it can be concluded that the choice of straws for forage, provided these have properly ripened, should be governed more by their appetising qualities than their composition.

1136 – Contribution to Our Knowledge of the Toxic Products of New Hay. — ZCHOKKE, E. (Beobachtungen über Vergiftungen mit Neuheu), in the *Schweizer. Archiv für Tierheilkunde*, Vol. LXIII, Part 5, pp. 192-202. Zurich, May 1921.

Although it is well known that new sweating hay sometimes disagrees with animals, especially horses, the scientific explanation of this fact has so far little foundation. The author, who bases his statements upon LAUPPER'S observations on the spontaneous combustion of hay (1), concludes that, in new hay, chemical decomposition takes place resulting in the formation of extremely toxic substances. This decomposition is due, in the first place, to the action of enzymes, which on being set at liberty in the dying plant, cause a rise of temperature varying from 40°-45° C.

At this temperature, the conditions are favourable to the growth of many fungi that at once produce actual fermentation. Besides the *Mucorineae* and species of *Aspergillus*, the following micro-organisms also appear: — *Bact. coli, Bact calefactor, Oidium lacti, Bact. fluorescens liquefaciens, Bact. fluorescens non liquefaciens, Bact. herbicola aureum, Bact. herbicola rubrum, Bact. mesentericus vulgatus, Bact. mycoides, Bact. Zopfii, Bact. aerogenes, Bact. megaterium, Bact. levans* and, especially, the thermophilous species, *Actinomyces Thermophiles, Thermomyces lanuginosus*, and *Thermoascus aurantiacus*, which can raise the temperature up to 73° C. During this time, evaporation takes place in the hay, and the water condenses on the cold parts. Probably metals such as iron and manganese, that can act even if only traces are present, bring about, like actual catalysts, oxidation phenomena (raising the temperature to 280° C), thus causing the formation of different new products. It is doubtless the iron which plays the rôle of fire-carrier and induces the ignition of the heated hay.

---

(1) See *R.* April 1921, No. 440; See also *R.* Dec. 1914, No. 1145. (*Ed.*)

The products of this chemical decomposition are volatile compounds, ethereal oils, and although these gradually evaporate and finally completely disappear, while present, they endow the hay with certain toxic properties. The author further mentions a fact showing that toxic products can be formed even in old hay, if it be exposed to great heat. A fire having broken out in a barn, 65 cattle were taken back to the cow-sheds some days later. Suddenly 15 of these animals were seized with diarrhoea, drowsiness, violent palpitations of the heart, while eczema made its appearance on their backs, etc. The origin of all these symptoms could be traced to the rain-water dripping off the barn after having passed through the heated hay that was even partly carbonised by the fire. The drops falling on the animals' skin cause actual dermatitis, and gave rise to internal troubles when they found their way into the food in the feeding-troughs. Experiment proved that this water had fatal effects upon rabbits and mice.

All the observations made on the formation of these poisonous substances may be summarised as follows :— The quality and quantity of the new products arising in fermenting hay depend on its composition and degree of maturity, the micro-organisms developing in it, and the intensity of the fermentation process.

Since this phenomenon cannot be prevented, the time-honoured precept of never using new hay till 3 months after it has been made, should be scrupulously obeyed.

1137 - **Researches in Austria on the Acidity of the Most Important Cattle Foods on the Market.** — WILK, L., in the *Zeitschrift für das Landwirtschaftliche Versuchswesen in Österreich*, Year XXI, pp. 202-203. Vienna, 1918; Summarised in *Biedermann's Zentralblatt*, Year XLIX, Part 7, pp 267-269. Leipzig, July 1921.

The author has analysed a good many cattle foods, and tested a sufficient number of samples of those given in the following Table, to enable him to divide them into sub-groups, and also to classify them according to their content in free fatty acids.

This table shows that the percentage of neutral samples, and of those poor in acids, never fell lower than 50, except in the cases of groundnut and sesame cake. It was generally above 60, and in the cases of the sunflower and maize residuum cake was as high as 80. The percentage of samples with a high acid content, which from a physiological point of view can just be regarded as permissible for stock-feeds, varied from 11.1 for sunflower-seed cake, to 21.0 for molasses feeds, *i. e.*, between $^1/_{10}$ and $^1/_5$ of all the samples.

The group of substances that were rich in acids, and hence liable to being already to a certain extent rancid, showed the greatest variation, and should only be used with extreme caution for feeding cattle. Hence, in normal times, 7.7 %-43.3 % of all the samples (from the maize residuum to the sesame cake) should not be fed to stock, or if given, special precaution must be observed

Percentage Distribution of the Samples in the Three Sub-Groups.

	Poor in acids and neutral Per cent	Average acid content Per cent	Rich in acids Per cent.
Pumpkin cake	63.7	20.5	15.8
Sunflowers-seed cake	78.8	11.1	10.1
Colza cake	69.5	20.7	9.8
Linseed cake	63.7	20.8	15.5
Maize residuum	80.1	12.2	7.7
Groundnut cake	43.8	16.6	39.6
Molasses feeds (« Melasse futter »)	70.5	21.0	8.5
Sesame cake	41.8	14.9	43.3
Rice meal	51.7	16.9	31.4

The author then mentions all the foods of which the fatty-acid content had been determined during the three years of the experiment (1915-1917). The foods are classed according to the oleic-acid content of the fat. The millet-meal (" Hirsefuttermehl ") contained most oleic acid, 91.66 % (as against 84.47 % in 1904) Horse chestnuts which had 4.58 % free fatty acids proved the most neutral of all the foods tested for oleic acid during the 3 years, although in 1914, hempseed cake (with 4.65 % free fatty acid) was the most neutral.

The author discusses the most neutral and most acid respectively of the commonest foods on the market. During the 3 years of the experiment, pumpkin-cake, with 0.44 % of free fatty acids, was the most neutral, whereas one groundnut cake proved the most acid

As the chief object of these researches was to determine the relation between the amount of fat and the percentage of free fatty acids, the author gives in another Table (basing his calculations on the data in the previous Table), the samples of foods that are respectively the poorest, and the richest, in fatty matter The poorest is a food containing molasses which has 0.33 % of fat, the richest, a pumpkin-cake with 29.9 %.

The author considers it of the utmost importance that these experiments should be continued, in order to obtain sufficient data to serve as a basis for the future compulsory determination of the quantity of free fatty acid present in cattle feeds, in order to estimate their quality and, within certain limits, their freshness. The results of the analyses, that have been made for 4 years (1914-1917) form a good foundation for this work.

[1137]

1138 - **Olive Pomace in Cattle Feeding.** — I. CUGNONI, C., in *L'Industria lattiera e zootecnica* Year XVII, No. 19, pp. 176-177; No. 22; No. 23, pp 226-227; No. 24, p 235. Reggio Emilia, 1919; Year XVIII, No. 2, 1920. — II. DE BENEDICTIS, A., *La Propaganda agricola* Series II, Year XII, No. 3. Bari, February 15, 1920. — III. DE PITARQUE Y ELÍO J., in *Hojas divulgadoras, Ministerio de Fomento, Dirección General de Agricultura, Minas y Montes*. Year XV, Nos 11-13, pp 11 and 15. Madrid, June-July, 1921

I and II. — The virgin pomace remaining after the olives have been pressed, as well as the exhausted pomace which is left when the oil has been extracted by means of a solvent, can be used as a cattle feed, provided they are separated by winnowing from the ligneous part of the stones and skins.

Prof. G. BRIGANTI (*La utilizzazione dei cascami dell'oliviculture nell'alimentazione del bestiame*, published by Frat. Jovane di Gaetano, Salerno), who has frequently studied the utilisation of this residuum, is of opinion that when the oil turns rancid, it produces great acidity in virgin pomace that has been kept for some weeks, and therefore it is unsafe to advise the use of this refuse as a cattle food until it has been ascertained, by careful experiment, that the acid fatty matter is not injurious to stock.

The question of the use of olive pomace has been again brought forward by Prof. C. CUGNONI, who carried out experiments on 3 cows at the « R. Stazione Sperimentale di Caseificio » at Lodi, in 1917, to determine the effect of virgin pomace upon the quality and quantity of the milk produced, and to ascertain any possible variations in the live-weight of the animals and their state of health. The experiment, which lasted 3 months, was divided into 3 equal periods of 30 days.

During the 1st and 3rd periods (the control period), a basal ration of hay + maize meal + bran + beets was fed to the 2 cows; during the 2nd period (experimental period), the bran was replaced by a quantity of pomace of the same food value, to which had been added (as it contains very little nitrogen) 15 % groundnut cake which is very rich in protein; that is to say, that 2 kg. of bran were replaced by 1.8 kg. of pomace plus 15 % groundnut cake.

The pomace used was very fresh, and had been freed from fragments of kernel by means of an ordinary wheat-separator after having been first spread out for 4 days on the floor of a well-ventilated room. The bran, maize flour, and pomace were fed as a mash. The cows ate the pomace at once, and during the time they were given it, increased slightly in live-weight, and yielded a little more milk. The milk was also richer and its organoleptic qualities were not in any way altered.

From the results obtained, M. CUGNONI concluded that: — 1) Virgin pomace, in order to be readily eaten and well utilised by stock, must be separated from the fresh unfermented residuum of olives; 2) it must be consumed as soon as possible, and not allowed to become stale; 3) well-prepared pomace, carefully-preserved to which other food substances have been added, has the same effect as wheat bran upon milk and fat production and upon the live-weight of the cattle to which it is fed; 4) in calculating the amount of pomace to be given, the total fat content of the ration must be taken into account; this ought not greatly to exceed the known maximum limits; if these are passed, the pomace would have an injurious effect by decreasing the coefficient of digestibility; 5) the transformation value of pomace is superior to that of bran, so that its use is much to be recommended from the economic standpoint.

III. — M. Joaquìn de PITARQUE Y ELío, director of the Stock Breeding Section of the " Granja-Escuela de Agricultura " of Saragossa (Spain) recommends, among other rations suitable for rearing stock, the following which contains olive pomace: — For *draught-oxen* weighing 5 to 6 quintals, silage of Gramineae and Leguminosae 15 kg + 5 kg. oats + 2 kg. olive pomace + straw *ad lib*; for *pigs that are being fattened* 5 kg. siloed pulp + 1 kg. chopped lucerne hay + 1 kg. maize grain + 0.5 kg. bean meal + 0.8 kg. olive pomace in the initial ration, and 4 + 0.6 + 1.5 + 1.0 + 0.5 kg. in the final ration.

The Tables in the Appendix give the composition of the olive pomace as follows: Dry matter 88.3 %; digestible proteins 4.3 %; digestible fats 13.10 %; digestible carbohydrates 30.8 %.

1139 - **Deficiency of Mineral Substances and Protein in Cattle Feeds as the Cause of the Licking Habit.** — See No. 1132 of this *Review*.

1140 - **A German Study of the Transmission of Coat Colour in Thoroughbreds.** — STERNFELD, R., in the *Zeitschrift fur Gestutkunde und Pferdezucht*, Year XVI, Part 4, pp. 69-76. Hanover, 1921.

An account, for the use of breeders of some researches on heredity in horses, and of the practical conclusions to be deduced from them as regards the breeding of thoroughbreds. (1) Since the colours most frequently met with in pure-bloods are bay and chestnut, both black and white being comparatively rare, researches on the hereditary transmission of coat colour are much simplified.

A) BAY AND CHESTNUT COATS. — The Author based his study on the data given in the " General German Stud book " (*Allgemeines Deutches Gestüt Buch*). By selecting from this material some chestnut stallions with numerous progeny, it was found that, in addition to many chestnut foals, there were a considerable number of bays, which is not surprising, seeing that many of the dams of the foals in question had bay coats. Where however the sires were bays, there were more bay than chestnut foals among the offspring.

Although it may be suggested that this phenomenon is due to the fact that thoroughbred stallions usually have bay coats and also, are seldom mated with chestnut mares, this does not solve the question, but only delays solution.

In addition to these bay sires, there is a small number of stallions, also bays, occupying a special position as regards transmission of coat colour. Thus, on examining the lists of the numerous progeny of Ard Patrick, Dark Ronald, Dolomit, Fervor, Pekin, and Manners, a black or white individual is occasionally found among bay foals of all shades, but never a single chestnut.

---

(1) For more detailed information, especially as regards the fundamental facts see STOEVER, A. W., *Die Vererbung der Haarfarbe beim Vollblutpferde*. August Reher, Berlin, 1917.

There must therefore be two quite distinct classes of bay sires, seeing that there are no intermediate stallions between those begetting many chestnut foals, and those whose offspring are all bays. One of these classes produces a large number of chestnut foals, whereas the progeny of the second are all bays, no matter whether the stallions are mated with chestnut or bay mares, respectively.

It is evident that the reproductive cells of each individual contain certain factors which are different in the two classes of bay horses, that is to say, the character, presence of black pigment, is dominant as regards the character, absence of black pigment. Although the pedigrees of pure bays siring only bay offspring does not contain fewer chestnut animals than that of the impure bays, an examination of these pedigrees leads us to the important conclusion that each bay individual is the result of the union of two bay parents, whereas among the impure bays, there are many horses resulting from the mating of a bay or chestnut sire or dam.

Clearly it is necessary, in order that a bay individual may appear, that one of its two parents has transmitted the factor of the black pigment characterising the bay horse.

An impure bay will only have inherited this factor from one parent, whereas the chestnut animal will have inherited it from neither. Given that, as is well-known, each individual receives exactly equal hereditary portions from both parents, a pure bay horse has the factor for black in each reproductive cell, the impure bay in half the cells, and the chestnut has it in none of the cells.

Thus, if a bay stallion is mated with a chestnut mare, it is easy to see that 75 % of the resulting progeny will be bays (impure bays: pure bays = 2 : 1), and 25 % will be chestnusts. On the other hand, where a chestnut is mated with an impure bay, and an impure bay with a pure bay, 50 % of the foals will belong to each type.

Although, in practice, these theoretical results cannot be observed with the same regularity in each isolated case, yet a large number (hundreds or even thousands) of matings between impure bay sires and dams would always give, with almost mathematical accuracy, the proportion of 75 % bays and 25 % chestnuts. In the same way mating impure bay stallions with chestnut mares will always produce impure bays and chestnuts in the proportion of almost exactly 50 %, respectively, as is also proved by an examination of the Stud-Book.

B) BLACK AND WHITE COATS. — The union of 2 black individuals may at any time give rise to chestnut or black offspring, but never to bay foals ; this shows that the bay factor is dominant over the factor determining the extension of black. Consequently, a black foal can be obtained from mating two bays, or a bay and a chestnut. As regards the white horse, there is no question of the presence of a pigment, but on the contrary, of its absence from more or less of the hair, whilst the skin is pigmented.

It is thus evident that mating with a white horse may at any time produce a white individual, even if the parents are impure bays. On the other hand, unless one of the parents is white, the foals will never be white.

C) PRACTICAL CONCLUSIONS. — The practical consequences resulting from these laws of transmission can only be considered to a limited extent in actual breeding operations. Nevertheless, they enable paternity to be established with certainty in cases where it is doubtful. They also show perfectly clearly that each individual transmits only what is present in its reproductive cells, but that none transmits better or worse than another, i. e., prepotency is of no account in the transmission of coat-colour On the other hand, it would be a mistake to regard other characters as necessarily correlated with the colour of a horse's coat. A white animal may transmit the colour of its coat to all its offspring without transmitting its other characters to the same extent.

The author then discusses the alleged inferiority of pure-bred mixed bays as race-horses, which he proves to be a fallacy by reference to some lists of famous mixed (or impure) bay stallions and mares in Germany. Finally, in discussing the somewhat prevalent idea that, in the progeny of certain stallions and mares, a particular coat-colour regularly denotes a more satisfactory individual than other shades, and that the coat-colour may be a visible token of the transmission to an unusual extent of the prepotency of an ancestor having a coat of the same hue, the author remarks that though it may be possible to conceive that some connection exists between colour and performance (such as in racing), no such correlation has ever been established as regards the numerous characters determining the racing capacity of thorough-breds.

In the author's opinion, the importance of these laws of colour inheritance consists in the fact that the hereditary characters of an animal cannot be influenced by any ancestor, but on the contrary, the genetic constitution of the individual depends solely upon the characters directly transmitted to it by its sire and dam.

1141 – **Results of Measuring and Weighing the Different Classes of Half-Bred Horses, at the Chief Stud Station of Beberbeck (Hofgeismar, Hesse-Nassau).** — MÜLLER, W. in the *Zeitschrift für Gestütskunde und Pferdezucht*, Year XII, Part 5, pp. 96-100. Hanover, May 1921.

From measurements and weights of Belgian Rhenish draught-horses (1) recorded by Dr. HÜBENTHAL for the purpose of determining the development of the different parts of the body of these animals, it would appear that during the first year the increase in height is very pronounced, but ceases between the second and third year, whereas the chest continues to become deeper until the third or fourth year.

In order to obtain a general idea of the growth of half-bred horses the author proceeded, independently of HÜBENTHAL's work, to measure and weigh the young horses at the chief stud station of Beberbeck. As his examination of the animals was only of a preliminary character, he only determined the height at withers, the circumference of the thorax, the circumference of the cannon-bone, and the weight.

(1) The horses were measured and weighed in the middle of April and middle of October 1920 (*Author*).

These zoo-metric data clearly show that the growth in height of the half-bred horse does not cease, as it does in the case of the draught-horse, at the age of 3 years. Taken as a whole, the animal grows more and increases more in weight during the first 3 years. Up to their third year, stallions are much heavier and more powerful than the mares, but then the difference becomes less.

Towards the end of autumn, 1919, more detailed measurements could be taken of the mares of the 1916 class. The results are given in Table II. The proportions and live-weight of these mares in November 1920 are given in Table III.

An examination of these Tables shows that all the half-bred Beberbeck mares, except 2, had not finished growing by the age of 4 years, since several of the animals gained 4 cm. in height after that time. In some cases, the height of the croup remained the same, in others it increased 5 cm. The depth of the chest increased in nearly all the mares as did also the length of the haunch, croup, and chest, the circumference of the thorax, and the live-weight. In 50 % of the cases, the circumference of the cannonbone was found to have increased.

As regards the treatment of the young classes, the author draws attention to the fact that, for the first three years, the animals were frequently turned out to exercise. The mares were served when about 3 ½ years of age.

1142 - **The Barb As an Army Horse.** — VERDIN, R., in *The Revue Agricole de l'Afrique du Nord*, Year XIX, No. 101, pp. 537-539. Algiers, July 1921.

In his work on the origin, shape, character and performance of the Barb or Barbary horse, the author draws attention to the fact that the present type of this breed differs greatly according to the place where it is found. Thus in the region of Till, where few if any attempts at breeding are made, the animals are smaller than those in the Hauts-Plateaux, but more strongly-built, have thicker legs, a longer and stronger head with more powerful lower jaw, short strong loins, rounded croup, and rather thick hocks; in short these horses show little trace of good blood. On the other hand, beyond Till, in the region of Tiaret, in the plain of Aribs, near Aumale, in the plains of Mina and Relizane, Châteaudun du Rhummel, Ain-M'lila, Barika, Batna, and Kenchela, in the district of Setifia, M'Sila, etc., the Barb has all the characters that fit it for a good saddle or army horse.

It is larger, more handsome, shows its high breeding ; its head is expressive, the eye full and large, and the whole animal is symmetrical Horses from these districts are very suitable for improving the Barbary race. Beyond the Great Plateaux, the Barb of the Sahara is gradually replaced by the " mehari ", which is a very efficient substitute. This type is chiefly kept by the principal native families. The animals differ little from those of Tiaret and Boghar, but give more evidence of breeding; they have a spare frame, their sinews are strong, standing well apart, their feet are small, and they are very sure-footed.

In spite of the remarkable qualities of the Barb as regards endurance, hardiness, thriftiness, resistance to discase and high standard of health, the war has brought out its defects as an army horse. These faults could, however, easily be remedied by selecting the best type of animal with a dark coat, refusing all unsuitable animals at the service Station, and making every effort to obtain dark-coated stallions and brood-mares.

On account of the trouble caused by the perpetual excitement of entire horses, the author advocates the compulsory castration of all army horses.

1143 - **The Sardinian Donkey** (1). — MORESCHI, B., in the *Giornale di Agricoltura della Domenica*, Year XXXI, No. 35, p. 275, 1 fig. Piacenza, August 15, 1921.

After Spain, Italy is the country possessing most donkeys. According to the 1918 census, there were then 949 162 of these animals in Italy as against 875 728 in 1905. The great increase in the last 10 years is due to the war, for nearly half the horses and mules were taken for military purposes from the various districts, so that their place had to be filled by donkeys. Over $^1/_5$ of the donkeys of Italy (205 000) are to be found in Sicily. The whole Valley of the Po has less than 150 000, but Southern Italy is far better off, and Sardinia has 35 000 donkeys and possesses a special breed.

---

(1) See E. MASCHERONI, *The Rearing of Donkeys and their Crosses with Horses in Italy and her Colonies*, in *R*. February 1920, pp. 130-138. (*Ed.*)

The Sardinian ass probably belongs to SANSON's " African species ". It is characterised by its small height (about 90 cm.; rarely, 1 metre), the great uniformity of the type, its symmetry, except as regards the head, which is too heavy, the solidity of its skeleton, and its grey coat with the Saint Andrew's Cross.

As it is very docile, this donkey does not need breaking in. It begins to work when about a year old, and acts as beast of burden, riding or draught animal. It is also used to work the *norias*, which raise the water required for watering the kitchen-gardens, etc. The Sardinian donkey can carry about 220 lb., and draw a vehicle with a load of some 880 lb. It is very thrifty, living on roadside herbage, or when there is no work and it is turned out on waste ground, upon a handful of barley and a little chopped straw.

Before the war a Sardinian donkey cost from 20 to 50 *lire*, but in 1919 the price was 300 *lire*, and is now still higher. This increase in price is largely due to the fact that they are much in request since it has been discovered, that the flesh of the Sardinian donkey is tender and delicate, and can hardly be distinguished from veal.

The coat is usually grey, but sometimes dark-brown, with light areas on the inside of the thighs and round the eyes and mouth; this perhaps is a sign of crossing with SANSON's " European species ", though in reality, the so-called European and African species are nothing but varieties.

In Asinara, there is a breed of donkey that has become wild; most of them are grey, but albinos frequently occur. These animals are easily domesticated, and possess unusual strength.

Occasionally donkeys like the grey ones in shape and size, but with black or dark-brown coats free from any white areas, are to be met with in Sardinia.

Owing to its small size, the Sardinian donkey cannot be used for mule-breeding, which is in fact not practised in the island.

1144 – **The Cattle of Central Laos and Siam** (1). — SEILLIER, E. A. (Directeur des Etablissements Lapique à Napê, Laos), in the *Bulletin Agricole de l'Institut Scientifique de Saigon*, Year III, No. 7, pp. 220-224. Saigon, July 1921.

In his article on the importance and methods of live-stock rearing in Central Laos and Siam, the author says that the chief cattle-breeding districts are the Province of Savannaket, the south of the Province of Cammon (Valley of Se Bang-Fai in Siam), and the Provinces of Lakhone and Nong-Khai, all districts where cattle are numerous.

As the inhabitants of these provinces consume little beef, they are able to send a considerable amount to the two great markets of the south : Korat (Siam), Kratia (Cambodia), and to Thaket, whence it can be despatched to North Anam, since a cold-storage plant has been installed at Ben-thuy. The number of animals exported annually (5000 to 6000 from the three Siamese provinces) is relatively large, and the author foresees that the cattle industry will develop greatly in the future, as soon as a better market becomes available, for there are large areas of uncultivated land that are wholly unsuited to rice and many years must elapse before other crops can be grown. Further, the registration of cattle which has now been enforced for some years in Siam, and will soon be extended to Laos, offers a certain guarantee against theft, and will therefore contribute to encourage Stock-breeding.

---

(1) See *R.* March 1919, No. 333. (*Ed.*)

BREEDS. — The cattle of Laos and Siam are composed of a mixture of types, and it is thus extremely difficult to determine any distinct breed. Two pigments are met with, the coat-colour varying from ebony black to white, and passing through all the chromatic scale of greys, reds, and wheat colour. Some of the animals have long lines, but most of them are short. In spite of the great differences existing between the various shapes and colours of these animals, the author believes that he has succeeded in distinguishing a type which, from its frequent occurrence, may be regarded, if not as a race, at any rate as a sub-race, for it seems quite fixed, and is perpetuated, in spite of the mixtures and degeneracy involved by the total absence of a breeding system in the country. The characters of this type are as follows — Short lines, very short head, broad forehead, horns slightly raised and spreading, body cylindrical, legs fine, chest not deep, coat brown-black with a mahogany or brown mule-stripe on the fore-hand, and a grey one on the hind-hand, slightly humped. On the whole the animal is small, but well-shaped, with little bone ; its weight at the age of 6 years varies (without fat), between 269 and 300 kg. Of the other cattle, some are distinctly of the Hindoo, and others of the Yunnan type, which is easily explained by the intercommunication between Siam, Burma, and China.

BREEDING. — There is no system of breeding : the calves, bulls and cows are born, grow and reproduce their kind without any interference on the part of the owner, who often does not know how many cattle he possesses, and does not trouble about them in any way. The animals that survive have evidently good constitutions. On the other hand, as a result of this method of rearing, they are very wild, and can only be caught with the greatest difficulty. The best months for calving appear to be December and January. The calves are born in the dry season, and thus are sufficiently old to stand the heavy rains which begin in June. Very few calves are born before December or after January. Cows that have calved in December or January, do not come again in heat before April or May.

BULLS. — As the native does not scruple to castrate all the fine bulls, in order to obtain good draught oxen, the only animals left for breeding are small or badly shaped. The method adopted for castration is very primitive, and consist in crushing the testicles, so that often this incomplete operation is useless, for the testicles only develop to a less extent.

FEEDING. — The animals are out at grass all the year and housing is quite unknown. The chief forage during the dry season, when the grass is scanty or tough, consists of the ricestraw left on the fields after threshing, or of the stools that are still standing. This food, which the cattle eat with avidity, appears to be well assimilated, since in spite of its low nutritive value, they do not become thin, although given no other rations. In January all the fields are set on fire (1) and until the grass has grown again, the stock have to content themselves with what they can find. Since, however, the number of head is very small in comparison with the vast areas they range, the cattle do not lose much flesh, and get on quite well until the grass shoots plentifully once more, after the usual February rainfall.

Dressing-yield. — An appended note gives the dressing yield of the cattle reared in Laos and Siam. The author mentions the following interesting details :— The carcasses of Laos oxen weigh from 120 to 220 kg., the average weight being 150 kg. without the head. In spite of their somewhat light weight, these animals have not the defect characterising most primitive races, viz., that owing to the poor development of the muscular tissue, the proportion of net meat to gross weight is much less than in the European breeds (2).

The formation of the Laos animal (round croup, cylindrical body, and great muscular development) renders its meat yield equal to that of European cattle of the first quality ; it is the thickness of the chine and sirloin that increases the percentage of net meat and makes these oxen so valuable.

The chest is rather high, but thick ; there is little flesh on the flat ribs. To sum up : the Laos ox has no hump and when highly fed, these animals run more to meat than fat. Meat covered and streaked with fat is of rare occurrence. When the bulls are castrated young, the beef is fine-grained. At present, however, the animals slaughtered are bulls (or oxen that have been castrated), from 2 to 3 years of age, so the meat is rather coarse.

Conclusions. — From the above facts, the author believes himself justified in concluding that the cattle of Laos and Siam, like those of Tonkin and Anam, are degenerating, as they have reached the critical stage when degeneration proceeds rapidly. The author however hopes that as a result of selection a presentable herd may be got together in 10 generations from the elements present in the country itself, or in the neighbouring States. In his opinion, the best method of selection would be to retain all the bulls and cows of the required type for 6 generations. From the 7th generation, it would be possible by carefully sorting the bulls, or by introducing new bulls of perfect shape, to breed for lighter bone and for muscular development, by intercrossing the animals until the desired type was fixed. No improvement in the milk yield could be expected, for owing to local climatic conditions, the breed would never produce good milch cows.

---

(1) This annual burning of the fields appears to produce no effect upon the cattle parasites (ticks, leeches, etc.). (*Author*)

(2) According to data sent to the *Bulletin Agricole de l'Institut Scientifique de Saïgon* by M. Le Louet, Chief of the Cochin-China Veterinary Service, at the Saïgon abattoir the average return $\frac{\text{net-weight}}{\text{live-weight}}$ varies between 45 and 52 %. (*Author*)

[1144]

As regards the quality of the meat and the dressing yield of the Laos and Siam cattle, the beef is fairly good in quality, and there is less waste than with meat from Australia and Argentina where, owing to the introduction of English breeds (especially Shorthorns), there has been a tendency to develop unduly the fatty tissues to the detriment of the muscles.

1145 - **The Cattle of French Guinea.** — *La Revue Générale du Froid et des Industries Frigorifiques*, Year II, Vol. II, No. 6, p. 206. Paris, July 1921.

Guinea possesses numerous sources of wealth, and among the most important, is its large stock of cattle, which is capable of still further increase. The finest herds are to be seen in the region of Fouta, which is inhabited by the *foulas*, an ancient race of nomadic shepherds. The animals are usually small, but sturdy and in good condition. During the winter they graze on the grassy plateaux, and during the dry season feed in the great deep valleys that intersect these plateaux. Like all the other herds of the country, these herds have decreased owing to outbreaks of epizootic disease of varying severity, of which the consequences must not be denied or exaggerated. It has often been stated that the cattle of Guinea had lost all their value, having been decimated by terrible pests. This is fortunately not the case, and now, as in the past, the Fouta remains the source of supply from which the neighbouring countries of Senegal, Sudan, Portuguese Guinea, and especially Sierra Leone, obtain their cattle. During the war, the provisioning of the troops, and the large consignments of cattle sent to the Cold Storage Factory, at Lyndiane, contributed to the impoverishment of the Guinea herds. The value of the stock, however, which is still considerable, is estimated not to have been reduced by as much as $^1/_{10}$. Statistics show that Guinea cattle still number about 400 000 head, and probably this figure, which is based upon the returns of the natives, who do not like the full amount of their possessions to be known for fear of increased taxation, is far too low. The number of cattle exported, which in 1914 was over 12 000 and reached 17 000 during the war, now tends to decrease. In 1919, hardly 7000 head were exported, and in the three first quarters of 1920, there was a further drop to below 3000.

This is due to the efforts of the Government which is doing its best to restrict exportation. It should be remembered however, that as the Custom Offices are very far apart, there is much opportunity for fraud on the land frontiers, so that probably the figures returned are much below the truth, and can only serve to give a rough idea of the real number of cattle leaving the country.

The number of raw cow-hides exported affords a good means of estimating the size of the herds. Since 1913, the average weight of hides exported amounted to 1000 metric tons which represents, assuming the average weight of a hide to be from 12 to 15 kg., more than 8000 animals sent to the abbattoir. If to this number are added the average exportation returns viz., 10 000, the normal annual loss of the herds would be 18 000 to 20 000 head, which does not appear excessive. From these observations, it may be concluded that the cattle of Guinea have not been reduced to the extent alleged and that, if were systematically managed, they might be a source of large revenue to the Colony.

1146 - **Experiments Made in the United States on the Effect of Hydrocyanic Acid in Sudan Grass on Cattle.** — SWANSON, C. O in *Journal of the American Society of Agronomy*, Vol. XIII, No. 1, pp. 33-36. Washington, Jan. 1921.

As occasional cases of poisoning of cattle due to eating Sudan grass (*Sorghum exiguum*) had been observed, the Dairy Department of the Kansas State Agricultural College conducted experiments in 1919, with 6 Holstein cows put to pasture from July to October on a plot of 5.4 acres of Sudan grass. Samples of this grass were tested for hydrocyanic acid content. In October 2 other cows which had not eaten any Sudan grass were placed in this pasture. The following is a summary of the first results obtained: —

Although hydrocyanic acid was found in large amounts in Sudan grass used for pasture, no harm resulted to the cattle.

Liberation of hydrocyanic acid is apparently associated with enzyme action. Digestion in water at room temperature for several hours and subsequent distillation gave larger amounts of hydrocyanic acid than if sulphuric acid was added. Hot water and dry heat diminished the amount of hydrocyanic acid obtained, whilst slow drying caused it to disappear. Tests made on wilted samples or those several days old may be considered as worthless. Tests made immediately on frosted grass gave very high amounts of hydrocyanic acid, but this disappeared rapidly as soon as the plant began to wilt and was completely dispersed when the plant was dry.

While in the case of the two cows who had never previously eaten any Sudan grass there seemed to be no ill effects, under other conditions it was proved that immunity was not due to habituation.

These results do not permit any definite conclusions to be drawn but it is proposed to extend the investigations.

1147 - **German Experiments on the Value of Urea in the Feeding of Sheep and Other Ruminants.** — VOLTZ, W., in I. *Mitteilungen der Deutschen Landwirtschaftsgesellschaft*, Year XXXIV, No. 27, pp. 372-375. Berlin, July 1919; II. *Biedermanns Zentralblatt*, Year XLIX, part 7, pp. 269-272. Leipzig, July 1920.

In view of the fact that at the present time in Germany the amounts of vegetable protein required for feeding cattle are inadequate, the question of the substitution of amides and especially synthetic urea for vegetable protein has become of great importance. As a preliminary experiment gave encouraging results, further experiments were undertaken with sheep. The typical ration consisted of rye husks and chopped rye-straw, both disintegrated, dried and finally ground ("Strohstoff"), prepared according to the BECKMANN method (1) through the action during varying periods of a 1.5 % caustic soda lye. The protein content of the " Strohstoff " was estimated by the STUTZER method. The amounts of digestible protein were so minute that they could not be in any way considered to be connected with the possible formation of animal protein; moreover these amounts were far less than the amount accumulated in the tissues.

---

(1) See *R.* April 1921, No. 406, III. (*Ed.*)

In addition the animals were fed on boiled starch and sugar or the equivalent starch value in the form of starch alone. The daily dose of urea was at the rate of 30 grammes per head and the ration was completed by the addition of mineral salts. The animals which were of the long haired Merino variety (*Kammwoll-Merino*), nine months old, and each weighing from 20 to 30 kg. at the beginning of the experiment, received daily the following amounts of mineral salts:

Calcium carbonate . . .	15 gm.	Potassium sulphide.	1 gm.
Sodium	5 »	Magnesium oxide.	1 »
Sodium phosphate . . .	4 »	Iron chloride	0.2 »
Potassium sulphate. . .	4 »	Total of food salts.	30.2 gm.

No compounds containing iodine or fluorine were given. The potassium sulphate was reduced by the intestinal bacteria. Although the feeds given could not contain any vitamines, the author did not trouble to provide special feeds rich in these substances, as he thought that the bacteria digested by the sheep contained them in sufficient quantity. As a matter of fact, during the whole period of the experiment (over six months) the general condition of the animals under the special treatment was never impaired.

As regards the utilisation of urea, experiments with three lambs gave identical results which are not quoted by the author, who only gives the results of a long series of continuous experiments made with one lamb. These results (see Table annexed) afford convincing proof that urea is a perfect substitute for vegetable protein in feeding-stuffs.

Throughout the series of experiments the faeces always contained 25 % more protein than the vegetable foods in the ration. For the proper growth of the wool 0.7 gm. of nitrogen had to be absorbed daily. The lamb's fleece contained 87.39 % of dry matter and 9.95 % of nitrogen.

Growth of wool during the 155 days of the experiment	1090.5 gm.
Growth of other epithelial products, about	100.0 »
Increase in weight reckoned for the 155 days . .	7556.8 »
Weight of the lamb on the first day of the first period	kg. 29.25
Weight of the lamb on the last day of the seventh period	» 37 15
Actual increase in weight . . .	7900 gm.

The ratio between the increase in weight, reckoned on the balance and the growth of wool, and that resulting from the actual weighing may be considered as quite satisfactory, the latter being 343 gm. (4.5 %) only in excess of the former.

The author them deals with the question of the synthesis of protein in the animal organism and quotes the thesis of ABDERHALDEN (1), which

lays down, that, in non-ruminants, urea cannot be utilised for flesh formation. This theory is further supported by the works of WEISKE, ZUNTZ, C. LEHMANN and especially M. MÜLLER. According to the author KELLNER's theory, according to which amides are never utilised by the animal organism except in rations deficient in protein, cannot be maintained. Amides on the contrary should always be added to digestible protein and in feeding rations the amount of nitrogenous food material should be determined by the amount of digestible nitrogen.

1148 - **The Marseilles Breed of Pig.** — GOUIN, R., in *La Petite Revue agricole et horticole*, Year 27, No. 633, p 123. Antibes, August 28, 1921.

The author draws attention to the good qualities and defects of the Marseilles breed of pig, and suggests improvements which he thinks could be advantageously introduced into the method of rearing.

The Marseilles pig has not yet attained a uniform type, but gives evidence of being the results of various crossings. It is remarkably prolific, the average litters containing 8 to 12 young, while litters of 14 are common. A sow farrowing three times in the year can produce 40 pigs annually.

The young animals do not mature quickly on account of wrong feeding at the time of weaning, so that the pigs take too long to increase their weight from 12 to 20 kg. As the breeder has no milk products, he uses nothing but wheat offal, which too often contains inert or even poisonous substances. The author especially advises the larger and more systematic use of groundnut cake which should be broken up into quite small pieces, or powdered, and added to the warm or cold rations at the moment of feeding. By changing the diet in this way at the time of weaning, it is easy to gain a month.

Another very common fault of the breed is the excesive length of the pasterns. This can be remedied by selection, but the addition of bone phosphate may also assist.

To prevent outbreaks of infectious pneumo-enteritis, the author says that the animals and their sties should be kept scrupulously clean.

1149 - **Pig-Breeding on the Hills of Piedmont** (1). — VOLANTI, A (Zootechnical Section for the Province of Alexandria), in *Il Coltivatore*, Vol 67, No 23, pp 141-145, 5 figs. Casale Monferrato, August 20, 1921

On the hills of Alexandria, excellent results have been obtained by crossing the Large White Yorkshire, an improved breed, with the local Reggio breed. The conditions obtaining in the district are well suited to the Large White, for small holdings predominate, there are plenty of vineyards and trees, and few dry meadows; further, the pigs are reared in sties.

The Large Black Yorkshires have also been tried, but with less success (at all events so far as the pure-bred animals are concerned), for they are not so well adapted to home-rearing as the Large Whites. On the other hand, their products are preferred by the pork-butcher.

---

(1) For further details on pig-breeding in Italy, see *R* July-August 1920, No. 779; *R.* June 1921, No 658; *R.* August 1921, No. 842; *R* September 1921, No 939 (*Ed.*)

If the local breed is crossed with the Yorkshire (either Large White or Large Black), the hybrids are most prolific, the litters often consisting of 11 piglings instead of the 6 or 7 usually farrowed by the Reggio sow.

1150 – German Experiments Made on Feeding Pigs with Rations Containing Large Quantities of Fish Meal. (1) — MÜLLER, K. (Direktor der Versuchswirtschaft für Schweine haltung, -fütterung und -zucht in Ruhlsdorf Kreis Teltow), in the *Deutsche Landwirtschaftliche Tierzucht*, Year XXV, No. 32, pp. 333-334. Hanover, August 1921.

With a view to deciding to what extent the amount of fish meal could be increased in fattening pigs without detriment to the health of the animals and the quality of the meat, experiments were carried out in 1920-1921 at the experiment farm at Ruhlsdorf for the keeping, feeding and breeding of swine.

The experiment was divided into 2 periods, each lasting 4 weeks. During the 1st period, the animals were fed fish-meal, potatoes and beets, and during the 2nd, potatoes entirely took the place of the beets. Eight pigs born in July and August respectively, which weighed at the end of the year 50 kg. on an average, were used; 5 of the animals belonged to the improved native breed, while the 3 others were crosses between it and Yorkshires, Berkshires, or Hildesheim pigs.

During the whole period of observation, the animals showed no serious symptoms, which is a fact worthy of notice, seeing that they consumed large quantities of fish meal containing much more sodium chloride than is normally present in commercial meal. The composition of the meal used in the experiments was as follows:— Crude protein 60.20 %; crude fats 1.17 %; sodium chloride 6.43 % : the crude protein content was thus higher than the average (52.5 %), whereas the crude fat content was below the average (2.1 %) which had much to do with the fact that the quality of the meat and fat of the animals fed on this flour was not affected.

The potatoes (" Professor Wohltmann ") given to the pigs during the experiment contained 14 to 16 % of starch; the beets were of the half-sugar variety known as Meyer Friedrichswerth's " Zuckerfutterwalse ", with a dry matter content of 15 %.

After having accustomed the pigs to larger amounts of fish-meal, the first experimental period (Feb. 3-Mar. 2, 1921) was entered upon; during this, the animals ate potatoes *ad lib.* and a mixture of 16 kg. of beets to 0.9 kg. of fish meal. The amount they consumed may be regarded as fairly satisfactory. During the 2nd period (Mar. 14-April 10), they ate to satiety a mixture of 16 kg. of potatoes and 0.6 kg. of fish-meal; as there were no beets in the ration, the consumption was less than in the 1st period.

(1) See *R.* Dec. 1915, No. 1356. (*Ed.*)

Details relating to the food consumption and the increase in weight of the pigs during these two experimental periods are given in the annexed Table: —

Food Consumption and Increase in Live-Weight During the Two Periods of Experiment with Fattening Pigs.

Period	Amount of food consumed per head and per day kg.	Composition of ration			Average increase in weight per day and per head	Amounts of food necessary to produce 1 kg. of live-weight		
		Fish Meal	Potatoes	Beets		Fish Meal	Potatoes	Beet
1	14.30	0.39	6.95	6.95	0.603	0.64	11.53	11.53
2	10 64	0.39	10.25	—	0.639	0.61	16.04	—
Average	12.47	—	—	—	0.621	—	—	—

Although it may be said that with a ration of different composition, the amount of food consumed daily might have been about 2 kg. more, the quantity actually eaten was satisfactory.

The pigs consumed considerable quantities of this ration (upon which they were exclusively fed), seeing that their daily food contained as much as 0.39 kg. of fish-meal. Assuming the percentage of digestible protein to have been at least 50, each animal thus consumed with the fish meal 200 gm. of digestible protein.

The ration contained nearly exactly the amount of digestible protein (255 gm.), and the starch values (2.05 kg) necessary according to KELLNER to fatten pigs, so that the increase in live-weight ought to have been sufficient. It was not so however, for the average only rose to 621 gm. per day, whereas in other fattening experiments made in the winter of 1920-21, at the experiment farm, the daily increase in live-weight was 840-920 gm., being thus from 200 to 300 gm. more than when the pigs were given large amounts of fish-meal.

From what has been said, it is evidently possible to fatten pigs on rations consisting exclusively of potatoes and fish meal; a satisfactory result must, however, not be expected. It is probable that the animals would have put on more flesh, if only half as much fish meal had been given them (200 gm.), other foods rich in protein being substituted for the remaining half.

An estimate of the returns shows that considerable quantities of food are necessary to produce 1 kg. increase in live-weight, at all events, during the first period. As regards the second period however, the amount of food consumed is more in accordance with the figures obtained in previous fattening experiments. In any case the experiment cannot be said to have been successful from this point of view.

The increase in the individual live weight of the animals during the time the experiment lasted (Feb. 3-April 10, 1921), was as follows:—

Local improved breed (5 pigs): 26 + 28 + 39 + 29 + 42 kg.; average 35 kg.

Cross-bred pigs (3 animals): 41 + 31 + 32 kg.; average 35 kg. Thus the average increase in weight in the two groups was exactly the same. At the same time, there were marked differences. so that the average results must be regarded as due tc mere chance.

The figures given for the 3 first animals of the improved local breed represent the weights of pigs from the same litter, but the very fact that the first pig gained less live-weight than the other two, shows that it is not satisfactory, in this case, to have compared animals of the same litter The two last pigs of the improved breed were the offspring of one boar, but of two sows of the same ancestry, yet they fattened very differently. As regards the half-breeds the largest increase in live-weight was gained by the product of a cross (Large Yorkshire ♀ × Hildesheimer) ♂ × Large shire Yorkshire, whereas the other two pigs were the offspring of the cross Berkshire ♂ × local improved breed, and belonged to the same litter

As regards the young pigs of the best litter hitherto farrowed at the Ruhlsdorf Experiment Farm, none of them was able on this special ration to attain the average increase in live-weight for the fattening period.

1151 – **Bee-Keeping in the Trentino, Italy.** — BONI, G (Direttore dell'Istituto d'Agricoltura di San Michele sull'Adige, Trento), in the *Agricoltura italiana*, vol. XVII, No 8, pp 238-240 Ancona August 1921

Except for some portions of the Valley of the Adige and of the basin of Lake Garda, which are devoted to the intensive cultivation of the vine. the whole of the Trentino is eminently suited to bee-keeping, as are indeed all semi-mountainous or mountainous districts where the meadows, orchards and woods offer a rich and varied flora to bees.

Apiculture is a very long-established industry in Trentino. The agricultural College of San Michele has successfully carried out a most active propaganda for the substitution of a hive with moveable frames (preferably the SARTORI type), for the primitive construction used by the villager.

During the war, the bee-keeping industry suffered greatly, but is now beginning to revive, as the great demand for swarms, and the high prices they fetch, abundantly testify. The Provincial Agricultural Council of Trent, and the Agricultural Institute of San Michele are encouraging the reconstitution of this industry by providing travelling instructors and short theoretical and practical courses of lectures, the gratuitous distribution of hives (in future the Italo-American DADANT type will be the one selected for this purpose), and sending out experts to visit the bee-keepers. In the southern part of Trentino, the *aurata ligustica* bee has always been kept, but the black German and the gray Carnic breeds have penetrated into the northern valleys, so that hybrids resulting from crosses between the *aurata* and these two breeds are frequently found

1152 - Pisciculture in Switzerland in 1920 (1). — *Bulletin Suisse de Pêche et de Pisciculture*, Year XXII, No. 6, pp. 90-93. Neuchâtel, June 1921.

The following information has been taken from a Report issued in 1920 by the Swiss "Departement de l'Intérieur".

In 1919-1920, 208 breeding stations were working during the incubation period (as against 216 in the preceding year), and 146756000 incubated eggs produced 118 131000 fry, of which 117 302 337 (126 863 037 in the preceding season), were placed in public waters, including 185 337 fishes of 1 summer, or 1 year. (See table p. 1462).

The fry produced by incubation were as follows :—

(a) *Native species :—*

Salmon	1 223 000
Salmon-trout	68 000
Lake trout	3 990 000
River and brook trout	8 965 000
Salmo alpinus	3 372 000
River char	1 554 000
Corregones	82 253 000
Pike	16 403 000

(b) *Foreign Species :*

Fountain salmon	61 000
Rainbow trout	242 000
Total.	118 131 000

The Confederation granted 44 210 fr. to the Cantons for pisciculture, (39 700 fr. in 1919), chiefly for raising fry and stocking the waters.

1153 - Experiment Station of Pisciculture at Evois, Finland. — BROFELDT, P., Evois Fiskeriförsökstationen, Resultatet av dess 25 åriga verksamhet, 1892-1917, in *Finlands Fiskerier*, vol. VI, 1920. Helsingfors, Fiskeristyrelsen : Summarised in the *Allgemeine Fischerei-Zeitung*, vol. XLVI, No. 12, pp. 152-155. Munich, June 1921.

An Experiment Station with an annexed College of Sylviculture and about 7 200 hectares of forest under its management, was opened as long ago as 1892, at Evois, a small village 40 km. northeast of Tovastehus, one of the stations on the railway-line connecting Helsingfors with north Finland. Subsequently, a Piscicultural Experiment Station was started, to which in 1901 was added a School of Pisciculture. At the head of this Stations there is a Director (M. Pekka BROFELDT) assisted by a fisherman, who goes out fishing with the students and also completes the very complicated forms giving all data concerning the fisheries, and the various fish introduced into the numerous lakes and streams.

The station has under its supervision 27 lakes with a superficial area ranging from 1 to 50 hectares (total 260 hectares), and about 14 km. of watercourses.

The lakes are situated in the Kumoälv region. The country consists of sterile moors with stands of spruce and pine. The soil is sandy and stony, and almost entirely uncultivated; marshes and ponds abound.

The water of the lakes is usually turbid, and of a dark colour, it is only clear in 4 cases. It contains much humic acid and iron, but little lime. The bottom is covered with mud, which is usually soft and loose. The depth of most of these lakes is from 6 to 7 metres.

As a rule, the water is cool even in summer; the temperature at the bottom of the shallowest lakes (2 m.) never rises above 10° C., and usually remains below 4° C., though that of the upper layer may reach 20° C. in summer.

Most of the lakes are gradually being filled up by water-weeds.

The scanty flora on the banks consists of rushes, reeds, and pondweed (*Potamogeton*). Attempts have been made to increase the vegetation by the introduction of new species, but with little success, for all the nutritive matter available is used by the wild native plants. Under these conditions, the natural fauna, consisting for the most part of *Limnoea* and other molluscs, is very limited, although it is much more plentiful (as are also the fish) in 4 lakes in which flax is occasionally retted. In 4 small, manured fish-ponds there is abundant vegetation.

The plankton is very little developed: it consists chiefly of rotifers, copepods, cladocera, and the protozoon *Dinobryon.*

The natural ichthyofauna is chiefly composed of the following fish:— Perch (*Perca*), common roach (*Leuciscus rutilus*), common pike (*Esox lucius*). Other rarer species are:— a small perch, the "pope" (*Acerina cernua*), the lota (*Lota lota*), the "rudd" or "red eye" (*Leuciscus erythrophthalmus*) and the bleak (*Alburnus lucidus*). For the last 25 years, researches and experiments have been made to increase the fishing returns by stocking these poorly-provided lakes with new species. The following have been placed in the water:— Perch (*Perca lucioperca*), *Micropterus salmoides*, tench (*Tinca tinca*), the ide or nerfling (*Idus miniatus*), common bream (*Abramis brama*), fountain salmon (*Salvelinus fontinalis*), river char (*Salvelinus umbla*), salmon (*Salmo salar*), river trout (*Salmo fario*), rainbow trout (*Salmo irideus*), smelt (*Osmerus eperlanus*), crucian carp (*Carassius carassini*), *Coregonus maraena*, *Coregonus albula*, pike (*Esox lucius*), and eel (*Anguilla anguilla*).

The introduction of the bream was attended with great success. *Coregonus maraena* and river trout have also become acclimatised, although the latter are still relatively rare in the waters of Evois. The river-trout are incubated at the Experiment Station. Positive results have been obtained by stocking with perch, crucian carp, tench, rainbow trout, fountain salmon, and *Coregonus albula*, but all the nerflings, river char, salmon, and smelts, as well as *Micropterus salmoides*, have completely disappeared.

Because the common bream was introduced when adult, it has become acclimatised in nearly half the lakes and can be caught as plentifully as the indigenous perch, pike, and roach. As it is a very prolific fish, some of the fry have to be distroyed. The average live-weight of the eatable individuals never exceeds 600 gm. During the first summer, the fry usually, attain the length of 3 cm.; they seldom grow to 6 cm. Spawning takes place at the end of May, when the temperature of the water is 20° C.

The smelt is very common in the north, and can easily be introduced into many of the lakes. The introduction of the fry generally gives discouraging, and always uncertain results, owing to the lack of plankton without which these fish cannot live. During its first year the smelt attains the length of 20 cm. The number taken are from 6 to 10 % of the total catch. The average live-weight of a smelt is from 700-1000 gm. It spawns in the middle of October at a temperature of 4° C.

Coregonus albula is the largest and commonest fish of the great lakes of Finland. It did very badly, however, in the lakes at Evois, where it suffered from want of food, as it lives entirely on plankton Though over 51 million fry have been introduced into these lakes in the course of some years, only a thousand fish have since been caught. The individuals that survived grew well, they were 14 cm. long in the 2nd year, 27 cm. the 3rd, and 34 cm. the 7th.

Perca lucioperca did not prove so satisfactory, although it was induced to spawn every year, the eggs being deposited as a rule after June 15, when the temperature of the air was 20° C. (water temperature 14°-26° C.).

In the ponds, the fish grew to as much as 8-10 cm. during the first summer, but in the lakes they remained very small

Crucian carp only flourished in one lake (superficial area 7 hectares, depth 4 metres), which had been fertilised by retting flax; the fish caught annually weighed altogether 32 kg.

Eels spread everywhere after they were first introduced, and could frequently be caught but they were all very small. The average weight of all the eels caught in one year is about 250 gm., although occasionally it is as much as 700 gm

The roach is the commonest of the indigenous species. At first it represented 70 % of the total number of fish caught, and it is still taken oftener than any other. The average weight of the individuals caught is 25-50 gm.

The perch also remains small. Average live-weight at first 31 gm.; later, 39-55 gm. This fish spawns as soon as the ice melts, when the temperature of the water is about 5° C. The common pike caught weighed 500 gm. on an average. In order to facilitate the introduction of new species of fish, many pike as well as roach, were taken. Though the number of roach in the Evois lakes were thus much diminished, the pike still always represented as before over 20 %, and sometimes even 30 % of the total catch. This fish spawns soon after the melting of the ice.

PRODUCTION OF THE LAKES. — The average production of all the lakes during the 25 years of experiment was 3.69 kg. per hectare, and varied during the different years between 1.65 kg. (1894) and 6.52 kg. (1915). The average production of the various lakes was most irregular, being highest where flax was retted, for the vegetable matter introduced into

[1153]

the water caused a richer fauna to develop. Thus Kaitalampi (surface 2.72 hectares, depth 4 m.) had only produced 3 kg. since 1896 until the last few years, when fish caught weighed, respectively, 14, 15, 20, 70, and 24 kg. The average production of Valkea-Mustajärvis was 15 kg. in 1900, 14.5 kg. in 1901, and 31.5 in 1902, whereas the large lake, Alimäinen Rautjärvis, (superficial area 52 hectares, depth 10 metres), through which run the effluents of all the other lakes, only yielded an average of 2.56 kg.

CONCLUSIONS. — From what has been said, it appears that the introduction of new species of fish into such barren waters is practically useless.

The remarkable increase produced in the number of fish by retting flax in the lakes confirms the satisfactory results obtained by ZEHMEN, STRUCK, etc., who manured the water with fermented plants.

Where the application of fertilisers does not seem likely to have a lasting effect upon the margin of the lake, it may perhaps be possible, by their use, to obtain a regular increase of the fish supply in waters that are deficient in mineral salts.

1154 - The Effect of Food Conditions Upon the Intensity of Parasitic Infestation in Fish.

— DEMOLL, in the *Allgemeine Fischerei-Zeitung* Year XLVI, No. 12, pp. 136-140. Munich, June 1921.

Prof. WOHLGEMUTH, of the Hofer Institute at Wielenbach, carried out experiments in 1920-1921, with a view to determining whether any great difference would be observable in the spring in the health, mortality, and parasitic infestation of carp that had been well supplied with food during the winter, and of those that had been provided with nothing to eat. He also wished to discover whether under unsatisfactory food conditions certain species of parasites disappear.

The carp forming the subjects of the experiment were divided between two wintering tanks of equal size and character, in such a way that whereas one lot had plenty of food at its disposal, the other larger lot was obliged to pass the winter fasting.

POND No. 43.

Stocked with 100 *Fish of one Summer.* (5 individuals examined).

Carp. No.	1 Blood	2 Epidermis	3 Branchiae	4 Intestines	5 Kidneys	6 Remarks
1	—	—	*Sanguinicola inermis* eggs. All encysted.	*Eimeria* in small numbers.	*Sanguinicola inermis*, encysted eggs.	Condition fair.
2	—	—	Isolated individuals of *Dactylogyrus*.	*Eimeria* in considerable numbers.	—	Condition fair.
3	—	—	*Sanguinicola inermis*, fairly numerous. *Gyrodactylus* isolated individuals.	*Eimeria* in considerable numbers.	*Sanguinicola*, encysted eggs.	Very thin.
4	—	—	*Sanguinicola inermis* some encysted eggs.	*Eimeria* numerous.	—	Condition fair.
5	—	—	—	*Eimeria* very numerous	—	Condition fair.

POND NO 44

Stocked with 9190 *Fish of One Summer.* (5 individuals examined).

Carp No	1 Blood	2 Epidermis	3 Branchiae	4 Intestines	5 Kidneys	6 Remarks
		Dactylogyrus isolated individuals.	*Dactylogyrus* in considerable numbers *Gyrodactylus*, some encysted eggs of *sanguinicola inermis*	*Eimeria* in large numbers		Very weakly specimen
2	—	*Cyclochaeta* (isolated) *Saprolegniae* *Gyrodactylus* in moderate numbers.	*Cyclochaeta Dactylogyrus* and *Gyrodactylus* in fairly large numbers. *Sanguinicola* encysted eggs	*Eimeria* in large numbers		Condition fair Beginning to be infested with *Saprolegniae*
		Cyclochaeta. *Gyrodactylus*	Sanguinicola eggs not encysted, *Cyclochaeta*, *Gyrodactylus* all fairly numerous	*Eimeria* in large numbers		Condition fair Beginning to be infested with *Saprolegniae.*
		Cyclochaeta *Dactylogyrus* *Gyrodactylus* Eggs of *Dactylogyrus* ?	*Sanguinicola* encysted eggs *Dactylogyrus* *Gyrodactylus*	*Eimeria* numerous	—	Very thin, at the point of death Already dead
		Cyclochaeta *Dactylogyrus*	*Cyclochaeta* *Dactylogyrus*	—	—	Slightly decomposed, very thin

The fish selected were carp of one summer, and infested with parasites Before they were introduced into the winter tanks they were examined with the result that *Piscicola, Dactylogyrus, Cyclochaete,* and *Chilodon* were discovered on their branchiae and epidermis *Eimeria* in their intestines, and *Trypanoplasma* in their blood In October, 1920, two trout ponds, (Nos. 43 and 44), each of 100 sq. m were stocked with 1 year old carp 6 to 8 cm. long; 100 fish being put into the first pond, and 9190 into the second

On April 19, 1921, fishing was begun in the two ponds No 43, which had been stocked with 100 carp, still contained 56 (56 %), whereas No. 44 into which 9190 carp had been introduced, only contained 1003 specimens (11 %).

As soon as the fish were removed from the water, they were at once examined The annexed tables give the results of this examination.

It was found that the live weight of specimens from the more densely stocked wintering pond was slightly greater than those from pond 43. Only 1 out of 10 individuals had however survived, in every case, owing to rigorous natural selection, the largest and strongest fish had always been preserved, which explains why the live weight of the carp left in the thickly populated pond was higher than that of the pond into which fewer fish has been introduced so that the struggle for life had been much less acute, and therefore even the less vigorous specimens had managed to survive This fact is the more important seeing that the condition of the best specimens of the 9190 summer carp was much worse than that of the fish of the other lot

From a comparison of the lists of the autumn and spring parasites, it would appear that one series had completely disappeared ; this may however be due to the life-history of these pests. In any case, no very important conclusions could be drawn from a comparison of the results of the autumn and spring examination.

As regards parasitic infestation at the end of the winter, the data afforded by the two series of experiments are of great interest.

In the case of all the survivors of the 9190 fish, the epidermis proved without exception to be infested with *Dactylogyrus* and *Gyrodactylus*, and in 4 out of the 5 specimens examined, *Cyclochaeta* was also present, whereas none of the other lot of carp was similarly attacked. As *Gyrodactylus* and *Dactylogyrus* were found on the branchiae of both lots, but on the epidermis solely of badly nourished individuals, it may be concluded that overcrowding (facility of contagion) is not the cause of parasitic infestation. The epidermis is only attacked when the fish is badly diseased or badly nourished, even though the parasites may be already present in large numbers on the branchiae.

Although it is possible that the invasion of the epidermis may be due not to want of resistance but to the emigration of parasites from the over-crowded branchiae, these experiments prove in any case that good nutritive conditions have an influence upon parasitic infestation.

1155 - **Artificial Fertilisation and Incubation of the Shad.** — PIROLA, E., in the *Bollettino della Società Lombarda per la Pesca e l'Acquicoltura*, Vol. XIV, No. 8-9, pp. 81-87 8 figs Milan, August-September, 1921.

The shad is a marine fish with migratory habits; one form known as the Twaite shad (*Alosa finta*) to distinguish it from the Allice shad (*A. vulgaris*), has adapted itself to fresh water conditions. It has a finer flavour than the marine type, and the most tasty specimens come from the Lake of Como.

The author decided to carry out experiments on the artificial fertilisation and incubation of this fish, as scientific literature contained only vague information respecting its reproductive processes, although BOWERS (Washington) had treated the question at length as regards the American shad (*A. sapidissima*), a much larger form with very different habits living in brackish water in North America.

The author's experiments, which he describes in detail, had very satisfactory results. In a few days, he was able to put into the water some 500 000 fry of *A. finta*. The incubators were the same as those used for *Coregonus* with slight modifications. Fertilisation was effected dry.

The incubation tank was kept supplied by water heated electrically to 20° C.

FARM ENGINEERING

1156 - Decree of the French Minister of Agriculture Dated June 17, 1921, Respecting Enterprises for Mechanical Ploughing. — *Journal officiel de la République française*, Year LIII, No 163, pp 7009-7010 Paris, June 19, 1921

Article 1. — Contractors who undertake mechanical ploughing for others and are using more than 2 machines, or sets of total power of at least 200 H P. may receive assistance from the State

Should the petitioner be at the same time a threshing contractor, the H.P. required by the threshing apparatus may be deducted from the minimum H.P. prescribed for mechanical ploughing apparatus or sets, provided that the total power of the said mechanical ploughing apparatus or sets is not below 100 H.P.

In exceptional cases machines for use in viticultural, horticultural, and kitchen-garden work shall be permitted to represent a total not exceeding 100 H.P., but they shall be not less than 10 in number.

Article 2. — All requests must be addressed, on Jan. 15 each year at the latest, to the Minister of Agriculture, who will acknowledge their receipt.

Article 3. — The assistance given by the State consists of premiums calculated on the basis indicated by the decree of March 31 and includes the additional premium provided for co-operative societies. The premiums are only for the mechanical ploughing apparatus or sets, threshing plants being excluded. These premiums are placed at the disposal of the interested parties in the following manner:—

(*a*) One half at the date when the demand is approved,

(*b*) the remainder in amounts of ¼ at a time, at the end of each of the first two agricultural seasons, and on production of the proofs required by article 4.

In case of accident, the beneficiaries shall be required to replace the destroyed apparatus or sets, and shall request, in the case of new purchases, a premium the amount of which shall be fixed after taking into account the sums already paid by the State and the amount of insurance-money already received.

Article 4. — The proofs of the areas to be ploughed shall consist in the production of the summary and detailed statement for the Commune showing the extent of the arable land, and giving the names of the farmer working them, and the sums paid by the latter for the work performed. These said statements after having been certified as correct by the Mayors, shall be sent every year not later than August 15 to the Directors of the Agricultural Services of the one or more Departments where the work is being done, who after due verification as required, shall forward the said documents, with their remarks, to the Minister of Agriculture.

Article 5. — Should one of the conditions of the agreement not have been fulfilled at the end of the first season, or should an incorrect return knowingly have been made, the half of the premium already paid shall be refunded to the Treasury by order of the Minister of Agriculture.

If one of the above-mentioned conditions remains unfulfilled at the end of the following seasons, the portion of the premium corresponding to the sum mentioned in par. *b* of Art. 3 shall not be paid.

Article 6. — Farmers who desire to benefit from the premiums provided in the present Decree, must submit to all the measures of control and verification prescribed by the Minister of Agriculture.

1157 - **Agricultural Machinery in Spain.** — *The Engineer*, Vol. CXXII, No 3424 p. 163. London, August 12, 1921

Reports received in the Department of Overseas Trade from the Commercial Secretary to his Majesty's Embassy at Madrid with regard to openings for machinery in Spain state that, although Spain is primarily an agricultural country, the Spanish farmer has not kept pace with the times. The most antiquated methods are still employed. Grain continues to be cut by scythes and threshed by trampling while wooden hand ploughs are in common use. The change which is inevitably taking place is retarded by ignorance and prejudice. An innovation in one district is slow to react in the next. In short, the opening in Spain for agricultural machinery is wide, but new business often involves educating the buyer first. The tariff on these goods has been recently raised 50 per cent.

The tractor has not yet established itself definitely in Spain, and the various exhibitions which have been held in the past year or so have not had much apparent success. The public interest has been small and the sales of machines through the exhibitions are said to have been disappointing. The chief advantage of these shows seems to lie in the extensive Press notice they have received. The market for tractors is more for the future than the immediate present, though the time is opportune for manufacturers to lay the foundations of business by making their machines known.

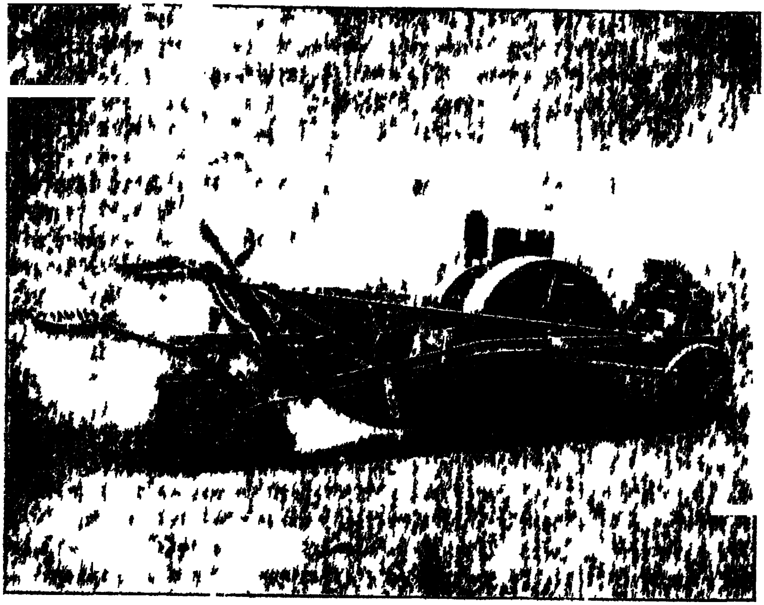
Winnowing and cleaning machinery is made in Spain, though there is certainly a margin for popularising the use of modern machines of which, it is suggested, the British manufacturers might take advantage, if able to compete in price. Milling machinery is partly imported and partly manufactured in the country. The demand for wine and cider presses is largely supplied by local production, but there seems to be an opening in the Vigo district. Drilling and threshing machines are not much used. On the other hand, there is a growing foreign trade in small motors for agricultural use. In this the Swiss and Germans are keen competitors.

In the Barcelona district water turbines are likely to be largely required for the numerous power plants which are being put up all over the country. At present this trade is almost wholly in the hands of Swiss and German manufacturers, but it remains to be seen what effect on this demand will follow the Royal Decree of June 14th, obliging future holders of water power concessions to use Spanish machinery whenever possible. Centrifugal pumps are also largely required for irrigation purposes. Light cheap pumps and motors are at present supplied by American, German, Norwegian and Swiss makers.

In the carpentering and cabinetmaking industries much work is done by hand which could with advantage be done by machinery The manufacture of all sorts of house furniture has developed considerably of late years and a large export trade has been established But in order to introduce the machinery manufacturers must either send travellers who are able to explain the advantages of their machines, or they must appoint agents with security in their appointment for a number of years It is stated that propaganda confined to the sending of catalogues will lead to business

1158 – **The "Maskell Junior Motor Plough".** — *The Implement and Machinery Review*, Vol 46, No 549, p 1401 London, January 1, 1921

The Maskell Junior Motor Plough is specially designed to meet the needs of those who require a smaller outfit than a tractor and a multiple furrow plough, and also those whose system of cultivation demands that operations be conducted in the minimum of space and with the greatest possible economy of the headlands



"Maskell Junior Motor Plough"

This machine will plough a furrow 6 to 9 in deep and 9 to 12 in wide under ordinary conditions and the adjustments for width and depth are made easily. It is a self-contained single-furrow machine with an over all length of 12 ft, a width of 4 ft. 3 in, a height of 3 ft 6 in, and a weight of 10 cwt Steering may be either by handles as the operator walks behind, — a preferable arrangement in difficult working conditions, —

or from a detachable driver's seat. The machine can be swung round on its driving wheel, and the same lever which raises or lowers the plough is used to adjust the depth of ploughing as the work proceeds.The outfit is balanced on one large driving wheel, and is supported by an idler wheel on the left side, which acts as a slight drag and gives the plough a tendency to run to the left. This idler wheel is adjustable vertically to run in or out of the furrow. Power is supplied by a fan cooled V twin cylinder BLACKBOURN engine giving 10 h. p. on the brake, on petrol. The drive is transmitted to the multiple disc clutch by a chain and by gears from the clutch to the single driving wheel. A pulley drive is supplied for such power work as is consistent with the size of the engine. Cultivating and other tools can be had, while the outfit is made self-steering by a furrow guide wheel.

Manufacturers: MASKELL MOTOR PLOUGH Co. Advance Works, Jews Row, Wandsworth, London, S. W. 19.

1159 - **The Beaters of Threshing Machines.** — CASTELLI, M., in *Il Villaggio ed i Campi*, Year XLVI, No. 23, p. 2. Rome, June 4, 1921.

The innovations introduced of recent years into the construction of threshing-machines have related chiefly to the details of transmission and mounting, or to improvements in various accessories (automatic feeder, bagger, straw elevator, etc.). and therefore to the reduction of labour. The essential structure of the thresher has remained unchanged since certain types became fixed; each country having a preference for the model it makes itself.

Except in the case of special forms used for paddy, forage, etc., beaters are always of two kinds, being furnished with either teeth, or bars. The former type is preferred by the American makers, and the latter by the European.

The toothed beater does the work mere quickly, but less perfectly, whereas the bar beater works more slowly, but injures the grain and straw less. The first kind is especially suited to America, where the threshing is done on the field at harvest time, or immediately after, and the large output of the machine is what matters most; the second is more adapted to the North of Europe, where the sheaves are stacked, often under cover, and the threshing is done by very few workers at a time when, owing to the season or the condition of the crops, there is nothing requiring attention on the farm.

The author has studied these two types of beater, in order to decide which is the more suited to agriculture in Italy, where the conditions more nearly resemble those obtaining in America, than those of Northern Europe. He examined the capacity and qualities of the beaters from the following points of view:—

1) Method of feeding (lengthwise, that is to say the end of the sheaf is inserted first; or crosswise, the sheaves being put in parallel to the axis of the beater, so that the ears are placed alternately right and

left), and hence the possibility of using an automatic feeder, straw-stacker, etc.

2) Breaking the straw.

3) Efficiency in separating the grain, and the effect of the speed and of the regulation of the distance between the beater and the concave.

4) Rupture or integrity of the grain.

5) Wear and tear and life of the machine, repairs.

6) The production, and therefore dimensions of the machine.

7) Power required.

A toothed beater can only be fed lengthwise but a bar-beater can be fed lengthwise and cross-wise, provided that the length of the beater is not less than that of the straw. This method of feeding is the rule for bar-beaters, for thus the greatest advantage can be obtained from the character of the beater, whereas if the sheaves are not inserted lengthwise although some of the special advantages of this type are secured, the chief are lost.

In the case of short straw and clean wheat, provided the machine is sufficiently wide, the cross-wise fed bar-beater has many advantages (regularity, saving of fatigue to the man feeding, adaptability to automatic feeders of simple construction, little broken straw, excellent working of straw-shaker, bagger, and elevator). These good points certainly outweigh its defects (small output, requires more power, deficient speed and regularity). When however as often happens in Italy, the straw is long, full of weeds, and of a variety that is difficult to thresh, and further where the threshing operations take place on sloping ground, where the necessary narrowness of the threshing machines precludes all question of cross-wise feeding, the superiority of the bar-beater begins to become more doubtful. Therefore in order to make a satisfactory choice, a number of other circumstances have to be taken into consideration.

Apart from the breaking of the straw (though sometimes this is desirable) the loss of grain by incomplete separation or through breakage are very important matters

The grain is detached by shock, repercussion or as the result of friction ; thus the first type of beater is much more susceptible to variations in speed than the second, and only works well within very narrow speed limits. BALASSA (*Die Dreschmachinen*) gives 29 to 32 m. per second as the peripheral speed of bar beaters, and from 14 m. (small machines) to 20 m. (large machines) for toothed beaters In large American threshers of modern construction, the peripheral speed of the beater is as much as 32 m. per second, but the author has found 10 m. per second quite sufficient, at all events for very dry sheaves and dry straw. With the bar beater, variations in speed result in rupturing the grains, or preventing their complete separation. The same occurs with the toothed beater, but to a less extent, so that practically, unless the speed is reduced beyond the minima given, the only effect of lessening the speed is a decrease in the output.

On the other hand, whereas it is possible to alter the output of the bar beater any way for the time being by increasing or decreasing the distance between it and the concave, this method of regulating the action is much less efficacious in the case of the toothed beater unless the teeth are conical or angular, which seldom occurs.

It is alleged that the beater with teeth breaks the grain too much, and sometimes lets ears pass intact; there is something to be said on both these counts, but as honey-comb sieves are in general use for the mechanical sorting of the grain to serve as seed-corn, the first objection is of little weight, and the ears that escape threshing are very few in number unless only the tip of the sheaf is presented, for example by an automatic feeder, and in such cases as in that of the American threshers, it is necessary to have an elevator for the ears that are refused by the sieve, and return them to the beater. If, however, the feeding is done by hand, and the shears held *slightly obliquely*, no loss of whole ears is possible.

It must be added that the bad repute into which the toothed beater has fallen is also due to the use of antiquated types, with few rows of teeth made of unsuitable material, or unpractical shapes (conical or angular), and badly affixed to the bars, thus easily injuring the grain.

A rapid, toothed beater of the modern American type with about 300 teeth per linear metre (the teeth being arranged in 20 rows), working against a concave with 6 rows of teeth, gives perhaps double the hourly output of a bar beater of the same length but fed cross wise. This however depends little upon the dimensions of the machine which is always subordinate to the size of the sieves and shakers, though a beater 0.50 m.-0.60 m. shorter than the internal width of the frame may facilitate the use of an electric motor or internal-combustion engine carried by the threshing-machine.

Finally the moderately rapid toothed beater requires less power, and less regular working, which is of a certain importance when the beater is driven by electricity, or in the case of hand or horse-driven threshing machines.

After having examined the points in favour of both types of beater, the author comes to the conclusion that the superiority of the form with bars must be admitted when it is a question of cross-wise feeding (the length of the beater being not less than the height of the sheaves), whereas the toothed beater is to be preferred, when only lengthwise feeding is possible, or if it is desired to have a large output, and economise motive power, provided a little less regularity is no objection; for in this way, the work of the motor is lightened in the types of motor-thresher machines with internal combustion engines or electric motors, which are becoming increasingly common and tend to take the place of those driven by steam-engines.

1160 – **Machines for Treating Cotton Seed Against the Pink Boll-Worm.** — GHESQUIÈRE, A. I. (*Entomologist of the Belgian Congo*), in the *Annales de Gembloux*, Year 17, Part 7, pp. 234-238. Brussels, July 1921.

It has now been proved that the pink boll-worm (*Platyedra* [*Pectinophora*] *gossypiella*) passes the winter (the dry season) in a resting condition on the bolls that are left on the plants or have dropped to the ground at picking time, or else on the stored cotton seed.

In a pamphlet entitled " Machines for the Treatment of Cotton Seed against Pink Bollworm " (*Gelechia gossypiella* Saund.), Ministry of Agriculture, Egypt, 1917, the entomologist, G. STOREY, gives the history of the control measures adopted by the Egyptian Government since 1909, and describes the machines (giving their advantages and defects) which were made until the end of 1917 for the purpose of disinfecting the seeds of the cotton plant.

In addition to the campaigns undertaken against the boll-worm, with the hope of inducing cotton-growers to collect and burn the dead capsules, so as to reduce the danger of invasion in the following year, the Egyptian Ministry of Agriculture carried out a very complete series of experiments in order to discover the best way of killing the Bollworm larvae without injuring the seed.

The results of these experiments were published in the *Agricultural Journal of Egypt*, 1913, Vol. III, Part. II, by GOUGH and STOREY (" Methods for the Destruction of the Pink Bollworm in Cotton Seed ").

The conclusions were as follows :— Three different methods of destroying the larvae of the pest have been found efficacious and commercially practicable, viz. :—

I. — Hot air treatment ;
II. — Poison gas treatment :
III. — Immersion in a 1 % solution with a carbolic base (" Cyllin ")

Methods I and II can be applied on a large scale at all times and Method III is suitable before sowing ; once the seeds are put into sacks, nothing further can be done

Two machines were constructed, one using hot-air, and the other carbon disulphide. Both were exhibited at a meeting of planters, factory owners, and cotton merchants.

A report was published in the *Agricultural Journal of Egypt*, Vol. IV, Part II, STOREY : " Note on Large Scale Experiment against the Pink Bollworm of Cotton Seed. "

In spite of its efforts, the Ministry of Agriculture met with general apathy on the part of all persons interested, and in some cases, had to face actual opposition, many objections being raised against the machines, which were considered of too clumsy construction, and too cumbrous by some, while others feared the seed would be injured by the high temperatures employed, or objected to the poisonous and inflammable gases used.

The Entomological Section directed its whole attention to the hot-air treatment, and in order to encourage initiative, the Egyptian Government passed two laws about Dec. 15, 1916, the one obliging all cotton factories to treat their seed for the season 1917-1918 by means of a machine approved by the Ministry of Agriculture, while the other prohibited any cotton, whether seed or ginned, from being kept in the warehouse after May 1, except in the case of specially licensed warehouses, viz., those that had been disinfected and were so constructed that the moths could not find their way in, and lay their eggs on the seed.

Within a few months numerous machines were made in Egypt, England, and America and by the end of 1917, they could be classed as follows:

I. **Fumigating machines using** (*a*) **carbon disulphide,** (*b*) **hydrocyanic acid.**
II. **Hot air machines** (*a*) **using a current of hot air;** (*b*) **acting by radiction,** (*c*) **by direct contact with heated metal plates.**

This last type includes: — 1) the SIMON machine, definitively approved by the Egyptian Ministry of Agriculture, and made by MASSERI, CURRIEL and Co, 16, Sharia Nubar pasha, Cairo; 2) the MACRI machine, also approved by the Ministry: made by the Society for the exploitation of the Delta Zefta machine.

From the latest information received (Oct. 1920) from the Director of Belgian Agriculture, the British Cotton Growing Association considers that the question of the disinfection of cotton seed is solved by the use of the Simon machine.

1161 - **Utilisation of Waste Farm Products for Fuel.** — *Indian Engineering*, Vol. LXIX, No. 26, p. 362. Calcutta, June 25, 1921.

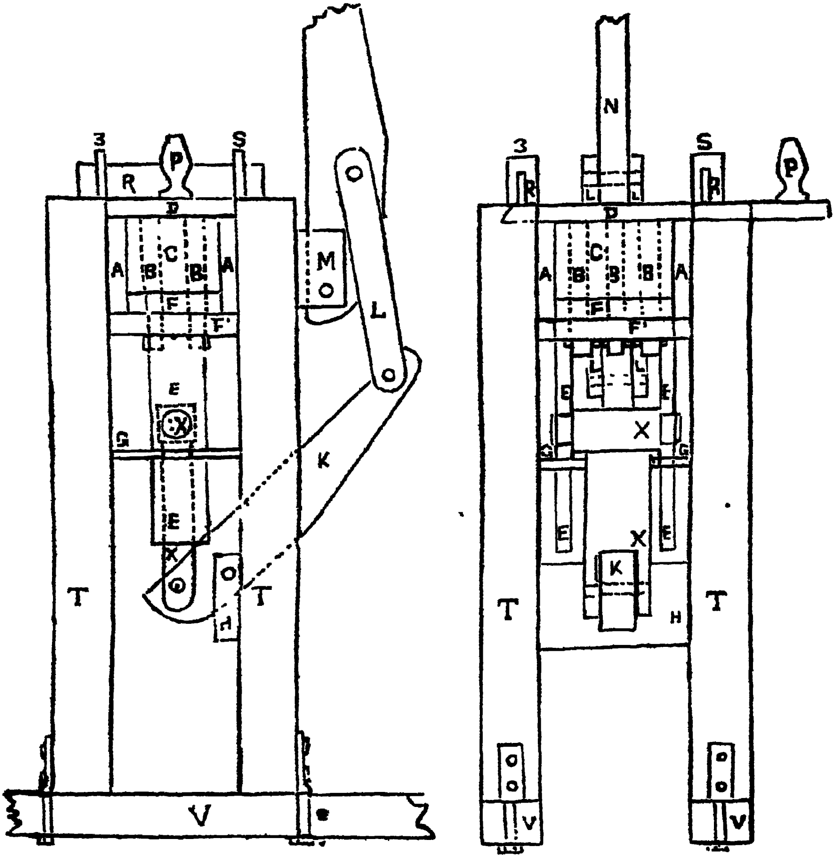
Waste farm products have been very successfully used mixed with coal-dust, in manufacturing briquettes for fuel. Such waste products as saw-dust, dead leaves, paper, wheat and coal husk, etc., are usually employed, mixed with clay as a binder and pressed in a suitable press. The mixture consists of 10 to 12 per cent. of coal or coke dust, and 15 to 20 per cent. of waste products and fat clay soil. When paper is used, it is first soaked for some days in water and the glutinous content in size acts as a binder. The following is a brief description of the press used in the manufacture of the briquettes:—

A chamber *C*, supported on four posts *T*, and made to receive the mixture for pressing, is traversed by vertical rods *B*, fastened on to a ***fixed*** plate *F*, which are employed for perforating the briquettes. A ***mobile*** plate *F'*, pierced with holes to let through the rods can be pushed from below upwards by the levers *K* and *N*, through two uprights *E*, guided by grooves *G*, and a connecting rod *X*. A cover *D* closes the top of the chamber *C* and is held solid by clamps *R* which are held in slots *S* bored in iron plates.

The method of working is simple: The mobile plate *F'* is lowered to the bottom of the chamber by raising the lever *N*. The cover *D* is drawn off by the handle *P*. The chamber is filled, the cover replaced and the lever *N* is forced down. Then the cover *D* is removed and, to free the briquette from the rods which have made the perforatione, the lever *N* is lowered to the ground. It remains only to lift off the briquette, by sliding it carefully, and setting to dry.

Pressure is exerted by means of two levers *K* and *N* connected by two connecting rods *L*. The lever *K* acts directly on the rod *X*. The lever *N* acts on the lever *K*. If the arms of the lever *K* are in the ratio

1 : 4 and those of the lever *N* in the ratio 1 : 7, the rod *X* receives a force equal to 4 × 7 = 28 times the force exerted at the end of the lever *N*. If a man weighing 75 kg. hangs on to the end of the lever *N*, the matter enclosed in the chamber will undergo a pressure of 75 × 28 = 2100 kg. a pressure which may be increased by lengthening the lever *N*.



Briquette Press, vertical Sections.

The measurements of the briquettes are 0.22 metre × 0.18 metre × 0.07 metre. When dry they have a mean weight of 3.5 kg. if made with coal dust.

The press is easily made with hard rough sawn wood and bolts. There is no fitting and little iron work. Thus the farm staff which looks after the cart repairs could make it. Moreover any hands which have not been discharged at the beginning of winter can be set to making briquettes when not otherwise employed.

1162 - **Paraffin from Vegetable Oil as a Motor Fuel.** — See No. 1169 of this *Review*

RURAL ECONOMICS

1163 - **Agricultural Costs and Sale Prices in Belgium before and after the War.** — RASQUIN, M., in the *Journal de la Société Nationale des Agriculteurs de Belgique*, Year III No 35, pp. 275-276. Brussels, Aug. 27, 1921.

The author sets out in the following tables the costs of cultivation and the sale price of agricultural products before and after the war.

AGRICULTURAL COSTS (in francs per quintal).

		Before the war	at the end of 1920
I — *Fertilisers and foodstuffs:* —			
Nitrate of soda		20	120
Sulphate of ammonia		24	135
Superphosphate		5	30
Basic slag		5	25
Kainite		4	13
Wool refuse		5	20
Linseed cake		20	90
Groundnut cake		18	95
Coconut cake		18	85
Maize		15	75
Bran		13	50
II. — *Machinery and implements:* —			
Plough		110	500
Reaper		900	4800
Mower		350	1800
Carts		1000	4000
Wagons		500	2200
Sacks		1	6
Shoeing		4	20
Wheel barrows		30	180
III. — *Salaries and wages:* —			
Driver (board and lodging)	annual	600	4000
Cowman (board and lodging)	»	500	3000
Servant (board and lodging)	»	360	1500
Journeymen	daily	5	17
Beet tilling	»	50	200
Beet pulling	»	60	250
Reaping	»	70	200
Threshing	per sack	1	6

SALE PRICES OF AGRICULTURAL PRODUCTS (in francs per quintal).

	Before the war	At the end of 1920
Wheat	19	90
Rye	20	80
White Barley	20	90
Oats	20	88
Hay	6	30
Straw	4	12
Sugar beets	3	16
Potatoes	8	35
Mangels	1.50	7.50
Butter (per kg.)	5	17

AVERAGE PRICES OF LIVE STOCK (in francs per head)

	Before the war	At the end of 1920
Horses	1200	6000
Cattle	650	1600
Milch Cows	550	2800
Sheep for grazing	30	180
Young pigs (two months old)	30	186

Before the war a young farmer about to start reqnired for the equipment of his farm in dead (including all agricultural machinery) and live stock a fixed sum of 1000 francs per hectare of his farm.

At the present time stocking a farm requires a capital of at least 3000 francs per hectare. Thus a farmer taking over a 100 hectare farm would incur initial capital charges of about 300 000 francs.

1164 - **Cost of Production of Wheat in a Commune in Romagna (Italy) during the Agricultural Year 1919-1920.** - SBROZZI D., in *L'Italia Agricola*, Year 58, No. 8, pp. 225-237. Piacenza, Aug. 15, 1921.

The author analyses the cost of production, in the agricultural year 1919-1920, for wheat grown on a 60 hectare farm in a commune in Romagna, the average yield being about 15 quintals per hectare. The year was unfavourable, because the high spring rainfall laid the crops and was the cause of much rust. The wheat followed a leguminous crop, a bean crop or a wheat crop, for the soil was improved and suited to a second crop. Ploughing was done by tractors of the CASALI cable machine type. Ploughing, manuring and cultivation were carried out intelligently and carefully. The varieties cultivated were Carlotta Strampelli, Gentil rosso and Shiriff Cologna. The author gives for the different headings of expenditure the unit price for each year from 1914 to 1920. Those only which relate to the first and the last of the series are reproduced here.

In 1887 the results of an enquiry by the Ministry of Agriculture over 244 farms producing 15 hectolitres par hectare shewed that the cost of production of wheat was 9.80 lire per hectolitre, not including rent, or 15.87 lire when the latter was also taken into account.

At the end of the last century Professors RAINERI and JEMINA stated that the cost of production of wheat in intensive culture following

COMPARISON BETWEEN PRICES AND SALARIES IN 1914 AND 1920

		In 1914		In 1920	
Price of 1 quintal of coal	lire	4.50		85	
1 quintal of wood	»	3	(1915)	18	(1919)

1165 - Respective Costs of Production of Green Forage and Silage Crops in Nebraska. (U. S.). — See No. 1026 of *Review* Oct. 1921.

AGRICULTURAL INDUSTRIES

1166 - Wines Made from Grapes Infected with *Eudemis* — HUGUES, E. (Chef de travaux à la Station oenologique de Montpellier), in the *Annales des Falsifications et des Fraudes*, Year XIV, No. 151, pp. 139-141. Paris, May 1921.

On one of the estates in the South of France, where the last crop had been imperilled at the time of the vintage by the attacks of cochylis and eudemis, the author gathered 2 lots of grapes at the same time from an Aramon vine. One lot had been punctured and much injured by these insects, whereas the other had hardly been touched.

As soon as these grapes were gathered, they were at once pressed, and a rapid examination of the musts obtained gave the results set forth in the following Table:—

TABLE I. — *Analysis of musts of sound grapes and of grapes infected with Eudemis.*

		Grapes must	
		Sound	Infected
Reducing sugar expressed as glucose . . .	gm. per litre	175.00	225.00
Total acidity expressed as H_2SO_4	» » »	5.48	11.10
Volatile acids	» » »	0.10	0.3
Alcohol by volume.	. . %	nil.	0.3°
Colour	. %	Colourless	Distinctly red

It was found, as has been recorded many times before, that the must of eudemis-infected grapes is much sweeter and has a far higher acid content than that of sound grapes. On the other hand analysis revealed the presence of 0.3° of alcohol, and 0.3 gm. per litre of volatile acid in the must of the diseased grapes, whereas the must from the sound fruit contained no alcohol, and a very small quantity of volatile acid. Thus before the grapes were picked, fermentation had already set up in the infected berries.

The two musts were fermented separately. When tunned, the amounts of wine and of pomace obtained were respectively as follows:— Wine (*vin de goutte* and pressed wine), per kg. of grapes 712.5 c.c. in the case of the sound grapes, and 647.5 c.c. in that of the infected grapes: promace per kg. of grapes, 125 gm. from the sound grapes, and 215 gm. from the diseased grapes. Thus the amount of wine obtained from eudemis-infected fruit is considerably less.

It may be supposed that as the grape, when attacked by the insects, had already developed all its tissues, the subsequent changes would be limited to an increase in the sugar content and a decrease in acidity. It would therefore appear that the pomace might furnish a measure of the weight which a given weight of diseased grapes would have attained if they had been healthy. Now, if 125 gm. of pressed pomace correspond to 1 kg. of sound grapes, 215 gm. correspond to 1.720 kg. According to this hypothesis, the loss that can be attributed to the attacks of the insect would be about 42 % of the crop.

On the other hand it was found that the must from the eudemis-infected grapes contained more sugar, and more acid than the product of normal grapes, and the wine had a higher alcohol and acid content. If however, the calculation is made for 1.72 kg. of sound grapes, instead of for 1 kg. of diseased grapes, the sugar content is lower, and the acidity higher (1).

An analysis made in February showed the results given in Table II. These show that whereas the composition of wine made from sound grapes was normal, the product of the infected grapes had a high alcohol content, and an excess of acidity; further, the dry extract was very strong, and possessed a peculiar, bitter taste. In addition, there was much free tartaric acid present, and the saccharimetric deviation was distinctly positive; this last abnormality is probably due to the presence of dextriniform substances.

TABLE II. — *Analyses of Sound Wine and of Eudemis-Infected Wine.*

		Wine from sound grapes	Wine from infected grapes
Alcohol	% in volume	10.3°	12.0°
Dry extract at 100°C.	gm. per litre	20.50	52.75

---

(1) See also: J. DUGAST, Vins anormaux, *Annales des Falsifications et des Fraudes* year 1917, p. 21. (*Ed.*)

It would thus seem that the effect of the attacks of the insects is to suppress, or at all events to hinder, the processes that usually take place towards the close of the ripening of the fruit, that is to say, the increase in sugar content, the diminution in acidity, and the transformation of the free tartaric acid, either by combination, or combustion.

1167 – **Non-Alcoholic Wines and Ciders** (1). — *La Cidrerie française*, Year 33, No. 6, pp 173-177. Paris, August 1921.

The President of the General Syndicate of Ciders and Fruits for Cider-Making of France made enquiries respecting the manufacture of non-alcoholic ciders and received the following note from the French Commercial Office for Switzerland

NOTE ON THE MANUFACTURE OF NON-ALCOHOLIC WINES AND CIDERS IN SWITZERLAND. — In order to obtain a non-alcoholic cider of good quality, it is necessary to mix apples of various kinds (sour and sweet), for the flavour depends upon the cider containing sugar, tannin, and acids in certain proportions. The apples should be chosen by an expert, for the kind of fruit selected determines the quality and clarity of the juice extracted. If sweet and acid apples are mixed in the right proportions, the juice expressed should be relatively clear and not require filtering.

Fruits of different kinds are not mixed as a rule, the apple juice being the extract of apples without any admixture of pears or other fruit.

The apples or grapes should be ripe, but not over-ripe. In no case is fruit used that is not sufficiently mature for the table. Should they be dusty or covered with soil, they may be washed, but if clean this is optional.

To extract the juice, the fruit is first pounded in stone mortars, and the pomace thus obtained extracted by a hydraulic press. It is of the greatest importance that, during pressing and the subsequent operations, the juice should never come into contact with iron, which imports a disagreeable taste. Iron utensils ought therefore never to be used.

Pomace is not tunned before pressing ; in fact, all the operations must be carried out rapidly so that the juice will not remain too long in contact with the air, which might start fermentation.

The hydraulic presses used in most of the Swiss factories are supplied by Messrs. RAUSCHENBACH of Schaffhausen (Switzerland).

As soon as the juice leaves the hydraulic press, it passes through a pipe to a metal sterilising apparatus filled with water at a temperature of 66° C. to 70° C. The juice, which is in a spiral aluminium tube, remains in the steriliser for half-an-hour at most, after which the operation is complete. It should be noted that, after this stage, the juice should never come into contact with the air.

---

(1) As regards the manufacture of alcohol-free ciders and wines, the pamphlet by M. LEUTHOLD, of Waedenswil (Zurich), and sold by him at the price of 0.75 Swiss francs, may also be consulted. M. A. BÖHI's (Bürglen, Thurgau) brochure also gives useful information concerning the manufacture of alcohol-free sparkling wines and champagne. It is sold by Messr. HUBER and Co., Frauenfeld at the price of 1.60 Swiss francs.

After sterilisation, the cider or wine is taken into receptacles holding 15 to 20 hectolitres from which all the air has previously been expelled. In these it remains for some weeks or even months before being bottled. The receptacles are provided with a fermentation indicator consisting of a black fluid contained in a glass spiral in the form of a horizontally-placed S, which turns white as soon as the fermentation begins.

Before bottling, the juice is filtered through asbestos and can be filtered several times if necessary, in order to render it perfectly clear, but it is better only to filter it once, for the repetition of the process affects the taste of the liquid. Asbestos filters are well-known, and their use is not a trade secret. They are made in Switzerland by Messrs. TH. SEITZ at Kreuznach-am-Rhein, and Messrs. HOENY, Mechanische Werkstätte at Ober Meilen.

The bottles used for alcohol-free wine or cider are not sterilised before being filled, but are very carefully washed. It should be noticed that the success of the preparation largely depends upon the scrupulous cleanliness of all the apparatus and bottles used.

The bottles, when filled with juice, are placed open in a metal vat provided with a cover. The vat is then filled with water at about 70° C, the water coming up as far as the necks of the bottles. Sterilisation is complete at the end of about half-an-hour. The bottles should be corked at once, to prevent the juice cooling. Metallic caps fitted inside with a ring of cork, are generally used in mechanical corking. This process appears the surest and most economical. It is necessary for the bottles to be hermetically closed in order to prevent any subsequent fermentation of the juice.

In making alcohol-free champagne or sparkling wines the same process is employed up to and including the bottling. Before sterilisation, the bottled juice is subjected to carbon dioxide under pressure of 2 to 6 atmospheres. This pressure varies according to the temperature of the wines, and the nature of the product required. It should be 2 atmospheres in the case of sparkling wines and 6 or 7 in that of champagne. A lemonade apparatus is generally used for introducing the carbon dioxide into the bottles, which should be made to withstand the pressure.

The corking operation is the same as for ordinary champagne bottles, the cork stopper being wired on. Sterilisation is effected later in the autoclave; the pressure in the interior of the apparatus must be increased progressively as the temperature rises, in such a manner that the external pressure balances the pressure inside the bottles. This is a very delicate stage of the manufacture, as the bottles easily explode. The bottles are then laid down in a cool place.

The pomace is as a rule used for the making of preserves, or for distillation. It is not dried, but is employed in its natural condition.

The " Alkoholfreie Weine und Conservenfabrik Meilen A.-G. ", at Meilen, made apple-honey for some years, but has since given up doing so. This product is obtained by merely evaporating the juice in the open air in a jacketed apparatus similar in shape to a kind of retort, that is always to be found in jam factories.

In the manufacture of alcohol-free wines and ciders, and also in that of apple-honey, no foreign substance (such as glycerin for instance), is ever introduced to promote coagulation.

The temperature of the work-rooms is not of special importance, for the operations must be performed as quickly as possible.

As regards the utilisation of the by-products, it appears from the experience of the Swiss factory, that all that can be done is to use them for distillation, or sell them to preserve factories. Generally, a preserve and jam factory is annexed to the alcohol-free wine factory.

The process described has not been patented, but patent machines are used, which can be procured, on application to the Firms whose addresses are given in this abstract.

1168 – **Yeasts From the " Sura " of the Coco-Palm** (1). — De Mello, F. (École de médecine de Nova Goa, Portuguese India), in the *Comptes rendus des Séances de la Société de Biologie*, Vol. LXXXIV, No. 11. pp. 584-586. Paris, March 19, 1921.

In Portuguese India, the name " sura " is given to the juice extracted from the spathe of the palm-tree which is also called in other places " toddy ", calloo, and arack. " Sura " supplies alcohol, vinegar, and a kind of sugar known as " jagra. "

Assisted by one of his students, M. F. Fernandes, the author isolated (by inoculating agar containing 4 % of glucose in Petri dishes) 17 cultures of yeasts capable of fermenting glucose, laevulose and mango juice but not galactose, lactose, and saccharose. The author has classified these yeasts as follows:— Genus *Saccharomyces* Meyen 1838 emend Vuill.: *S. surae* I sp. n.; *S. surae* II sp. n.; *S. toddyi* sp. n. Genus *Saccharomycodes* Hansen 1904: *S. palmarum* sp. n.; Genus *Atelosaccharomyces* of Bourm. and Goug 1909; *A. loyolinus* sp. n.; Genus *Zymonema* of Bourm. and Goug 1909; *Z. insulare* sp. n.

1169 – **Preparation of Paraffins from Vegetable Oil.** — Mailhe, A, in the *Comptes rendus de l'Académie des Sciences*, Vol. 173, No. 6, pp. 358-359. Paris, August 8, 1921.

Fatty oils cannot be distilled under ordinary pressure without to some extent decomposing. The author thought it would be possible to decompose them more completely if they were placed in contact with mixed dehydrating and dehydrogenating catalysts at temperatures varying from 550° C. to 650° C. For this purpose, use can well be made of electrolytic copper, associated with magnesia, alumina or kaolin. The mixture is made into balls with the help of an agglutinant, and the balls are heated in a copper tube. Linseed oil is introduced by means of a capillary tube into one of the ends of this tube. The vapours in passing through the mass of the catalyst, give rise to two classes of products, the one liquid and easily condensed, the other gaseous and capable of being collected in a gasometer.

---

(1) Regarding the fermentation products of palm sap, see *R* May 1915, No 546 and *R*. June 1921, No. 672. (*Ed.*)

The experiments described by the author show that the decomposition of linseed oil, using a copper-magnesia catalyst followed by hydrogenating the most volatile products with nickel, gives rise to aromatic carbohydrates. The fat chain has been cyclicised, and as the cyclic products thus obtained are free from sulphur, cyclohexane and its derivatives can be obtained.

It is evident that by this catalytic process, it is possible by starting with a vegetable oil, to obtain a volatile oil and an inflammable paraffin of a mixed character that can be used as motor fuel. Specific gravity of the volatile oil at 23° C., 0.7607; specific gravity of the paraffin at 21° C., 0.8644. They are both soluble in any proportions in alcohol.

1170 - **The Oxyhydridase of Milk.** — ALOY, J. and VALDIGNIE, in the *Comptes rendus des Séances de la Société de Biologie.* — Vol. LXXXV, No. 26, pp. 333-334. Paris, July 16, 1921.

The milk ferment discovered by SCHARDINGER that decolorises methyl-blue in the presence of formaldehyde, belongs to the class of ferments possessing both oxidising and hydrogenating properties, which are known as oxyhydridases. The authors isolated this ferment from milk by saturating it with powdered sodium chloride; leaving it to stand for 12 hours, then filtering it and finally precipitating the filtrate by a semi-saturated solution of ammonium sulphate.

The oxyhydridase thus separated gives the reactions of protein substances; it is insoluble in water, soluble in solutions of neutral salts, and precipitated from these solutions by acetic acid. It contains a considerable amount of phosphorus and iron and is thus a phospho-proteid.

1171 - **Géromé or Gérardmer Cheese.** — BLIN, H., in *L'Alimentation moderne et les Industries annexes,* Year XIX, New Series, No. 16, pp. 231-232. Paris, July 1921.

Cheese-making in the mountainous district of the Vosges is an industry dating back to very remote times. The earliest mention of the Géromé cheese was in 1070. The cheese-makers of the Remiremont district in the valley of Cleurie and Vagney have taken advantage of the syndical system to introduce considerable improvements into the manufacture of Géromé cheese, which has a formidable rival in Munster cheese.

In the Vosges the cows yield rich milk, of which the average composition, according to VACCA, is as follows: — Casein 3.14 %; albumen 1.19; fats 3.13; lactose 4.20; salts 0.72; water 87.62.

Géromé is manufactured in the Cantons of Gérardmer, Thillot, Saulxures, Fraize, and Remiremont. Taking one year with another, the total production is estimated at about 7 million kg., of a value of 5 600 000 fcs.

This cheese is prepared in the following manner: —

PRESSING. — As soon as the milk has been drawn from the cow, it is strained, and heated in a 50-litre copper caldron to 36° C. The caldron is provided with a wooden cover having, in the centre, a hole that can be closed at will by means of a disk rotating on a pivot. In factories where modern methods are adopted, the milk is curdled by liquid, unadulterable and constant preparations of rennet (commercial rennet).

In many places however the rennet is made from the fourth stomach of a calf, organs being selected which have reddish veins, and adhere to a slightly moistened finger. The stomachs are washed, inflated, placed to dry, and afterwards cut up (into quarters or thirds), and put in a bottle filled with water to which has been added a little salt, and a pinch of pepper. The bottle is corked, and after 3 to 4 days the rennet is ready for use. Two spoonfuls of rennet must be used for 50 litres of milk. The room temperature is kept at from 15° to 18° C.

CUTTING AND MOULDING THE CURD. — When the milk has coagulated, the curd is cut with a ladle made of tin or copper and shaped like an elongated shell with the two broader faces slightly compressed. The basin is covered again, and when coagulation is quite finished, that is to say from 1 ½ to 2 hours after the addition of the rennet, the whey is separated from the curd with a strainer of the same shape as the ladle, but a little larger (30 cm. × 17 cm. and 5 to 6 cm. deep).

The whey collected in the strainer is removed with the ladle, and the curd is again divided to facilitate drainage. The curd is placed into cylindrical forms or moulds of deal, 35 to 40 cm. high, and 15 to 18 cm. in diameter. Lower moulds are employed for cheeses that have already acquired a certain consistency without however being completely drained. One part is perforated with holes, the other which is not perforated, fits over it. When, after about 12 hours, the thickness of the curd is reduced by one half, the rack is removed and the cheese turned out into a dry mould. This process is repeated twice a day for 2 or 3 days.

SALTING, DRYING AND RIPENING. — Three or four days later, if the cheese is sufficiently firm, it is turned out on a board of beech wood sprinkled over lightly with salt. On this it is rolled, the operation being repeated on 3 or 4 consecutive days. From 30 to 35 gm. of salt are required for each kg. of cheese.

The cheeses should be washed over carefully with a cloth dipped in slightly salted water, and then turned, and this must be done for several days. As soon as they are firm, they are removed to the drier, which consists of superimposed shelves placed in a closed but well-ventilated, room. In summer, they are dried in the air, in boxes with wooden bottoms, the upper part being shaped like a roof and draped with muslin to keep off the flies. As sown as the skin is formed, and the body is hard, the cheeses are put to ripen in the cellar, which should be dry with openings to the north and south. The cheeses are frequently washed with tepid water containing a little salt, and turned. When they become brick-red, and the paste gives when pressed with the finger, they are ripe and ready for market. In order to produce a good cheese, continual attention is necessary for not less than 2 months. The largest cheeses take 3-4 months to ripen.

CHARACTERS OF GOOD GÉROMÉ. — This cheese should be rich inside, firm, and with few cavities. Badly-made Géromé cheeses break, crumble and are full of holes.

It takes 7.5 to 8 litres of milk to make 1 kg. of cheese, and a good Vosges cow will give enough milk annually for 260 kg. of cheese. Géromé cheeses are made of very different weights and dimensions, varying from 500 gm. to several kg. The small sizes sell quickest. They are packed for the market in small round, deal boxes.

1172 - **Bacteriological Investigation of Some Pork Butchers' Products** (1). — BORNAND, M., in the *Travaux de Chimie alimentaire et d'hygiene*, Vol. XII, Parts 3-4, pp. 119-125. Berne, 1921.

The author has studied the bacterial flora of several of the products of the pork-butcher, viz., 11 Bologna sausages, 2 "atriaux" (2), and 9 Vienna sausages, obtained in the market at Lausanne.

In all, he found a larger or smaller number of living bacteria. *Bacterium coli* was met with in 77.3 % of the cases, and *Bacterium proteus* in 27.3 %.

The above mentioned micro-organisms can cause poisoning and generally find their way into the sausages through want of cleanliness, the instruments that have been used for opening the intestines usually being employed for cutting up the meat. It is therefore of paramount importance that the hygienic conditions under which sausages, etc. are made should be under careful supervision.

1173 - **Oil From the Feet of Oxen and Sheep.** — BRUNO, A., in the *Annales des Falsifications et des Fraudes*, Year XIV, No. 151, pp. 137-139. Paris, May 1921.

Oil from the feet of oxen can be defined as oil extracted by prolonged decoction (10-12 hours) from the metacarpal and metatarsal bones of adult animals. As the extraction is repeated several times, and the bones treated are those running from the hoof to the knee or hock, the resulting substance is a bone-marrow fat which is for the most part liquid at ordinary temperature. In warm weather, however, a fair amount of stearopten is rapidly deposited, and in winter, the fat quickly assumes the consistency of an ointment. Ox-foot oil is much used as a lubricant on account of its "oiliness."

The oil floating on the surface of the water in which the bones are cooked is removed with a large spoon, and purified by re-heating with water, followed by careful decantation. According, to the temperature at which decantation is carried out, the oil may be entirely fluid, or contain a larger or smaller quantity of dissolved or solid substances; it differs also in character according to the animal, and the date of its slaughter. Thus ox-foot oil cannot be expected to have a constant composition.

The author having had occasion to make some of this oil, sent a pure, authentic sample to the Central Laboratory for the Prevention of Adulteration (*Laboratoire Central de la Répression des Fraudes*), where it was analysed by M. ROUILLARD. For purposes of comparison, sheeps-foot oil was also made and forwarded for analysis. The results obtained are given in the following Table.

---

(1) See *R.* Nov.-Dec. 1920, No. 1180. (*Ed.*)

(2) The name "atriaux" is given in the Canton of Vaud (Switzerland) to flat sausages containing chiefly chopped pork liver. (*Ed.*)

BELLIER resorcin test — Upper layer	pale pink	—	pale pink	—
BELLIER resorcin test — Lower layer	pale yellow	—	pale yellow	—

These two oils deviated from the customary zero when tested in AMAGAT and JEAN's refractometer, though this zero would have been registered if they had been mixed.

According to the author, ox-foot oil could be prepared from the terminal phalanges (after removal of the hoof) as well as from the metacarpus and metatarsus, though it would appear that little advantage would thus be gained in the case of the ox, and practically none with the sheep.

The by-products of this industry are the osselets which are of small value, and the cannon bones which are much used in the brush and the fancy turnery trades.

PLANT DISEASES

DISEASES NOT DUE TO PARASITES OR OF UNKNOWN ORIGIN.

1174 - **"Bramble-Leaf" ("Roncet") of the Vine Reported from Tripolitania** (1). — Felicioni, C., in *L'Agricoltura Coloniale*, Year XV, No. 10, pp 507-508, 1 plate. Florence, October 1, 1921.

With the development of vine-growing in the Italian colony of Tripolitania, a very severe form of rachitic disease with a course and symptoms very similar to those observed in typical " bramble-leaf " (" Roncet ") of the vine (*Vitis rupestris*) has made its appearance.

The disease seems to have been introduced in cuttings imported from Tunisia, and used for planting most of the Tripolitan vineyards.

Vines growing on their own roots are as much attacked as grafted stocks. The disease appears on one-year-old plants about July, or during the second period of growth, and causes the vine to produce a large number of small, finely dentated leaves; the internodes being frequently stunted and swollen, and the foliage covered with pale-coloured patches. These symptoms are particularly noticeable in the case of adult vines. Scars and dead patches occur also along the edges of the leaves especially at points where the dew collects, and flows. No alteration can be detected on the exterior of the roots and rootlets, which also do not appear to be affected by rot, although some broom-like malformations occur, and the cortical tissue becomes dark.

Mention should be made of the effect caused by the nature of the soil upon the gravity of the disease. Vines growing on the alluvial soil of Wudiâm are much more seriously attacked than others planted in sandy soils. In the author's opinion, this may be because the stiff clayey-sand forming the sub-soil does not allow the water to drain away, and hinders the proper aeration of the strata into which the deep roots penetrate.

DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS

1175 - **Control of Plant Parasites of the Walnut in France.** — See No. 1123 of this *Review*.

1176 - **"Record" Variety of Oats Resistant to Rust.** — See No. 1111 of this *Review*.

1177 - ***Sclerospora Sacchari*, the Sugar Cane Mildew in the Philippines.** — LEE, H A., and MEDALLA M G., in *Science*, New Series, Vol. LIV, No 1395, p. 271-275. Lancaster, Pa, Sept. 23, 1921.

In the beginning of 1920, a firm of Japanese sugar cane growers introduced cane points for use on their plantations in Rizal Province, Luzon, which they stated had been grown by the Experiment Station of the Japanese Government in Formosa.

In April 1921, the cane having been ratooned, numerous cases of etilation of the young plants were observed. Such plants were very conspiuous and could be observed at a considerable distance from the field. On the lower surface of the affected leaves a white spore mass was abundant. Microscopic examination showed as was expected the presence of *Sclerospora Sacchari* T. Miyaki. The mildew was missing in the fields of native cane adjacent to and surrounding the field of Formosan cane, which confirmed the suspicion that the fungus had been introduced from Formosa into the Philippines.

Measures have been taken to completely exterminate this disease by repeated ploughing of the affected field, burning the affected stubble and allowing the land to lie fallow. Steps to trace seed cane that emanated from the field are also in progress and it is probable that the disease will be entirely eradicated.

1178 - ***Erysiphe Poligoni* and *Sclerotinia Libertiana* Injurious to the Soya Bean in Baden, Germany.** — See No 1191 of this *Review*.

1179 ***Phytophthora* sp. and *Septoria Lycopersici* on Tomato Seedlings, in New South Wales.** — DARNELL-SMITH, G. P., in *The Agricultural Gazette of New South Wales*, Vol. XXXII, Pt 8. p 577 Sydney, Aug. 1921.

Tomato seedlings in certain districts in New South Wales were attacked last year by blight (*Phytophthora* sp.) and leaf spot (*Septoria Olycopersici*.

The part attacked is generally some portion of the stem in the majority of cases at or near the ground level. The seedlings fall over and wilt.

S. Lycopersici is recognised by pale or ochre coloured spots on which are produced numerous minute black bodies which contain the spores. Affected leaves have a tendency to curl.

The following control measures are recommended by the author :— 1) Remove and burn all diseased plants; 2) Spray the rest with Bordeaux mixture; should wet weather prevail, other sprayings may be necessary at intervals of about 10 days; 3) Avoid keeping the seed-bed too moist; 4) Water the soil rather than the plants; 5) Shelter the beds with some impervious material during damp weather.

1180 - *Physalospora Miyabeana* n. sp. and its Conidial Form (*Gleosporium*) Injurious to *Salix purpurea* var. *angustifolia* in Japan. — FUKUSHI, T., in *Annals of the Phytopathological Society of Japan*, Vol. 1, No. 1, pp. 1-11, figs. 8. Nishigahara, Tokio, July 1921.

In the early autumn of 1919 a number of diseased Japanese willows (*Salix purpurea* var. *angustifolia*) were observed near Sapporo. A preliminary examination of these specimens revealed the constant association of two forms of fungi, *Physalospora* and *Gleosporium* with the lesions. Since some species of *Physalospora* are known to possess a *Gleosporium* as their conidial stage, it may be supposed that a possible connection exists between these two fungus forms; this assumption has been verified by a number of cultural experiments.

The following autumn the disease reappeared in the same nursery. A *Gleosporium* was isolated from the affected leaves and stems of the *Salix* and the spores thus obtained were inoculated on healthy plants with positive results.

A more careful study of the symptoms of disease as well as the nature of the causal fungus has led to the conclusion that the disease is due to a hitherto undescribed species of *Physalospora*, and its conidial stage (*Gleosporium*).

It is highly probable that this disease has been prevalent for many years in several willow plantations in Hokkaido, since certain basket makers have notified an outbreak at Kotoni, Barato, Urashinotsu and Shinshinotsu in the province of Ishikari. According to one basket maker the disease has been prevalent at Kotoni for the last 7 years and in certain districts such as Motomura near Sapporo, willow cultivation has been abandoned owing to the severity of the trouble The affected branches are said to be liable to break at the lesions giving baskets of inferior quality on account of the brownish spots visible after the bark has been peleed off.

During the autumn of 1920, another type of willow canker disease, probably due to a fungus parasite belonging to the genus *Marssonina*, made its appearance in several willow plantations in the vicinity of Sapporo, and also in the Nursery where the first mentioned disease had been notified. According to the basket maker the second disease is less injurious to the willow than the first.

The disease caused by *Phys. Miyabeana* and its conidial form (*Gleosporium*) appears on the stems as well as on the leaves and chiefly on the upper part of the plant. The lesions on the stem are whitish-grey or grey in colour and elliptical in shape, varying from 5 to 30 mm. in length. Often the lesions become united involving a considerable portion of the stem or extending so widely as to completely surround it. The base of the petioles is often attacked, but the points of infection are by no means confined to this portion. The lesion is usually surrounded by a blackish border line with a considerably sunken central area, where minute black pustules are found in clusters which are conspicuous owing to the contrast in colour with the surrounding tissues. Later the lesion may become cracked and finally uncovered exposing the woody tissue by the peeling of the dead bark.

The indications of the disease on the leaves are dark brown spots on the upper surface. The spots are circular or outlined irregularly, measuring 2 to 5 × 3 to 7 mm., and often showing concentric marking. When the lesion involves the midrib, a considerable portion of it may be blackened lengthways.

The symptoms of the other disease probably due to *Marssonina* are quite distinct. The disease is characterised by elliptical tar-black lesions on the stem and black punctures on the leaf. The lesions on the stem are not sunken and the pustules are somewhat scarce and indistinct.

WEEDS AND PARASITIC FLOWERING PLANTS.

1182 - ***Amaranthus deflexus* and *Xanthium Commune*, Newly Recorded Weeds in New South Wales.** — MAIDEN, J. H., in *The Agricultural Gazette of New South Wales*, Vol. XXXII, Pt. 8, p. 580 Sydney, Aug. 1921

At a meeting of the Linnean Society of New South Wales on May 25, 1921, W. F. BLAKELY exhibited two weeds hitherto not recorded for the State : *Amaranthus deflexus* L. and *Xanthium commune* Britt.

A. deflexus L (" low amaranth ") is common along the railway line between Cowan and Hawkesbury River. The plant is widespread throughout Europe and appears as a weed in other parts of the world. It has the general appearance of *A. macrocarpus* Benth., a native species from which it differs in certain characteristics of flowers and fruits. In 1920 the same plant was recorded in Victoria.

X. commune (" Common cockleburr" of America), has recently been forwarded from Ebenezer. On investigation, two other specimens of this Composita were found at Cattai, near Windsor (1915) and near Dunedoo (1918) and identified as *X. Strumarium*, thus indicating that this obnoxious weed is spreading unnoticed. *X. commune* is similar in habit to *X. Strumarium*, but is readily distinguished by its characteristic fruits. It is apparently new for the Commonwealth.

INJURIOUS INSECTS AND OTHER LOWER ANIMALS

1183 - **Some Insect Pests of Cultivated Crops in British Guiana.** — BODKIN, G E., in *The Journal of the Board of Agriculture of British Guiana*, Vol. XIV, No. 2, pp. 132-139. Georgetown, April 1921.

In British Guiana, the insects most injurious to sugar cane, the principal cultivated crop, are those known collectively as " borers " which consist of 3 species of lepidopterous larvae, namely *Castnia licus* Fab. ("giant moth borer ") (1), *Diatraea saccharalis* Fab. (small moth borer) (1) and *D. canella* Hamps. (2), very similar to the preceding species in all its stages of development.

---

(1) See *R.* Jan. 1911, No. 353 ; *R.* Feb. 1912, Nos. 439-440 ; *R.* May 1919, No. 671. (*Ed.*)

These three insects pass their larval and pupal periods within the cane itself, thus causing weakening of the plant and material deterioration in the juice Their attacks are often followed by a complete destruction by termites.

Twenty years ago *C. licus* appears to have been unknown in this Colony. Since its first appearance however, it has multiplied at an exceedingly rapid rate and during 1919 on 16 estates, 91 479 moths were destroyed, and 1 600 046 larvae. Like many other injurious insects in this part of Tropical America, *C. licus* has invaded the cultivated areas from the forest region.

Birds, especially the " kiskadee " (*Pitangus sulphuratus*) and old witch (*Crotophaga ani*) are the most important enemies of this insect.

On all sugar estates, organised gangs, chiefly composed of native born children (Creoles) are employed in the destruction of *C. licus* and have grown remarkable clever at this work. After sending them into a field of canes recently cut, the roots are searched for traces of the borers and wherever scarring or open boring is observed a long hooked wire is introduced into the stumps; if the larva is present it is soon dragged to the surface. If this is not successful, the stump is partially uprooted and the larva or chrysalis thus secured. The caterpillars and chrysalides are kept by each child in an old tin and at the end of the day the contents are carefully counted and checked. Children provided with nets are also employed to catch the adult moths.

To destroy *D. saccharalis* gangs of children are sent through the fields of young cane and wherever a dead central shoot is observed it is cut off close to the ground and the larva or chrysalis secured and placed in a tin. In both cases the children are paid for their work. Three hundred specimens are sometimes collected by one child in one day. Cutting out cannot be continued after the canes are 4 months old. In 1919 22 779 354 caterpillars and chrysalides were thus destroyed.

The collection of the eggs of this lepidopteron is now carried out on most estates by means of a small gang of specially trained children who are well paid.

Two species of egg parasites of *D. saccharalis* (one of them *Trichogramma minutum* Riley is well known) are commonly met with and extremely effective. Several species of external Hymenopterous parasites also occur, one Dipterous parasite and a fungous parasite (*Cordiceps* sp.). The larva of an Elaterid beetle also preys on the early stages of *D. saccharralis*.

(2) See *R.* Feb. 1912, No. 439. (*Ed*)

Other pests which attack the cane are: 1) the weevil borer (*Metamasius hemipterus*) (1) which at times damages the stools and rooting system of the cane; 2) larvae of 2 Noctuid moths, *Remigia repanda* (2) and *Laphygma frugiperda* (3), which sometimes cause complete defoliation. These are destroyed by collecting in buckets containing paraffin and water. They become most numerous on the advent of rains after prolonged drought; 3) Two species of termites occur frequently and destroy all canes which have previously been weakened by borer attacks; the nests are collected in sacks, taken out of the field and burnt; 4) one species of mealy bug occurs at times in large numbers beneath the leaf sheath and when large numbers are present they undoubtedly weaken the vitality of the cane; these insects are destroyed in damp weather by fungi; in dry weather they multiply rapidly and remain healthy; 5) two species of *Cercopidae* occur at times in small numbers, but the damage done is generally speaking negligible, owing to the careful destruction of weeds in the sugar cane plantations.

The chief insect enemy of the coconut palm is the larva of a lepidopteron known as *Brassolis sophorae* L. which at times defoliates nearly every palm in the district. As the nests are large and conspicuous in the palms it is an easy matter to send up a child to cut down these nests. A large locust in one particular area has recently developed a taste for the foliage of the coconut palm and from time to time does marked damage.

In 1917, British Guiana experienced an invasion of locusts coming from Venezuela; after a strenuous fight for 5 months, it was successfully eliminated. When rice is in the nurseries, prior to transplanting, the larvae of the moth *R. repanda* often cause injury by feeding on the young shoots. The caterpillars have been destroyed successfully by flooding. The larvae of *D. saccharalis* frequently attack the fully developed plant.

Scale insects at times prove troublesome to citrus trees.

Cacao is more liable to fungoid diseases.

1184 - *Micrococcus (Staphylococcus) acridicida* Attacking Grasshoppers in Greece.

— KUFFERATH H, in the *Annales de Gembloux*, Year XXVII, Part 8, pp. 253-257. Brussels, August 1921.

Towards the end of May, 1913, the grasshoppers in certain parts of Greece were found to be suffering from a disease causing them speedily to lose their voracious appetite and die in a short time. The author on examining some of the infected individuals (received in June) under a low power lens, found them to be covered, especially on the abdomen, with small, white tufts, which were found to consist exclusively of *Micrococcus*.

After having isolated the organism, the author obtained pure cultures of four very similar species, one of which, a new species described under the name of *M.* (*Staphylococcus*) *acridicida*, proved to be of much practical importance. In August, the author sent it together with the three others to Athens, where it was the subject of two series of experiments.

(1) See *R* Mar. 1916, p. 35. (*Ed*)

(1) See *R.* Aug. 1914, No. 803, and *R.* Sept. 1914, No. 865 (*Ed.*)

(3) See *R.* Dec 1910, p 20; *R.* Sept 1913, No 1113; *R.* Sept. 1914, No. 865; *R.* April 1918, No. 495. (*Ed.*)

In the first, an emulsion of the fungus was introduced by inoculation between the second and third abdominal segment of the insects: death ensued within forty-eight hours. The second series of experiments consisted in spraying the vines with the emulsion, and feeding the grasshoppers on the leaves thus infected. The results obtained in both experiments were identical. These researches were interrupted by the war, but although incomplete, the experiments made in Greece would seem to prove that the ingestion as well as the inoculation, of this micrococcus, soon bring about the death of the grasshoppers.

Preliminary trials for the purpose of ascertaining the action of this coccus when ingested or inoculated into living insects (caterpillars of *Pieris rapae* and an adult specimen of *Locusta viridissima*) in Belgium have resulted in the death, after a variable number of days, of a considerable number of the infected insects and the discovery of the pathogenetic agent.

1185 - **Chalcididae Parasites of Coccids in Japan.** — NAKAYAMA, S., in *The Philippine Journal of Science*, Vol. XVIII, No. 1, pp. 97-100, pl 1. Manila 1921.

An enumeration of species in the subfamily *Aphelininae*, observed in various parts of Japan as coccid parasites.

1) *Ablerus perspeciosus* Girault, on *Aulacaspis pentagona* Targ.;
2) *Aphelinus fuscipennis* Howard, on *Aspidiotus perniciosus* Comst., and *Chionaspis* sp.;
3) *A. japonicus* Ashmead;
4) *A. mytilaspidis* Le Baron, on *Hemichionaspis aspidistrae* Sign.;
5) *Azotus capensis* Howard, on *Aul. pentagona*;
6) *Azotus chionaspidis* Howard, on *Chionaspis difficilis* Ckll. and on *Aul. pentagona*.
7) *Coccophagus lecanii* Fitch on *Ceroplastes rubens* Mask., *Phenacoccus pergandei* Ckll. and *Pulvinaria citricola* Kuw.;
8) *C. yoshidae* n. sp. on *Coccus hesperidum* L.,

12) *P. niigatae* n. sp. on *Aul. pentagona*;
13) *Archenomus orientalis* Silvestri, on *Aul. pentagona*;
14) *Casca chinensis* Howard. on *Chionaspis difficilis*.

1186 - **Natural Enemies of *Acanthopsyche junodi*, the Macrolepidopteron Injurious to *Acacia mollissima* in Natal, South Africa** (1). — SKAIFE, S. H., in *The South African Journal of Science*, Vol XVIII, Nos 3-4, pp 291-301, figs. 15. Johannesburg, July 1921.

After completing the work of G. C. HAINES up till now not reported, by personal observations taken in the plantations round Pietermaritzburg

---

(1) See also *R.* Aug 1919, No. 1241. (*Ed.*)

(Natal), the author gives a Summary of the investigations made the natural enemies of *Acanthopsyche junodi* Heyl (" wattle bagworm "), the worst of the pests of the black wattle *Acacia mollissima*. HAINES and the author examined in all nearly 60 000 bagworms; the life history of the wattle bagworm has already been studied in detail by FULLER and HARDENBERG.

Large numbers of the newly-hatched larvae are destroyed before they have an opportunity of forming their bags.

HARDENBERG mentions several kinds of spider which act as predaceous enemies of larvae just hatched. These larvae are dispersed by the wind, birds and insects, and carried to places where they die of starvation owing to lack of suitable food. Those that survive and manage to construct their bags enjoy a certain account of immunity for a time, as they are small, inconspicuous and well protected from their minor enemies. Later, however, the bags are very conspicuous and numbers of the larvae fall a prey to birds and rats (*Muridae*).

According to HARDENBERG there are 8 different species of insects parasitic on *A. junodi* viz. two Ichneumons, one Chalcid, and five Tachinids, but none of these had been determined, nor were their habits studied in detail. The author has observed only two of these parasites viz., an Ichneumon, *Philopsyche abdominalis* Morley, and a Tachinid, *Carcelia evolans* Wied., and notes are made on their life history and biological characteristics. *C. evolans* is in its turn preyed upon by a minute chalcid so far undetermined.

The bagworm is attacked by several diseases amongst which that caused by *Isaria Psychidae* Pole Evans, takes the first place. The efficacy of this very virulent fungus as a check on *A. junodi* is somewhat impaired by the attacks of another fungus, *Melanospora parasitica*, which grows on *I. Psychidae* and partially or wholly inhibits the conidia formation of its host.

Another virulent and extremely destructive disease of the bagworm is according to experimental results said to be caused by a filterable virus.

There are other diseases of an obscure nature to which *A. junodi* is liable, and which destroy the larvae It is as yet uncertain if these diseases are caused by bacteria or are due to disturbances in the normal physiological functions, or to both.

Out of a total of 59 687 bagworms examined, just over 1 % were destroyed by birds and rats, 19 % by insect parasites, 16 % by fungus disease, and 17 % by other diseases, making a total of 53 % destroyed. Despite the enormous numbers killed by the above agencies, the figures show that a far greater mortality must take place in the younger stages, from September to March. HARDENBERG estimates that the majority of bagworms which reach maturity are males, there being an excess of males over females of about 25 %. This agrees with the author's observations. Of the 47 % surviving, only 21 % will be females; in other words, out of every 100 bagworms found in the plantations in March, only 21 females will reach sexual maturity. These females will deposit some 40 000 to 50 000 eggs which will hatch the following spring. Assuming no yearly increase on the part of the bagworms, these eggs will be reduced to 100 by March, i. e. only one quarter of 1 % of the larvae hatched survive the early perils of their life. Even if this early mortality is taken into account, about which very little is known, it is by far the most important of the factors in the natural control of *A. junodi.*

1190 - ***Oncopera mitocera,* New Grass Pest in Queensland.** — DODD, A. P., in *Queensland Agricultural Journal,* Vol XVI, Pt 2, pp. 79 81 Brisbane, Aug 1921

During the drier months of 1920, viz. July to November, the farmers of the Atherton Tableland were seriously concerned at the ravages of a Macrolepidopteron caterpillar — afterwards identified as *Oncopera mitocera* Turner (fam. Hepialidae) — that threatened to destroy a great proportion of the pasture in certain areas.

This insect appears to be confined to North Queensland and possibly to the Cairns district. Early in 1911, F. B. DODD observed the moths flying very plentifully at dusk, on the edges of Evelyn Scrub, near Herberton. The first record of *O mitocera* as a pest, seems to be contained in a letter written by J. G. JONES of Ravenshoe on September 15, 1919. Nothing was heard of its occurrence round Yungaburra until August 1920 when the farmers suddenly noted the damage done by the pest. Probably the caterpillars had been there for several years, but never in such numbers as to attract attention. The moths have been noticed in considerable force at Kuranda and it is certain that larvae have been found in the scrubs around Babinda.

Thus, the species has been found in the Cairns district. at all heights from sea level to 3500 ft.

A description is given of the different stages of the insect, followed by details of its life history and habits.

The larvae remain hidden during the day at the bottom of a vertical tunnel specially constructed in the soil, and emerge at night to feed on grass blades. Apparently fresh leaves are not essential, as in the scrub the surface of the ground is bare of vegetation and no doubt in this case fallen leaves and vegetable matter are consumed.

It appears that the grass roots are not touched in any case, nor the underground roots. The grass apparently dies through the action of the caterpillar gnawing at the base of the roots from the surface.

There is no doubt that this species is a native of the scrubs where it may be still be found. With the clearing of land and planting with grass, conditions have been favourable to the development of this insect as a pest, and it apparently has not been followed by its natural enemies.

The principal area affected is in the immediate neighbourhood of Yungaburra, from Kulara in the north to Kureen in the south; in the older-established districts near Atherton and Kairi it has not made its appearance, and southward around Malanda, the caterpillars have not been found in the pastures, although abundant in the scrub. Another area infested, although not to the same extent, is situated eastward from Ravenshoe, on the higher land toward the Beatrice River, 3200 to 3500 ft. above sea level.

The pest occurs throughout these areas and almost every farm is more or less affected; the fields present a very ragged appearance instead of a luxuriant carpet of grass. The extent of damage caused by the pest is evident seeing that this occurs during the drier parts of the year when good grazing is most needed.

Certain spiders (*Attidae*) catch a few of the moths. No doubt nightjars destroy a large number, but in the open field of the Tableland, the absence of birds which might help materially to check the ravages of the pest is very marked.

Climatic conditions must be an important factor in the increase or decrease of these caterpillars, and heavy rain or an excessively wet season may restrict their numbers.

1191 - **Pests of Soya Beans Observed in Baden, Germany** (1). — VON WAHL, in the *Zeitschrift für Pflanzenkrankheiten*, Vol. XXXI, Parts 5-6, pp 194-196. Stuttgart, 1921.

A list of the pests observed during three years on some varieties of soya-bean at Augustenberg, Baden. So far only two fungi have been recorded: *Erysiphe Polygoni* DC., and *Sclerotinia Libertiana* Fuck. The young bean plants, which in the district studied come up from the end of April to the beginning of May, were severely attacked by *Arion hortensis* Fér., *Agriotes lineatus* L., *Melolantha vulgaris* F., *Agriolimax agrestis* L., *Porcellio* and *Oniscus* spp.

Towards the middle of May, *Phyllotreta nemorum* L., *Psylliodes chrysocephala* L., and *Sitones* sp. were seen on the soya beans..

After the end of June, *Thrips physopus* L., *T. longicollis* Uzel, *T. discolor* Hal (?), *T. major* Uzel, *T. Albopilosa* Uzel, *Aeolothrips fasciatus* L., *A. albocinctus* Hal., *Smymothrips biuncinata* Uzel, *Baliothrips dispar* Hal, *Lygus pratensis* Fall., *Siphonophora ulmariae* Schk., etc., all attacked the beans. At the end of July, 1916, *Tychea phaseoli* Pass. caused serious injury to some plants of soya.

In August in all three years, *Epitetranychus althaeae* Hanst. occurred in large numbers, and did much damage. *Arvicola arvalis* again proved a formidable enemy to the soya-bean, at Augustenberg, and perhaps mice also did some injury to this leguminosa in that neighbourhood.

1192 - ***Anthonomus cinctus* Reported in Orchards in Great Britain.** — HARWOOD, P., and C[HAMPION], G. C., in *The Entomologist's Monthly Magazine*, Series III, Vol. III, No 82, pp 226-227. London, Oct 1921.

A single sample of the weevil (*Anthonomus cinctus* Koll. [= *A. pyri* Boh. and *A. bituberculatus* Thoms.]) was captured in an orchard adjoining Darenth Wood (Kent). This Curculionidea has been found under the apple bark in conjunction with *A. pomorum* L. A subsequent visit to the same locality failed to produce any further specimens of *A. cinctus*, but it is probable that it will be found in other orchards in Kent in the near future

This insect may prove an undesirable addition to the British entomological list, if destructive in the larval state.

1193 - **Pests of the Weymouth Pine in Switzerland.** — BADOUX H., in the *Journal forestier suisse*, Year LXXII, No. 9. pp. 163-173, 1 plate. Berne, September 1921.

It was long supposed that the Weymouth Pine (*Pinus Strobus*) introduced into the Swiss foress had found a refuge from all pests.

In reality, however, this conifer is attacked in Switzerland by a number of animal and plant parasites.

Among the latter, the first deserving mention is *Cronartium ribicola* Dietr. (aecidial form: *Peridermium Strobi* Kleb.), the cause of "vesicular rust." This fungus seems to have made its first appearance in Switzerland on *P. Strobus* towards 1904; it was reported at this date as occurring in the plantations of the Commune of Locle, which consisted of trees imported from Germany. The parasite had however already existed for some time in Switzerland, especially in the Engadine, where it was observed, in 1895, on *Ribes petraeum*, by ED. FISHER, who at that very time suggested that the second host of the fungus was *P. Cembra*, as was proved to be the case actually in the Engadine, by G. SCHELLENBERG in 1903. Vesicular rust has of late years spread rapidly in Switzerland and is reported from all plantations or stands of *P. Striobus*. In the Canton of Zurich, the epidemic assumed such serious proportions that the private landowners who were formerly most enthusiastic about this pine, no longer dared to plant it. From the first data collected it would appear, that if a stem of a Weymouth pine is attacked at about the age of 10 years by the parasite, it is irremediably lost. If the trees have attained the age of 10-25 years, their destruction is not so certain. From a small experiment made in 1919, it may be considered, for the time being that trees of which the total circumference has been infected are certain to perish sooner or later.

The prophylactic control measures hitherto adopted are as follows:— (*a*) In the nurseries, only healthy, clean seed is planted, and this is immersed in a suitable antiseptic; (*b*) only healthy trees from nurseries immune from the parasite are used for planting; (*c*) all species of *Ribes* are excluded from the nurseries, and the latter are never installed near places where this plant is cultivated; (*d*) the cultivation of the Weymouth Pine is given up for some time in nurseries where the disease has been rife; (*e*) the

Weymouth Pine has been grown associated with other conifers and with foliage trees.

In Belgium, experiments have been recently made for the purpose of ascertaining whether there is any way of curing trees that have been attacked. The bark of some specimens of *P. Strobus* infected with "rust" were first scraped, so as to remove, as completely as possible, the portions invaded by the fungus, which were then collected and burnt. Next, the infected parts were painted over with permanganate of potash (a 10 % solution), pure formalin, pure paraffin, or carbolineum avenarius. The results obtained, however, do not lead to any definite conclusions; it is necessary for the experiment to be repeated on a large number of individuals. It may, however, be mentioned that in the spring of 1915, the trees treated with permanganate were completely cured and the other compounds were efficacious to a certain extent though not so definitely as the permanganate, the cure being partial only.

The Weymouth Pine is also attacked in Switzerland by other parasites though these so far, do not seem to have done it much injury; they are: *Armillaria mellea* Walh. (= *Agaricus melleus* Fl. dan.) and *Fomes annosus* Fr. (= *Trametes radiciperda* R. Hartig).

This conifer has also a certain number of animal pests in the Confederation.

The roe-deer, which have become fairly common in the Swiss forests during the last few years, often seriously damage the young trees by gnawing the bark.

The red field-mouse (*Hypodeus glareolus* Wagn.) (1) has here and there stripped off the bark of young individuals of *P. Strobus*.

Of the insect foes of the conifer, one aphis *Pineus strobi* Htg., has frequently appeared of recent years in stands 30 years of age or older. Opinions are divided as to the amount of injury it causes, but it is certain that the presence of a countless number of these insects engaged in sucking the surface of the bark cannot but interfere with the ordinary life-processes of the tree. The Scolytid coleopteron, *Xyloterus* (*Tomicus*) *lineatus* Oliv. has been recorded on felled trunks lying in the forest unstripped of their bark; *Pityophthorus* (*Bostrichus*) *micrographus* L. has been found on branches and small trunks: *Tomicus quadridens* Htg., *Myelophilus* (*Hylesinus*) *piniperda* L. and *M. minor* Htg., have been observed on the trunk and inside the shoots of the Weymouth Pine.

Curculionidae are also found here and there: the plantations have been much damaged by *Hylobius abietis* L., and trunks of *P. Strobus* that are infected with "vesicular rust" sometimes harbour individuals of *Pissodes pini* L.

The larvae of the hymenopteron *Lophyrus pini* L. (*Loph. similis* Htg.) have made their appearance regularly for some years towards the middle of September upon spring specimens of *P. Strobus* growing in the garden of the Zurich Forestry Institute, but without doing any great injury.

---

(1) See also *R.* June, No. 609. (*Ed.*)

Finally, the caterpillar of a microlepidopteron, *Dioryctria splendidella* H. S., has been recorded in stands of *P. Strobus* since 1919, in Höhragen and the Rüti, which are infected by " vesicular rust ". This insect only attacks trees that are already diseased and is therefore of but little importance from the forester's standpoint. It must, however, be remembered that it increases the injury caused by the " rust ".

GENERAL INFORMATION.

1194 - **The Agricultural Production of Czecho-Slovakia.** — *Bulletin of the Ministry of Agriculture of the Republic of Czecho-Slovakia*, Year I, No. 2, pp. 9-16, Prague, July 1, 1920.

NATURAL RESOURCES OF THE CZECHO-SLOVAKIAN REPUBLIC. — From the economic standpoint, Bohemia is one of the richest countries in the new State of Czecho-Slovakia. The superficial area is 52 000 km^2 and the Vetava and the Elbe (Labe) provide direct communication with Germany. Prague is the centre of the densest network of railways in the whole State and in Bohemia alone, there are nearly 5000 km. of railroads.

The country is rich and well cultivated. It supplies all that is necessary for the support of man, with the exception of salt, which must be imported from Germany, or Galicia. Cereals are the chief crops, after which come *beet roots* and the number of sugar-refineries is considerable. Bohemian *hops* of which the best come from Žatec and Rakovnik, are celebrated thoughout the world (area under hops from 1901 to 1910, 15 127 hectares; crop, 88 091 quintals). Some of the *vineyards* (Mělnik especially), produce a small quantity of choice wine (787 hectares; average production from 1901 to 1910, 11 385 hectolitres). The best variety of fruit is the *plum* which constitutes an important article of export (total crop from 1901-1910, 2 825 775 quintals).

Forests cover more than 1 561 000 hectares, some large owners possessing as much as 70 000 hectares. They are worked in a very intelligent manner (production in 1910, 3 242 717 m^3 of timber; 2 238 355 m^3

of fuel). They are also rich in game, as many as 700 000 head being killed in certain years. Bohemian pheasants have a high reputation, and there are more than 150 pheasant farms.

The most important *industries* of Bohemia are: 1) sugar-making, the sugar factories and refineries numbering 108 or over (production in 1912-1913: 7 517 000 quintals); 2) brewing (especially Pilsen beer). The beer is sent as far as America (annual output, 10 347 822 hectolitres). In 1910-1911 the number of breweries was 560.

Potatoes are much cultivated, most of the crop going to the distilleries (of which there were 316 in 1918-1919), and starch factories. The latter, 94 in number, use a great quantity of tubers; some also go to the glucose and dextrine factories. These industries have become the most important for export. The mineral waters have a world-wide reputation (K. Vary, Karlsbad, Bilína Marienbad, Franzensbad, etc.).

Mines are one of Bohemia's chief sources of wealth, the most important coal mines being those of Most, Kladno, Buštěhrad, and Rakovník, (output in 1911, 41 893 212 quintals of coal and 208 267 406 quintals of lignite).

Moravia (superficial area: 22 000 km^2), takes its name from the river Morava. The highest mountain peaks in the country are below 1500 m., there are no lakes, but about 50 mineral springs and the climate is temperate. At the time of the last census (1910), the population numbered 2 622 271 inhabitants. Moravia is an essentially agricultural and industrial country. Its principal products are *cereals*, *beetroots* and *wine* (between Znojmo and the Morava).

Sugar, *malting* and *brewing* industries are also well developed.

The basins of the Ostrava and Rosice are the centres of the *coal-mining* districts. The annual output of the mines exceeds 24 million francs (1911). The *textile* industry is concentrated at Brno.

Silesia has a superficial area of 5147 km^2 and 756 949 inhabitants. It is divided by the Moravian district of Mistek into two parts, the former provinces of Teschen (Těšín) on the east, and of Troppau (Opava) on the west. The country is mountainous and in the south abuts upon the Carpathian and Sudetic ranges; 50 % of the land is fields, 4 % pasture and 34 % forest. The harvests in 1914 consisted of 201 066 quintals of wheat — 675 018 quintals of rye — 384 323 quintals of barley — 936 453 quintals of oats — 4 500 000 quintals of potatoes — 455 172 quintals of sugar beets.

In 1919, the stock was estimated at about 24 118 horses — 111 217 cattle — 32 969 pigs — 47 781 goats — and 4 069 sheep.

Coal of excellent quality is mined in the Ostrava-Karvín basin, the annual output being 6 428 660 tons.

The *textile industry* is also flourishing: woollen goods are made at Bilsho, Krnov etc., linen thread and fabrics and cotton goods at Frýdek, etc. In addition there are sugar factories, breweries, factories of chemicals and by-products of wood, etc.

Slovakia is one of the most favoured countries of the world as regards abundance and variety of natural products especially those supplied by plants, and her industrial progress, which is as remarkable as it is recent, has not entailed the loss of her essentially agricultural character. In 1919, the stock was estimated at 149 299 horses — 897 410 cattle — 564 061 pigs — 532 320 sheep and 89 392 goats.

Flax and beet root are the most important *industrial plants.* The average crops from 1903 to 1912 (1) were: 5 581 284 quintals of wheat (area sown: 470 355 hectares) — 2 882 642 quintals of rye (261 471 hectares) — 5 299 883 quintals of barley (423 392 hectares) — 2 511 819 quintals of oats (277 700 hectares) — 1 756 865 quintals of maize (132 619 hectares) — 20 745 998 quintals of potatoes (259 746 hectares). About 60 456 hectares were under sugar beets (from 1903 to 1912). The total beet production (in 1914) reached 15 500 000 quintals. In 1918, Slovakia possessed 8 working sugar factories, and one that had been closed. The output of sugar is estimated provisionally at 316 102 quintals.

From 1918-1919, 430 *agricultural distilleries* of potatoes produced 108 483 hectolitres of alcohol and there are in addition 42 industrial distilleries. The 17 *starch factories* also take a large number of tubers. The *brewing industry* is not much developed. The output of 21 breweries in 1912-1913 was about 260 000 hectolitres.

The mountainous regions (the Carpathians) are rich is productive *forests.* According to private statistics, 2 million hectares are under forest which could produce annually 6 million m^3 of timber.

Iron, coal, salt, copper, silver etc. are chiefly found near Ŝtavnice, at the foot of the Tatra, and in the district of Marmoros. Over a hundred mineral springs have been opened, some of which are of first rate quality (Teplice, Trenčín, Pístány). The area of Slovakia is about 50 000 km^2 (preliminary data based on the publications of the former Hungarian kingdom).

TABLE I. — *Estates Administered by the Ministry of Agriculture of the Czecho-Slovakian Republic.*

	Forests hectares	Agricultural land hectares	Totals hectares
State lands	519 311	50 451	569 762
Grants of land	57 185	17 347	74 532
Estates belonging to the former Imperial Family	116 907	52 053	168 960
Totals . . .	693 403	119 851	813 254

Table II gives the results of the 1919 crops in Bohemia, Moravia and Silesia which are ¼ to ⅓ less than the pre-War returns (1914).

---

(1) These data refer to the "comitats" situated on the left bank of the Danube and on the right bank of the Tisza. (*Author's note*)

AGRICULTURAL INSTITUTIONS. MEASURES FOR THE INCREASE OF PRODUCTION. — The budget for 1920 presented by the Ministry of Agriculture to the Chamber shewed an expenditure of 139 259 621 crowns and a revenue of 81 652 833 crowns.

A new Agricultural Institute has been founded at Brno, in Moravia, a second was already in existence at Prague. The course of study lasts 4 years, after which the student (if satisfying the examiners), obtains the diploma of Agricultural Engineer.

There is an Agricultural College at Libwerda, where the course lasts from 2 to 3 years (1)

---

(1) See *R.* Jan. 1921, No. 5. (*Ed.*)

A Union of Czecho-Slovakian farmers of all classes has been formed at Prague.

About 130 000 hectares of Czech land have recently been reclaimed. According to the estimate of the Ministry of Agriculture there are still 1 million hectares of land in Czech territory and 650 000 hectares in Slovakia which ought to be reclaimed.

The State has allocated 15 millions of crowns under the heading of State Improvements Fund for reclamation work and 4.25 million crowns under the heading of Land Improvements Credit.

SUGAR INDUSTRY. — Sugar production is becoming one of the most important economic factors in the State, especially as the output of all the other countries of Europe has decreased by 50 million quintals.

According to the figures published by WILLET and GRAY of New York the beet sugar output for the year 1912-1913 was as follows.

TABLE III. — *Sugar Production in* 1912-1913.

Austria-Hungary	19 020 000	quintals
Germany	27 010 000	»
France	9 610 000	»
Belgium	2 990 000	»
Netherlands	3 160 000	»
Russia	13 740 000	»
Other States	7 170 000	»
Total	82 700 000	quintals

80 % of the total sugar production of the former Austro-Hungarian Empire is concentrated in Czecho-Slovakia : its annual pre-War production may be estimated at 11-15 millions of quintals, that of 1919-20 at 6-7.5 millions of quintals (1) (the output in Germany was 13 million quintals; in Russia 3.5 million quintals; in Sweden 14 million quintals; in Italy 1.5 million quintals; in Spain 1-2 million quintals; in Switzerland 40 000 quintals).

In 1912-1913 the number of sugar factories was : 108 in Bohemia ; in Moravia and Silesia 56 ; in Slovakia 9 : total 173.

The areas under beet were : 149 000 hectares in Bohemia, 110 000 hectares in Moravia and Silesia, 60 000 hectares in Slovakia ; total 325 000 hectares.

The amounts of beets used at the sugar factories were : in Bohemia 49 000 000 quintals ; in Moravia and Silesia 30 000 000 quintals ; in Slovakia 16 000 000 quintals ; total 95 000 000 quintals.

The sugar obtained was estimated at 7 817 000 quintals in Bohemia,

---

(2) According to figures furnished by the Union of Sugar Factories, the sugar yield per hectare is estimated at 37.2 quintals. In 1919, 36 million quintals of beets were lifted in the Czech countries (Bohemia, Moravia and Silesia). The area sown with beets was 175 251 hectares.

4 333 000 quintals in Moravia and Silesia, 2 850 000 quintals in Slovakia, total 15 000 000 quintals.

Sugar occupied the first place among the exports of the late Monarchy; in 1913 sugar to the value of 294 million crowns was exported. In 1919-1920, it is expected that it will be possible to export 3 million quintals valued at 980 million crowns.

The Republic of Czecho-Slovakia is one of the countries in which beet growing and the manufacture of beet sugar have made the most remarkable progress during the last 40 years. The War has however greatly injured the beet cultivation industry.

In 1919, the Republic of Czecho-Slovakia exported 2 826 990 quintals of sugar, distributed as follows: France 550 000, Jugo-Slavia 124 788, Germany 263 450, Siberia 288 302, Austria 1 600 450 quintals Thus over 50 % of the total sugar exported went to Austria.

The maximum price of sugar beets was fixed at 15 crowns per quintal for the year 1919-1920, and at 26 crowns per quintal for 1920-1921.

HOPS IN BOHEMIA — The hop growing region of Bohemia lies to the north of the country on the Saxon frontier between 50° and 50°.7 lat and 30° and 32° long. It consists of 3 chief divisions:

1) The red country of Žatec (Saaz).
2) The red country of Ouštěk (Auscha).
3) The green country of Dubá (Dauba).

Since September 17, 1912, a law has been passed prohibiting the sale under the name of " Bohemian hops " of hops coming from any towns other than Žatec, Ouštěk and Dubá, where there are special hop markets.

The red Saaz country, so called because only red-stemmed hops are grown (the cultivation of the green-stemmed variety being forbidden throughout the region by the Statutes of the Saaz planters), contains 11 295 hectares of hop-gardens, divided (in 1911) between 9218 cultivators. This district, which produces the most prized type of hop forms a vast, almost circular, basin surrounded on all sides by mountains. The best plantations are on the slopes of the hills where they are sheltered from the north and west winds.

The situation of the hop-gardens of Saaz is worth attention, as showing the importance attached to the protection of the plants, for whereas ordinary crops occupy the plateaux, the hops cluster along the slopes and in the valleys. Hence they enjoy specially favourable conditions of growth and the cultivators select the best spots with the greatest care. There ie a striking analogy between the situations occupied by the hop-gardens os the valley of the Rézat, at Spalt (the choice growth of Bavaria), and thosf of the Valley of the Eger at Saaz. The soils of the two localities are very different.

The annual rainfall is 500 mm., the average during the summer months, April to October, being 377 mm. It is be noted that it rains very little in the Saaz district, much less than in other parts and to this relative dryness are attributed the size and flavour of the Saaz hops.

The average annual temperature is 9°C.; in summer the temperature is about 15 C. The winters are cold, but it is sometimes very hot in summer, and after July, a period of drought sets in and often lasts until the end of harvest, being broken only by a few storms. August, when the hop finishes flowering, is a particularly fine hot month.

Owing to the configuration of the ground, the neighbourhood of the slate rocks of Štredohoří (Erzgebirge) and the basalts of the Riesengebirge etc., the soils are of very different composition. Near the town of Saaz the finest hops are grown on stiff clays, and are sheltered from the cold winds by chains of hills and mountains.

The red country of Auscha lies to the south of the Saaz district and here red-stemmed hops only are grown (2998 hectares were under hops in 1911). All the northern part of the region forming the red Auscha country proper, of which Auscha is to some extent the centre, is intersected by wooded hills separated by valleys whose abrupt granite slopes are covered by hop-gardens.

The mean annual temperature is the same as at Saaz, but the heat in summer is a little greater, the thermometer registering 17.5° C. on an average.

The annual rainfall is 613 mm., 416 mm of rain falling during the 6 summer months.

The soil is generally calcareous, and the rocks are masses of weathered basalt

The green country of Dauba is so-called because green stemmed hops are almost exclusively grown. It lies east of the Auscha district, exactly following its contours. Dauba is the smallest hop-growing region in Bohemia, having only about 539 hectares under hops. In character it is very diversified, high, wooded plateaux alternating with deep and very fertile valleys

Hop Cultivation. — This is practically of the same nature in the three districts.

In the autumn, the ground is ploughed deeply, and the clods are left untouched through the winter. In the spring, before pruning, the hop-gardens are again ploughed (but less deeply) along and across the rows, so as to form a square mound round each plant. The stocks are uncovered with a hoe.

Pruning takes place from April 15 to May 15, and is relatively late. Pruning is a little earlier at Auscha and Dauba than at Saaz where it is never begun before the end of April. During the summer until the flowering, the soil is lightly hoed to keep it friable and clean.

The hop-gardens are chiefly manured with dung, spread only once in two years and in the autumn before the first ploughing At Saaz, 8 to 10 kg. of manure is put round each plant; in Auscha, it is spread between the rows, 10 or 15 kg. being given to every two plants; at Dauba, the amount used is 5 kg. per plant. Chemical fertilisers are also applied. At the flowering time, the hop-vines are watered with dilute liquid manure. Some of the hops are grown on poles and the others on wire At Saaz, the wire props increase in number every year, and the oblique system is preferred. At Auscha and Dauba poles are more used, on account of the proximity of the forests and the low price of wood.

At Saaz the hop grows to between 6 and 7 metres on the hills and to 8 m. on the low-lying ground. It attains 7 to 9 m. at Auscha, but only 4 to 6 m. in Dauba, where the growth is less vigorous. If the vegetative development is too luxuriant, the top or side-shoots are removed, but a peculiar feature about hop-cultivation in Bohemia is that the bases of the shoots are not always deprived of their leaves. In Saaz hops are planted 1.30 m. to 1.50 m. apart, in a square, which means 4450-5950 per hectare. In the red Auscha region, the spacing of the rows is 1.25 m. to 1.50 m. In the green Dauba region, it is never more than 1.20 m. to 1.30 m. giving 7500-7900 plants per hectare.

In all 3 regions however 2 shoots only are kept per stock which allows the plants and rows to be closer.

Production however is not on a large scale. It is estimated that in order to obtain 50 kg. of hops, it is necessary to have 10 *schocks* (a *schock* consists of 60 plants) at Saaz, 7 at Auscha and 5 at Dauba The better the quality of the hops, the fewer are needed.

The crop often falls below these figures, and even in good years is only 8 to 10 quintals per hectare, according to district. The hops are picked with the greatest care, each flower being taken separately and freed from leaves or stalk. A first sorting is made during the picking, all the spoilt hops being placed on one side; the rest are removed in baskets to the barns and sorted a second time by 3 cm. sieves with a gentle backwards and forwards movement. Hops that are too large, or have grown two or three together, the leaves etc., remain in the sieves. Those that have passed through the meshes are removed by hand, and again sifted. The final residue is mixed with the hops rejected during the picking and sold as second quality hops.

TABLE IV. — *Distilleries and Alcohol Production (in hectolitres) in Czechoslovakia.*

	No. of distilleries	Alcohol produced	
		in 1917-1918	in 1918-1919
Agricultural distilleries:			
in Bohemia	300	33 729.56	50 808.32
» Moravia	161	29 430.55	36 417.33
» Silesia	101	7 314.63	10 305.94
» Slovakia	430	?	108 483.20
Industrial distilleries:			
in Bohemia	16	136 444.10	174 814.03
» Moravia	9		
» Silesia	4		
» Slovakia	42		

DISTILLATION — Table IV shows the amount of alcohol made in Czecho-Slovakia.

In 1914-1915, Bohemia produced 452 630 hectolitres of alcohol (52.93 % of the alcohol output of the Austria of former days) Moravia 214 496 hectolitres (25.08 %), and Silesia 71 478 hectolitres (8.36 %). Of the total alcohol production of Hungary, 36 % came from Slovakia.

In the year 1917-1918, the distilleries of Czechoslovakia used 18 000 quintals of potatoes and 518 000 beetroots.

The country has been able in consequence of the increase in potato distilleries to introduce improvements in soil-cultivation, the fattening of stock, etc. The legislation dealing with alcohol distilleries gives special privileges to agricultural potato distilleries. The smaller factories are favoured by a progressive tax based on the possible output of the distillery.

The amount of alcohol consumed in Czecho-Slovakia is estimated at 800 000 hectolitres, and half the distilleries are in full work. After the sugar-tax the alcohol tax is the source of greatest revenue to the State. In the budget of 1920, the proceeds of this tax were reckoned at 34 million crowns.

STARCH-MAKING. — The potato crop is of considerable importance in Czecho-Slovakia. According to the statistics (from 1903-1912) 508 210 hectares were under potatoes in the Czech countries and about 259 746 hectares in Slovakia. It is difficult to state exactly how many of these hectares are reserved for growing potatoes for industrial purposes properly so-called. The yield per hectare was 98.8 quintals (79.9 quintals in Slovakia) with a total production of 50 219 253 quintals (20 745 998 quintals in Slovakia). The districts where potatoes are most grown are Slovakia and the Czecho-Moravian plateau, and hence in the parts considered the richest from an agricultural standpoint, as possessing the most fertile soils. A large portion of the crop goes to the starch factories.

There are 142 starch-factories in Czecho-Slovakia, 94 in Bohemia, 29 in Moravia, 2 in Silesia and 17 in Slovakia. About 450 000 quintals

TABLE V. — *Alcohol Production and Exportation Returns for (pre-war) Austria and Hungary (in hectolitres).*

Years	Austria		Hungary	
	Production	Exportation	Production	Exportation
1910–1911	1 786 299	312 112	—	—
1911–1912	1 592 392	95 689	—	—
1912–1913	1 619 231	242 888	1 309 216	121 860
1913–1914	1 590 376	249 649	1 392 179	157 050
1914–1915	855 187	105 480	1 024 165	95 210
1915–1916	—	—	821 216	130 947

of starch, glucose and dextrine of the value of 19 million crowns, were produced before the war. These products have become in the course of time the basis of important export industries

In Czecho-Slovakia, 220 000 quintals of starch were consumed and about 230 000 quintals (of the value of 10 million crown) were exported to the other countries of the former Monarchy. The first States to which exports were sent were Austria, Jugo-Slavia Bulgaria, and Rumania

The 125 starch factories in Bohemia, Moravia and Silesia used before the War on an average, 2.2 million quintals of potatoes a year, while 1.2 million quintals were supplied to the 17 starch factories in Slovakia. The starch industry includes 3 branches, producing starch, glucose and syrup, dextrine and artificial gum. The 3 branches are very intimately connected, and must be regarded as forming a single industry. During the War the output decreased, as the Government did not allow the manufacture of starch from potatoes.

1195 – **Agriculture in the State of Rio de Janeiro, Brazil, According to the President's " Message ", Addressed to the State Assembly. (Session of August 1, 1921)** (1) — *Lavoura e Criação*, Year VI, No 8, pp 162-176 Rio de Janeiro, August 1921

The President of Rio de Janeiro, Dr Raoul DE MORAES VEIGA, in reviewing the economic condition of the country, enumerates the chief sources of revenue derived from the export taxes levied upon the most important agricultural products. Coffee occupies the first place, this tax alone furnishing $^4/_5$ of the total revenue from 1892 to 1900 Owing to the large amount of coffee grown, a monocultural system has been almost exclusively adopted, which is not suited to a fertile soil such as characterises this State. The crisis due to the fall in the price of coffee was especially acute in 1902, and hence the Government was induced to advocate polyculture During the War, coffee rose very much in price, and the returns from the export tax (to which must be added a supertax of 3 fr. per sack), increased. In 1919 this tax reached its maximum and brought in 6 198 691 *milreis* (1 gold *milreis* = 2 832 fr. at par), the supertax bringing in 2 273 453 *milreis*

In 1920, the tax on sugar amounted to 2 079 994 *milreis* and the supertax to 1 141 198 *milreis*, figures much higher than had ever been reached before In the same financial year, the export taxes on the following agricultural and stock-breeding products that chiefly contributed to the budget were as follows

Vegetable products	50 142 *milreis*
Maize.	60 900 »
Palm-oil	3 141 »
Horses	2 241 »
Mules	1 591 »
Cattle	13 343 »
Goats (1st six months 1921)	2 250 »
Pigs (1st six months 1921).	2 163 »

---

(1) For the Development of Agriculture in Brazil, see . *R* June 1921, No 592, *R* July 1921, No 700, *R* Nov 1921, No 1078 (*Ed*)

The tax on alcohol alone brought in 349 995 *milreis.*

From January 1, 1919 to June 30, 1921, 4 881 112 *milreis* were expended on the regulation of the rivers, improvement works, rural prophylaxis and similar objects.

By Decree No. 1721 of 1919, the " Inspectoria de Agricultura " (Agricultural Inspection Service) was re-established. It is connected with the Botanic Garden of Rio de Janeiro, and its function is to assist the Government in encouraging Agriculture, being especially intrusted with botanical prophylaxis, and the promotion of the purchase of Agricultural implements and machines, and of the study of crops, including sylviculture.

The " Inspectoria " has begun the gratuitous distribution of selected seeds. From August to October 1920, 31 500 kg. of seed potatoes and 13 007 kg. of the seed of " capim gordura rôxo " (*Andropogon rufus*) (1) were thus disposed of, and in addition, beans, rice and maize. This institution also facilitates the purchase of sulphur, agricultural implements, etc

A system of prize competitions for various crops has also been established.

The climate and rich pastures of Rio de Janeiro are admirably suited tor stock-breeding.

The shows held in 1918 and 1920 by the " Sociedade Nacional de Agricultura " at Cordeiro (Municipality of Cantagallo), proved the progress made in stock-rearing. The first Government Stud Station was founded at Cordeiro in 1920, and provided with pure-bred bulls (Polled Angus and Red Poll), bought in England and Argentina.

According to the figures supplied by the General Direction of Statistics, the State of Rio de Janeiro possesses: 556 220 cattle — 142 890 horses — 101 200 asses and mules — 63 510 sheep — 89 670 goats — 602 560 pigs

There is certainly a great future for stockbreeding.

A large refrigerating establishment is being built at Iguassú by the " Companhia Pecuaria e Frigorifica do Brasil ". Here the meat of cattle, sheep, pigs and poultry is not only frozen for export purposes, but is also canned, lard etc. are also manufactured.

The Lancashire General Investment Trust, Limited owns the Packing House at Mendes, in the Municipality of Barra do Pirahy (2).

The following industries are fairly developed: textiles (28 factories including 23 cotton, 2 silk, 1 wool and 2 lace factories); preserves (241 factories); sugar-making (the Municipality of Campos itself possesses over 30 sugar-factories); there are also 64 factories of various beverages.

1196 - **The Influence of Accessory Factors (Vitamines) on Dentition.** — HOWE P. R. in *Bulletin de la Société scientifique d'Hygiène alimentaire et d'Alimentation rationnelle de l'Homme*, Vol. IX, No 5, pp. 308-313. Paris, 1921.

The author describes the types of dental troubles produced in guinea-pigs by a diet based almost exclusively on oat-bread and skin milk, and therefore deficient in the 3 kinds of known vitamines. It would appear, that the same foods are required for the development and preservation of the teeth, as are indispensable to growth and the maintenance of health. These necessary articles of diet are: whole milk, fresh vegetables, and especially green vegetables, various leaves, fresh fruit and whole seeds.

1197 - **Maize in Bread-Making as the Cause of Encephalitis lethargica.** — VIGER, in *Comptes rendus de l'Académie d'Agriculture de France*, Vol VII, No. 31, pp. 652-655. Paris, October 12, 1921

In a memoir entitled *Contribution à l'étude de l'encéphalite léthargique et de la grippe infectieuse*, Dr. VEILLARD, of Meung-sur-Loire attributes *encephalitis lethargica* (Sleeping sickness), to a diet of bread containing maize and considers the disease to be very similar to pellagra. Bleached maize flours freed from oil are more dangerous when substituted for wheat flour than the yellow kinds. Dr. VEILLARD does not suggest that maize should be prohibited as an article of human food, but advocates most strongly that it should not be incorporated in flours in place of wheat flour.

CROPS AND CULTIVATION

1198 - **Relation of Cultivation of "Abaca" (*Musa textilis*) to Climatic Conditions in the Philippines.** — ROSALES, S. P., in *The Philippine Agriculturist*, Vol IX, Nos. 8-9, pp. 219-227. Los Baños, March.-April, 1921.

Abaca-growing is almost exclusively a Philippine industry, as the attempts made to cultivate it in other tropical countries have met with but little success. The fibre of this plant is widely known and extensively used in the manufacture of cordages, clothing, etc. Therefore every effort should be made to determine the parts of the Philippines where it is possible to grow *Musa textilis* Née. Climate is certainly the most important factor. Three types of climate can be distinguished in these islands:

First type: Total annual rainfall 2766 mm., no dry season. Humidity 78-88 % with slight variations. Temperature: . Average less than 27° C.

Second type: Total annual rainfall 2453 mm., dry season lasts 5 to 6 months. Humidity: wide range, 70-86%. Temperature: around 27° C.

Third type: Total annual rainfall, 1856 mm., dry season lasts 1 to 2 months. Humidity very small range. Temperature: around 26° C.

The great variations in the climate, and especially in the distribution of the rainfall in different parts of the archipelago, make it possible to grow practically all tropical products in the same region by artificial means, such as irrigation and shading.

Of the 3 types of climate described, the first is the most favourable for the growth and development of *Musa textilis*. This type of climate is found at Albay (total annual rainfall: Legaspi, 3572 mm.), Ambos Camarines (Paracale, 4825 mm.), on the east coast of Samar (Borougan, 4177 mm.), at Leyte and Mindanao and on the Northern coast of Mindanao.

Abaca can however be grown though to a more limited extent, with the second or third type of climate, such as is found at Cavite, Mindoro, Negros, etc. In the upland region of the province of Cavite (2nd type), the plant can be cultivated successfully, probably on account of the high altitude and consequently low temperature and great humidity. In the following Table comparisons of temperature are shown between the province of Cavite and the two provinces, Leyte and Albay which produce the largest amount of Abaca.

Temperatures of Leyte, Albay, and Cavite (in degrees Centigrade).

Provinces	Mean maximum	Mean minimum	Average mean $\frac{\text{max.} + \text{min.}}{2}$
Leyte	29.9° – 32.8°	21.7° – 24.2°	27.2°
Albay	29.8 – 33.7	21.6 – 24.7	27.5
Cavite	29.4 – 31.8	18.3 – 20.0	24.9

Although Cavite has a long dry season of 6 months' duration, its temperature is lower than that of Leyte or Albay; hence the evaporation from the soil and the transpiration of the plants are less active which tends to counteract the dryness of the climate.

1199 – **The Factors Determining Soil Temperature.** — KEEN, B. A., and RUSSELL, E. J. (Rothamsted Experiment Station, Harpenden, Herts.), in *The Journal of Agricultural Science*, Vol. XI, Part 3, pp. 211-239, 13 figs. Cambridge, July 1921.

The object of this paper is to discuss the factors influencing soil temperature. The flow of heat emanating from the interior of the earth's crust is however not taken into account, as this source of warmth is but of negligible importance as regards the soil. The authors also investigated the extent to which other measurements, such as air, temperature, hours of sunshine, etc., can be made to give information as to soil temperature in cases where direct determinations have not been made.

The material of this discussion is provided by readings of a continuous, self-recording thermometer buried at 6" in the soil at Rothamsted, and those of a series of other thermometers exposed on a screen open to the air, or buried in the soil. Sunshine and radiation recorders were also used. The soil above the thermometer was carefully kept free from all plant growth. The period dealt with is from Dec. 22, 1913 to Dec. 23, 1914, although the records have been and will be continued.

The winter temperature curves differ from those obtained in summer. In winter, there is practically no variation during the day, though fluctuations may extend over a several day period, the maximum of one day being the minimum of the next. In summer however there is a marked daily variation; the rise of the temperature which begins on the surface at day break penetrates to the 6″ depth at about 9.30 a.m. The rise is then continuous till about 4.30 p. m., when it slackens or ceases; after 5.30 p. m., there is a fall which is much slower than the rise, lasting till 8 a. m. or thereabouts. Thus, at the depth of 6″, the temperature rises for about 7 or 8 hours, and falls for about 15 or 16 hours, there often being a flat period of varying duration at each end. The mean temperature is passed about midday, and again at about midnight: the warm period in the soil is thus from midday to midnight, and the cool period from midnight to midday. The soil maximum at 6″ is attained about 3 hours later than the air maximum on the screen.

The maximum soil temperature is not very closely correlated with the number of hours of sunshine, the coefficient for the whole observation period, February 2—December 23, 1914, being 0.434 ± 0.032. The coefficient is even less (0.357), when account is taken only of the hours of sunshine up to 12.30 p. m., which alone would be expected definitely to influence the maximum soil temperature. On the other hand, the extent of the temperature rise at 6″ depth is closely correlated with the amount of solar radiation as recorded by the WILSON radio-integrator (the correlation coefficient being +0.877 ± 0.009), and to a less extent (correlation coefficient +0.78 ± 0.015), with the hours of sunshine.

The extent of the daily rise is adversely affected by rainfall, but apparently not by wind. The surface of the soil gives a temperature considerably above that of the air. At 6″ depth however the temperature is so much diminished, that the maximum is approximately the same as in the air during summer, though it is about 3° C lower in winter.

The cooling of the soil, which determines its minimum temperature, is increased by clear nights, but is retarded during autumn by rainfall which prevents the soil from cooling as much as it would otherwise. The cooling of the soil does not usually proceed as far as the cooling of the air. In summer, the soil minimum may be 6° or 8° C above the air minimum, and in winter, it is 3° C or more above; further, the minimum soil temperature is attained earlier in summer (7.45 a. m.) than in winter (10.30 a. m.), whereas in the air, the minimum is attained at approximately the same time (3.45 a. m.), all the year round.

The maximum temperature at 6″ depth during the summer was usually about 22° C, though it rose to 26.5° C on one occasion; the minimum was about 18° C, rising to 21° C. The mean temperature was about 20° C. This mean value was found to show less relationship to radiometer or sunshine values than the maximum temperature. The amount of soil moisture however showed a tolerably clear connection. Though the data are not strictly comparable, it is evident that the soil warmed as it dried, and cooled as it became moist. The transition from winter to summer values takes place quickly, as a result of a concurrent increase in soil dryness and in solar radiation. In early winter the cooling of the soil is also rapid; this is probably due to the fine October nights when radiation is considerable; rainfall retards the process of cooling.

It thus appears, that the edaphon, or soil population, enjoys a warmer climate than that of the atmosphere; further the climate is also moister; the conditions of the surface soil during summer resemble those of a 20° C incubator.

As regards instruments for determining soil moisture, the ordinary 12" soil thermometer, when used alone, proved unsatisfactory; its readings corresponded with the minimum but not with the mean temperature. The air thermometers were also insufficient by themselves, although the mean soil temperature is often about 3° C above the mean air temperature. A fairly, satisfactory value for the mean soil temperature is obtained by regarding the maximum air temperature as the maximum soil temperature, and the 12" soil temperature at 9 a. m. as the minimum and when taking the mean.

An increase in either the hours of sunshine, or the radiometer values, results in an increase in the ratio. $\frac{\text{soil amplitude}}{\text{air amplitude}}$; if the one increases, so does the other, and an increase in the thermometric variation of the soil as well as an increase in that of the air are also associated with an increase in this ratio.

The article concludes with an appendix containing: a description of the recording soil thermometer used, designed by Sir Daniel HALL, description of the British Meteorological Office type of Soil Thermometer, the Air Thermometer, the WILSON Radio-integrator, and the CAMPBELL-STOKES Sunshine Recorder, all used in these observations.

1200 – **Aqueous Vapour Pressure of Soils.** — THOMAS, M. D. (Utah Agricultural Experiment Station). in *Soil Science*, Vol. XI, No. 6, pp. 409-433, 5 figs., bibliography of 35 works, Baltimore, June 1921.

In all soil studies a knowledge of the soil solution *in situ* is highly desirable both as regards the mechanical action of the soil particles upon the solution and the influence of any dissolved material. When the soil solution is removed by centrifuging or by applying pressure, it is evident that the liquid thus obtained cannot exhibit the same properties as when distributed over the surface of the soil particles. The vastly greater water-holding capacity of clay, as compared with sand, and also the absorption of such salts as sodium carbonate necessitate special methods of research. The most obvious physico-chemical method to use in studying soil solution directly in the soil is the freezing-point lowering; this has been extensively employed by BOUYOUCOS and others, though there are several serious objections to it. Of these, the chief is that since the soil cannot be thoroughly stirred, the observed depressions do not indicate the true freezing points, and the results are therefore at best merely relative. Further the method is not applicable to the drier soils. Again, it is possible that the relations which obtain at ordinary temperatures do not hold at the freezing temperature though these discrepancies would not probably be large. BOUYOUCOS' dilatometric method seems to give very significant information over a range of moisture content extending from somewhat less than wilting coefficient, to very wet, but gives no details about "hygroscopic" moisture except to fix its maximum and indicate that it is held by very powerful forces. Hence the general application of this method is a matter of considerable difficulty. The conductivity method may be useful in supplying qualitative evidence as to the soluble salt content of the soil solution when the moisture content is high, but it fails when applied to drier soils. Cultivation experiments also give very limited results, the wilting coefficient and the toxic limits of alkali salts vary with different atmospheric and bacterial conditions, so that it is difficult to assign to them any exact theoretical significance.

On the other hand, the vapour pressure of the soil solution should supply abundant quantitative information about the soil, for this function being a property of the free energy at the surface of the moisture film, is fundamentally bound up with such other properties as the osmotic pressure, moisture equivalent, concentration of dissolved substances and the effective diameter of the soil particle, (that is, the total surface of the soil) Thermodynamic relations are known or can be deduced, by which most of these properties can be calculated directly from the vapour pressure

Precise measurements of the vapour pressures of certain solutions have been made by several investigators. Two general methods have been used : 1) The static in which the pressure differences are observed directly on manometers ; 2) the dynamic which consists in passing a known volume of air through a substance, collecting and weighing the vapour, and computing the partial pressure from the gas laws. The experimental difficulties, which would be even greater for soils than for solutions, led the author to abandon the static method temporarily in favour of the dynamic method. He used an apparatus by which it is possible to measure accurately the aqueous vapour-pressure lowerings of the soil to 0.01 mm of mercury at 25° C.

The author applied this method to a sand from River Heights, 2 clay loams, and a silty clay separate (the clay portion of a soil separated by decantation) He also determined the effects produced by salts causing the so-called alkalinity of the soil sodium chloride, sodium carbonate and sodium sulphate.

The vapour-pressure-moisture curves are shown to be rectangular hyperbolae when traced over a wide range of moisture contents. This means that the vapour pressure is proportional to the reciprocal of the moisture content.

As for the three sodium salts, they are absorbed by the silty clay loam, to the extent respectively of 10-44 % of the chloride, 70 %, of the sulphate and 85-90 % of the carbonate, though the chloride and sulphate can be extracted completely. By analysing the energetic functions of the soils studied, the author was able to determine the correlations between vapour-pressure and .the following properties hygroscopic coefficient, wilting coefficient, moisture equivalent, BOUYOUCOS' "solid water," capillary potential, surface tension, and curvature of the moisture surface.

The author intends continuing his investigations, but hopes that the work will appeal to others, and that vapour-pressure studies will take an important place in soil researches.

1201 – **Measuring Soil Toxicity, Acidity and Basicity.** — CARR, R. H. (Indiana Agricultural Experiment Station, La Fayette, Indiana), in *The Journal of Industrial and Engineering Chemistry*, Vol. XIII, No. 10, pp. 931-933. · New York, October 1, 1921.

It is well known that a very acid condition of the soil is unfavourable to the growth and development of many plants. The cause of this poor growth has been attributed to lack of available calcium and magnesium, to the presence of toxic salts of aluminium and iron and to the presence of free acid (H-ion concentration). The fact that aluminium salts are toxic has been reported by many workers. The extent to which iron is toxic when associated with aluminium in acid soils is not so well understood, but the author believes, that the conditions making it soluble enough to be toxic occur infrequently.

The author has made a study of soil composition and toxicity as related to the root rots of maize, and has attempted to develop a method for determining soil acidity based upon the fact that in the absence of calcium, magnesium or other bases in the soil, the aluminium and iron salts can act as bases to form soluble salts. It was noticed by COMBER (*Journal of Agricultural Science* X, 420, 1920), that when an alcoholic solution of potassium thiocyanate was shaken up with an acid soil, a red colour developed, more or less in proportion to the acidity of the soil This red colour was due to the formation of ferric thiocyanate from soluble ferric iron in the acid soil. The presence of aluminium in the alcoholic solution can readily be shown by the addition of a few drops of an alcoholic solution of logwood which produces a blue colour somewhat in proportion to the amount of aluminium.

If 50 gm. of 10-mesh soil are treated with 30 cc. of a saturated solution of potassium thiocyanate in 95 % alcohol and shaken for 2 minutes, the liquid will become pink or red if the soil is acid. On adding from a burette a 0.10 N. alcoholic solution of potassium hydroxide until the colour disappears (at which moment a change takes place at H-ion concentration of $P_H = 5.5$) the amount of lime required by the soil is obtained. Each cubic centimetre of 0.10 N base is equivalent to 200 lb. of calcium carbonate per acre. If no red colour develops, the soil is basic, and by adding from a burette a 0.10 N alcoholic solution of hydrochloric acid, the calcium carbonate equivalent of the soil may be determined.

The author tried this method on 20 soils and determined the calcium carbonate recovered after some pot culture experiments. Hence it appears, that the method suggested lends itself to the determination of either the acid or basic condition of a soil, as well as of the soluble aluminium and iron present.

1202– **Nitrification in Some South African Soils.** — HALL, T. D. (School of Agriculture and Experiment Station, Potchefstroom, South Africa), in *Soil Science*, Vol. XII, No. 4, pp. 301-363. 10 figs., bibliography of 49 works. Baltimore, October 1921.

Although the study of the rate and amount of nitrate formation as a means of judging the biological activity and also the general fertility of the soil has received a great deal of attention in Europe and America, and has not been neglected in India, Australia, and other countries, it appears that no quantitative data exist respecting nitrification in the soils of South Africa.

The subject is of special interest, because the application of mineral nitrogenous fertilisers to soils in South Africa has not given the expected returns, and in some cases none at all. Green manuring with Leguminosae has proved the only manner of applying nitrogen that has given satisfactory results at the Potchefstroom Experiment Station The fact that the average South African soil is poor in phosphates may be sufficient to account for the lack of response when mineral nitrogenous fertilisers are applied alone; but soils, with a low nitrogen content according to European standards, often give excellent returns in South Africa, when the rainfall is sufficient and no nitrogenous fertiliser has been used.

The author therefore undertook a series of experiments with the object of obtaining quantitative data on nitrification in South African soils for the purpose of comparison with the soils of other continents and of ascertaining whether the process of nitrate formation is as active as has been assumed. The scheme of his work was as follows: 1) to ascertain the amount of nitric nitrogen in the virgin, cropped and cultivated soils around the Potchefstroom Experiment Station, at various seasons of the year and after various crops; 2) to correlate the seasonal variations of nitrate with the climatic conditions; 3) to ascertain the amount of nitrogen in the first 5 feet of the soil in various sections of the locality studied; 4) to compare the nitrifying powers of each of the successive 5 feet of soil and see how far nitrification was active; 5) to see how much limestone and slaked lime affected nitrification on dry-land plots growing potatoes; 6) to compare the nitrifying powers of irrigated and long cultivated land with virgin dry lands in regard to the various amounts of blood-meal and ground limestone applied, 7) to find out how much nitric nitrogen was added to a soil by cowpeas (*Vigna Catjang*) alone, lime alone, and by mixtures of the two; 8) to compare the nitrifying powers of soils from different parts of the South African Union with one another, and to ascertain the nitrogenous fertiliser most easily nitrifiable (whale guano, fish guano, cyanamide, dried blood, ammonium sulphate, cow-pea hay and sewage sludge); 9) to compare the nitrifying powers of virgin and cultivated soils of the same type; 10) to correlate, if possible, the nitrifying power of soils with the amount of rainfall in the area whence they came; 11) to compare the nitrifiability of ordinary whale-guano, ether-extracted whale guano and sulphated whale-guano; 12) to compare the nitrifiability of small and large amounts of nitrogeneous fertilisers and to ascertain, if possible, which is better for comparing the nitrifying powers of various soils.

The examination of 54 samples of soil from various parts of South Africa showed that the nitrification in them was much less than in the 45 humid soils investigated by LIPMAN and his collaborators, or even in the majority of the soils of the semi-arid districts of California and Colorado, but it was greater than in the Texas soils.

[1282]

In short, though nitrification is good in South African soils as compared with soils from some areas, it cannot be said to be exceptionally active. The data confirm what has already been recorded in the West of North America, viz., that in the soils of arid and semi-arid regions nitrification is not very intense, nor is it always greater there than in the soils of humid areas. In the region studied by the author (that of summer rainfall), however, the nitrification seems quite adequate for the average crop production. The last study showed that 5 % of the soil nitrogen on the Potchefstroom Experimental Station could be nitrified under optimum conditions in 30 days. This means a capacity for producing about 180 pounds of nitric nitrogen per acre-foot, which is however a higher capacity than was shown by most samples of the soils tested. Nevertheless nitric nitrogen was always found on the dry-land plots, even at the time of the most active growth of the maize crop.

The seasonal variation data seem to point to better and more active nitrification at Potchefstroom than at Rothamsted, but as seasonal-variation field data from Ithaca, N. Y., show larger amounts of nitric nitrogen to be present than in Transvaal soils, it cannot be affirmed that nitrification is generally more intense in these soils than in the soils of most temperate climates. It can however be stated, that where the maximum rainfall and temperature coincide, there is a maximum nitrification at the time of greatest crop growth. Thus it seems that there is not much need of nitrogenous fertilisers in the summer rainfall area. On the other hand, farm practice shows great benefit from nitrogenous manures in the Cape areas of winter rainfall, where the optimum conditions of moisture and temperature occur at different times.

1203 – **Direct Application of Mineral Phosphates to the Soil in the United States.** — STONE, R. W. (United States Geological Survey, Washington, D. C.), in the *American Fertilizer*, Vol. LV, No. 9, pp. 82-94. Philadelphia, October 22, 1921.

The use of crude mineral phosphate for direct application to the soil has considerably increased in the United States during the last few years, and it seems, that excellent results have been obtained as regards crop

Years	Phosphate sold	Phosphate exported	Phosphate sold for direct application

* 1 *long ton* = 1016 kg.

yield. Several companies, especially in the Florida and Tennessee phosphate fields, are handling this product. In 1914, the United States Geological Survey, in its annual statistical enquiry, asked producers to state the quantity of crude phosphate sold for direct application to the soil. The total of such returns from the miners however does not represent the total quantity sold for direct agricultural use, for some of the phosphate is sold to grinders who do not report to the Geological Survey.

Nevertheless, the annexed figures may be interesting as suggestive of the trend of the fertiliser business, and as a means of comparing the quantity of phosphate sold for direct application with the total amount of mineral phosphate sold and exported from the United States since 1914.

1204 - **Experimental Researches on the Manufacture of Nitrates by the Biochemical Oxidation of Ammonia, in France.** — BOULLANGER E., in *Annales de l'Institut Pasteur* Vol XXXV, No. 9, pp 575-602. Paris, 1921.

The point of departure of these experiments was MUNTZ and LAINÉ's work on intensive nitrification and the formation of nitrifying beds with a high yield. (*Annales de la Science agronomique*, Series 3, No. 2, 1906).

These two investigators had concluded from their researches :

1) that peat is an excellent medium for bacterial nitrification.

2) that by using peat for the construction of nitrifying beds from which flows a constant supply of ammoniacal liquid, it is possible to nitrify (per day and per cubic metre of peat), 1000 litres of ammonium sulphate solution containing 7.5 gm. of the salt per litre, and also to obtain 5 % or 6 % solutions of calcium nitrate by making a series of similar beds, and allowing the nitrified solutions to pass from one to another, adding each time, as the liquid leaves the preceding nitrifying bed, a fresh dose of ammonium sulphate in the proportion of 7.5. gm. of the salt per litre of liquid.

If these results obtained in the laboratory during a short time, and with simple bell-jars could be obtained upon a large scale and continuously, it would be possible to consider the question of manufacturing by this process large quantities of nitric acid, which according to the figures given above, might amount to some 90 tons of calcium nitrate per hectare and per day.

Experiments in this direction were made by the author in 1917-1918.

In this first memoir he gives a summary of the results of his laboratory experiments.

These were carried out in a desiccator at 28° C., and in 4-litre bell-jars filled, either with fragments of peat or of some other bacteria-supporting material, which was regularly watered by hand with a solution of ammonium sulphate. These bell-jars had been previously sown with active cultures of nitrifying ferments, such as are easily obtained from scoria partially immersed in 100 cm^3 of OMELIANSKI's ammoniacal medium (1) to which had been added a little soil.

---

(1) *Archives des Sciences biologiques de Saint-Pétersbourg*, 7, 1899, p. 291. (*Author's note*)

The results obtained led to the following conclusions which define the conditions under which the industrial application of biological nitrification can be attempted.

a) THE CONDITIONS UNDER WHICH THE NITRIFICATION BEDS ARE STARTED, AND THE MAXIMUM VOLUME OF THE DAILY OUTPUT. — The large amount of ammonium sulphate (200 litres per cubic metre of peat per day) used at first paralysed the development of the nitric ferment, which is inhibited by excess of ammonia. Therefore, very small quantities must be employed at the beginning. The peat should be watered per cubic metre and per day with 20 to 40 litres of solution only containing 2.5 gm. ammonium sulphate per litre, in order to allow the nitric ferments to develop in the beds and to prevent the incomplete oxidation of the ammonium and the formation of nitrites.

The amount of the solution can be gradually increased, but must never exceed 200 litres per cubic metre of peat per day, in the case of the solution containing 7.5 gm. of ammonium sulphate per litre, and no preformed calcium nitrate. Larger quantities (300 litres and more), leave a considerable and increasing amount of ammonia unnitrified and it is impossible to continue in this manner.

When the peat was watered with solutions containing, in addition to the 1.5 gm. per litre of ammoniacal nitrogen to be oxidised, 40 to 50 gm. of pre-formed calcium nitrate, the nitrification process was much slower, and it was necessary to reduce the amount of solution to a maximum of 75 to 100 litres per cubic metre of peat per day.

b) THE RIGHT KIND OF AMMONIACAL SALT TO USE. — At the beginning the presence of nitrates greatly hinders the increase of the nitrifying bacteria. The first waterings should be made with a solution of ammonium sulphate, and not of ammonium nitrate, in order gradually to accustom the micro-organisms to the nitrate formed, and to promote their multiplication.

When a sufficient number of bacteria have developed, there is no objection to the use of a solution of ammoniacal nitrate, obtained by dissolving this salt in water, or in the nitrified liquid, or by the double decomposition (by the sulphate or carbonate of ammonia), of the solution of calcium nitrate that has flowed from the nitrifying beds.

The best results are obtained by the application of the solution of ammoniacal nitrate produced by the double decomposition (brought about by the bicarbonate or sesquicarbonate of ammonia) of the solution of calcium nitrate flowing from the nitrifying beds. This double decomposition effected by the ammonium carbonates has also great advantages from the industrial standpoint, viz. the suppression of the calcium sulphate which consequently has not to be separated and removed, the recovery of the calcium which can be returned to the nitrifying beds, the more ready evaporation of the nitrate solutions in the absence of calcium sulphate in solution, etc

c) MAXIMUM NITRATE CONCENTRATION OF THE NITRIFIED SOLUTIONS. — In roderto obtain concentrated solutions of calcium nitrate, it is not necessary to make a series of 8 or 9 similar nitrifying beds and to let the nitrified liquid flow from one to the other, after the addition of the amount of ammonium sulphate necessary to bring the ammoniacal nitrogen content up to 1.5 gm. per litre, and the separation of the precipitated calcium sulphate. This end can be attained more easily by causing the effluent to pass repeatedly through the same nitrifying bed, after adding each time a fresh quantity of ammonium nitrate. The highest concentration the author was able to obtain was 138.2 gm. of calcium nitrate per litre, but this amount gradually checks the nitrification process. Regular oxidation of the ammonia could however be obtained with a concentration of 120 gm. of calcium nitrate per litre.

For industrial purposes, a method similar to that employed in vinegar factories could be adopted with advantage. When the nitrifying beds are in full working and contain enough calcium nitrate to produce a nitrifying liquid with about 21.5 gm. of nitric nitrogen per litre (or 12 % of calcium nitrate), a portion of this nitrified liquid is removed, the rest being returned to the bed. To the portion removed are added water and ammonium carbonate in sufficient quantities to produce a solution containing 20 gm. of nitric nitrogem, and 1.5 gm. of ammoniacal nitrogen per litre; it is then again passed through the nitrifying bed. After its passage, this solution gives (owing to the slight concentration due to evaporation), a liquid containing about 21.5 gm. of nitric nitrogen per litre, the amount of the output being from 50 to 75 litres per cubic metre of the substratum per day. In this way there is one solution only for watering the peat, and all the nitrifying beds work under similar conditions.

d) EXPERIMENTS WITH DIFFERENT MATERIALS FOR THE NITRIFYING BEDS. — The use of peat for beds discharging nitrate solutions has many inconveniences from the standpoint of industrial work on a large scale. Peat is not homogeneous in structure, is difficult to crush and crumbles a great deal when kept. Further, the presence of organic matter causes some initial loss of nitrogen owing to denitrification, and gives rise to highly-coloured solutions of calcium nitrate, while the progressive disintegration of the fragments of peat etc. induces warping.

Peat can well be replaced by pozzolana, a very fine porous volcanic scoria, which when used in pieces the size of a cherry-stone, gives excellent results, superior to those obtained with peat.

1205 – **Experiments with Zenonite as a Manganic Fertiliser. in Italy,** (1). CAUDA, A., in *Il Coltivatore*, Year 67, No. 26, pp 243-245. Casale Monferrato, September 2[illegible], 1921.

The author first deals with the effect of manganic fertilisers in general and then describes his manurial experiments with zenonite.

The idea of using manganese dioxide as a fertiliser originated in the frequent need experienced by plants of finding oxygen at their disposal when growing on badly aerated soil, or at seasons when it is difficult to work the ground, and especially when it is a question of replenishing the lower strata of the soil with substances that easily yield free oxygen. Numerous successful experiments were made in digging in manganese dioxide to a considerable depth, the growth of the underground portions of the plants being increased by this treatment. This application of dioxide of manganese was termed *oxygenic fertilisation.*

---

(1) A silico-manganiferous mineral taking its name from Monte Zenone, (Liguria, Italy). It is put on the market by the "Mineraria Italiana," Genoa, Via XX Settembre 3-17. According to the statement of the Firm, zenonite contains: 45-50 % dioxide of manganese — 3 % oxide of iron — 5 % calcium oxide — 0.5 % phosphorus — 37-42 % silica.

The experiments carried out by the author on the elongation of roots under the chemostatic action of manganese compounds, as compared with the effect of other salts, have shown the superiority of manganese dioxide in this respect, even in comparison with sodium nitrate.

It was found that plants with fleshy tubers or roots, such as potatoes, the *Liliaceae* etc., benefit greatly by deep treatment with manganese.

Other compounds of manganese, such as the chloride, carbonate and sulphate, were recommended and used advantageously as fertilisers. In almost every case manganese chloride, a salt that diffuses very readily, produced an increase in the yield.

The plant has no real need to use manganese as a food and hence the compounds of this metal do not act directly, but as catalysers, or rather as solvents. In fact, they gave good results whenever they were associated with other nutrient substances which form essential elements of the plants, food supply.

Dioxide of manganese not only plays an active part, in so far as it liberates oxygen, but also, on being transformed into manganic acid, it serves as a solvent for the otherwise insoluble substances present in the soil and thus acts as a potent agent for their removal. Potassium, calcium and magnesia are all rendered soluble by manganic compounds. Recent experiments have shown that the potash of leucite is rendered more easy of assimilation by the simultaneous application of manganese dioxide.

It is also well known, that certain important bacterial processes in the soil are rendered more intense and rapid by the presence of manganese; such for example is the case as regards nitrification, although the denitrification of the organic matter is hindered by the manganese.

Taken as a whole, the results of these experiments prove, that manganic fertilisers should be employed where there are reserves of substances requiring to be dissolved and quickly put into circulation, but if there is no such accumulation, manganese may hinder the development of the plant and retard the growth, especially of the green organs.

Certain plants derive benefit from a manganic fertiliser, while others do not, clover belonging to the latter class and white mustard to the former. In the case of cereals, the weight of the grain, but not always that of the straw, is increased by manganese.

Thus the application of dioxide of manganese as a fertiliser can be generally recommended as a useful adjunct for rich soil, or as a means of utilising the potassic reserves present in the soil. It may also be good for rice fields and " marcita ".

Manganic fertilisers are not more used because there is considerable uncertainty as to their application, a question needing many experiments: further these compounds are rare and expensive. They can, however, be replaced by soil from manganese-bearing deposits, which are by no means uncommon in Italy. Zenonite, which contains up to 45 % of the dioxide, makes an excellent substitute for pure manganese compounds.

A manganic fertiliser could be used with advantage for:

calcareous and magnesian soils;
leucitic, volcanic and felspathic soils;
soils rich in organic matter;
damp, poorly-aerated soils;
white, cold soils.

In other cases, it is possible that the addition of manganese would not increase the crop as much as other fertilising substances.

The addition of fertilisers to soil has sometimes the effect of causing the crop to develop late, such substances having a depressing effect upon the plants and retarding their growth. After a time however the plants grow more luxuriantly, the weight of the crop is increased and sometimes, the yield is larger than in the untreated fields. Such fertilisers should therefore be applied at the right date, some time before sowing, and with due regards to the general conditions of the environment (light, heat, damp).

Zenonite is a dark-coffee coloured powder with high specific gravity.

If applied at the time of sowing to haricot beans in pots with calcareous soil in which potatoes have been previously grown, it gives satisfactory results. In each pot, which is 21 cm. high, and 21 cm. in diametre, 40 gm. of zenonite are spread in two layers (one at some depth and the other near the surface), at the time of planting the seeds.

	Date of sowing Aug. 16, 1921	
	with zenonite	control without zenonite
Height of beans on Sept 5, 1921	15 cm.	20 cm.
Colour of leaves	light-green	dark-green
Appearance of leaf blade	extended	curled over at the edges

Later, the difference in height was less accentuated, and the height and lateral development of the beans fertilised with zenonite was greater than in the case of the control plants

1206 - **Contribution to the Study of Wheat Scald. — Researches on the Physical, Chemical and Agricultural Characters of the Grain, in Italy.** — DRAGHETTI A., (Forlì R. Laboratorio autonomo di Chimica Agraria), in *Le Stazioni Sperimentali Agrarie Italiane*, Vol LIV, pp 257-277. Bibliography. Modena, 1921.

The author reminds his readers that the actual composition and external appearance of wheat kernels alter considerably according to different conditions of climate, soil and cultivation; this is clearly shown by the phenomenon of scald, which is due to great heat and drought overtaking the crops before they are ripe, and does most harm to relatively late maturing varieties. The author mentions some data obtained respecting the yield of 22 kinds of wheat grown in a comparative acclimatisation experiment at the Experiment Farm of the " R. Laboratorio di Chimica Agraria " at Forlì, during two consecutive, but entirely different, years; one 1919, being nearly normal, and the other, 1920, exceptionally hot and dry during the spring months, the most important for the growth of cereals. Hence the interest of the data quoted, for they probably represent the greatest variations in the character of wheat kernels that can be attributed to meteorological conditions, and allow the following conclusions to be drawn.

The 1920 crop, compared with that of 1919, is characterised by: 1) lower germination, and a less degree of purity, the average percentages being respectively 5 and 4; the germinative property is similarly changed; 2) the lower weight of the individual grains in the case of all the late varieties, although the grain of the early and of some of the fairly early wheats, such as the Rieti Fam. 11, the Cervari, and the Sicilian Toselli was heavier, owing to their not being susceptible in the same degree to scald; 3) lower specific gravity of all the kinds except Rieti Fam. 11, and the non-lodging, half awned Fam. 96, although their kernels were smaller; 4) a certain irregularity in the size of the kernels, which in 1920 was generally greater in the case of the earliest varieties, less in the late ones, and almost equal in the moderately early kinds; 5) a high nitrogen and crude protein content in every case, except Apulia, a very early drought-resisting variety with normal grain; 6) the soluble nitrogen content does not appear to be affected by the stunting of the grain, for in some varieties it was equal or even higher, although all the other characters had been much altered

As regards the behaviour of the soft grain and the hard grain during these two years, it may be mentioned that: 1) the proportion of hard grains was highest (taking the entire harvest) in 1920; although the two hard Cologne varieties formed an exception to this rule, their hard kernels having greatly decreased in number in 1920; 2) the absolute weight, specific gravity and nitrogen content of the hard kernels varied within rather narrow limits whereas these characters showed considerable differences during these two years in the case of the soft kernels; 3) in consequence, while in 1919 the hard kernels were richer in nitrogen than the soft kernels of the same year, the reverse occurred in 1920; therefore the statement that hard kernels have always a larger nitrogen content than soft, is only true as regards wheats that have grown and ripened normally.

Plant and Culm

No. OF VARIETY LINE OR HYBRID	PLANT				CULM						
	Weight gm	Well developed culm	Weight of culm	Observations	Type	length in cm		No. of internodes	Diameter of lowest node	Quality of culm 1 = good 3 = bad	Observations
						without ear	including ear				

Ear and Kernels

EAR							KERNELS						
Weight in gm	No of nodes of rachis	No of atrophied or badly-developed spikelets	No of well developed spikelets	D = density of ear	P = productive value	% of husk and awns	Weight gm	No of kernels	Weight of 1000 kernels	% of kernels	Other observations	Quality	General notes special notes on the plot and on the different characters of each plant

What has already been said justifies the statement that good grain for bread-making is almost always characterised by the quality of soft kernels, the influence of the hard kernels depending solely upon the proportion in which they are present in the mass. This proportion is very variable from one season to another, but is much influenced by good cultivation and the improvement of the variety by selection.

As regards the effect of the conditions under which the plant has grown upon the physical and chemical characters of the kernels it must further be conceded that hard grains are a more highly evolved and persistent type, chiefly perhaps, on account of the position of the ear, which allows such kernels to develop more easily, even when the environment is not favourable to the parent plant.

1207 – **Organisation and Development of the "La Estanzuela" Phytotechnical Institute (Uruguay) for National Seed Production and Wheat Selection.** — I. BARRIOLA, P. J., in *Revista de la Asociación Rural del Uruguay* Year I, No. 5, pp 397-401, 4 figs. — II. DELLA ZOPPA J. G., *Ibidem*, pp. 393-396, 3 figs. — III. FISCHER G., *Ibidem*, pp. 386-392, 4 figs. Montevideo, May 1921.

I-II. — The Institute known as "La Estanzuela" is divided into two sections: the Phytotechnical Institute and the Seed Service ("Semillero Nacional"), one being complementary to the other.

The work of the Phytotechnical Institute chiefly consists in scientific and technical researches, undertaken with the view of obtaining selected seed and creating new types especially adapted to the different physiographical zones. It also includes the introduction, testing and acclimatisation of agricultural and forage plants. The personnel consist of the Director, assisted by two agricultural-engineers, a cultivator, laboratory assistant, and a staff of agricultural workers.

The seed service is entrusted with the general administration of the establishment, the breeding on a large scale of the types obtained by selection, the direction of the progeny fields on the farms set apart for breeding purposes and finally, the classification and sale of the products of selection.

The work is directed by an agricultural-engineer with the help of an expert, a chief cultivator and a staff of agricultural workers and labourers.

The land under the management of the Institute (418 hectares), is divided as follows: Experiment field No. 1: 3 hectares — Experiment field No. 2: 10 hectares — Experimental Rotation field: 10 hectares — Farms for seed breeding and the cultivation of forage plants etc. 250 hectares — Cattle enclosure: 90 hectares.

The remaining 55 hectares consist of the area occupied by buildings, threshing-floors, roads, etc.

In addition to the central building in which are installed the laboratory, museum and administrative offices, there are also a large granary for cereals, and a barn for keeping maize in the cob with a capacity of 60 000 kg.

The Institute also possesses a complete stock of agricultural machines, a herd of cattle, numerous draught-horses, a stock motor-plough and a complete equipment of graded sieves for the mechanical sorting of seeds.

The laboratory is provided with all the necessary apparatus for research work (genetic, botanical and chemical), while the experiment field is well supplied with the nets and isolation cages necessary for selection and hybridisation.

On page 1528 is reproduced one of the forms used at the Station for the registration of wheat selection returns.

III. — Hitherto, the most interesting results have been obtained from the work on wheat selection.

Some pure lines of distinct types have already been ontained, such as *Americano* 26*n* *Americano* 44*d*, *Pelon* 33*c*, and *Duro* 45*b*, which have retained for a considerable period their special characters combined with high yield.

Among the hybrids obtained by crossing these pure lines, the results of the cross (cross III) between *Americano* 26 *n* (♀) and *Americano* 25 *e* (♂) deserve special mention.

The data collected during the period 1919-1921 bring out very clearly the increased fertility of the hybrid (the figures refer to 3 of the best families), as compared with that of their two parents (See Table below).

Yield (in quintals) of grain per hectare of Cross III and of its parents

	1918-1919	1919-1920	1920-1921
Americano 26 n (♀)	14.1	15.6	11.1
Americano 15 e (♂)	10.7	13.8	9.4
» III a	19.4	—	—
» III a 2	—	17.3	—
» III a 21	—	—	17.7
» III b e	20.0	—	—
» III b e 2	—	14.4	—
» III b e 21	—	—	16.3
» III b u	21.4	—	—
» III b u 3	—	14.3	—
» III b u 31	—	—	11.6

Numerous crosses were carried out in 1919, especially, *Americano* 44 *d* × *Pelón* 29 *k* and *Duro* 106 *d* × *Pelón e*. In the F_1 hybrids, are found characters intermediate between those of the two parents, Pelón (awnless) being however predominant as regards awn development; in fact, the hybrids are either quite awnless or have short awns near the tip only.

1208 – **Sterility in Wheat Hybrids.** — SAX KARL, in *Genetics*, Vol. 6, No. 4, pp. 399-416. Baltimore, July 1921.

Partial or complete sterility is of frequent occurrence in crosses between distinct species. Within the same genus certain species are sterile when crossed, while other combinations are completely fertile. Partial sterility may cause the elimination of certain classes of gametes and prevent desired re-combinations of characters in the generation. Sterility may also occasion abnormal vegetative development. It is therefore desirable to determine the sterility relations of the species of economic genera.

The present study is concerned with the genus *Triticum*, and deals with the following points: 1) the endosperm development in fertile and sterile crosses — 2) hybrid vigour (heterosis) in fertile and partially sterile hybrids respectively — 3) lethal factors in wheat crosses — 4) sterility in the F_1 hybrids — 5) size of pollen grains in parents and hybrids.

The following species of wheat were used in this study.

Triticum vulgare:
  1) Pacific Coast Bluestem (of Australian origin);
  2) Amby (awnless wheat from Australia);
  3) Marquis.
Triticum compactum:
  1) Washington Hybrid 143 (from White Track × Little Club 1898)).
Triticum durum:
  1) Kubanka (Russia).
Triticum turgidum compositum:
  1) Alaska (bearded, with branching head).
Triticum polonicum:
  1) Polish.
Triticum monococcum.

As regards the possibility of reciprocal crosses, these species can be divided into 3 groups:

a) *monococcum* group: *T. monococcum*;
b) *dicoccum* group: *T. dicoccum*, *T. durum*, *T. turgidum*, *T. polonicum*;
c) *vulgare* group; *T. Spelta*, *T. vulgare*, *T. compactum*.

In making crosses, only 6 or 8 spikelets were left on an ear, the central flowers being removed. The remaining flowers were emasculated, and the ear wrapped in tissue paper both before and after pollinating, to prevent any access to foreign pollen.

The degree of sterility in the hybrids was determined in 2 ways:

1) The number of grains per spikelet was obtained for parents and F_1 plants.
2) The percentage of sterile pollen was determined (the anthers were detached and the pollen shaken out on a slide smeared with a fixative, a drop of lactic acid was added, and the preparation covered and sealed with Canada balsam).

I. THE F_1 ENDOSPERM IN FERTILE AND STERILE HYBRIDS. — The endosperm resulting from the immediate cross (that is to say, the endosperm developing in the fruit of the female parent), contains, on account of double fertilisation, chromosomes contributed by both parents. In wheat, the embryosac is derived from a single megaspore (one of the 4 resulting from the reduction division), and contains the haploid number of chromosomes. In the same way, the egg nucleus and the two polar nuclei also contain haploid chromosomes. The grain resulting from the immediate cross will be called the F_1 *grain* and the endosperm, the F_1 *endosperm*. The F_1

grain contains the embryo of the F_1 plant. The grains borne on the F_1 plant will be designated F_2 grains, and the endosperm, the F_2 endosperm; these grains contain the embryo of the F_2 hybrid.

When the hybrid grains (F_1 endosperm) were examined, it was found that all combinations which later proved to be partially sterile, had small wrinkled grains, while the fertile combinations had well developed grains often larger than those of the *female* parent.

These biometric data fully confirmed what has been said above.

II. — HYBRID VIGOUR (HETEROSIS) IN FERTILE AND PARTIALLY STERILE CROSSES. — The F_1 plants of the fertile and the partially sterile hybrids are taller than the parents. The fertile F_1 hybrids resulting from crosses of species in the *dicoccum* group are slightly taller than the average of the parents.

Parents		Sterile Crosses		Fertile Crosses	
Kubanka .	39.9	Bluestem × Kubanka . .	23.3	Bluestem × Amby . . .	51.6
Alaska . .	25.3	Kubanka × Bluestem . .	26.4	Amby × Bluestem . . .	31.7
Bluestem .	29.8	Bluestem × Alaska . .	23.1	Bluestem × Hybrid 143	53.5
Amby . .	38.6	Alaska × Bluestem . . .	22.5	Hybrid 143 × Bluestem	20.1
Hybrid 143	16.6	Kubanka × Amby . .	26.5	Amby × Hybrid 143 . .	43.0
Polish . .	39.1	Amby × Kubanka . . .	16.5	Hybrid 143 × Amby . .	29.2
Marquis .	28.8	Kubanka × Hybrid 143 .	29.7	Marquis × Amby	33.6
		Hybrid 143 × Kubanka .	15.7	Marquis × Hybrid 143 .	30.3
		Alaska × Amby . . .	24.8	Kubanka × Alaska . . .	48.2
		Amby × Alaska . . .	18.2	Alaska × Kubanka . . .	34.4
		Alaska × Hybrid 143 . .	25.4	Kubanka × Polish . . .	42.0
		Hybrid 143 × Alaska . .	14.6		
		Polish × Hybrid 143 . .	22.2		
		Hybrid 143 × Polish . .	17.4		
		Marquis × Kubanka . .	22.0		
		Marquis × Alaska . . .	18.5		
		Marquis × Polish	19.2		

The fertile crosses between *T. vulgare* and *T. compactum* result in F_1 plants, which are on an average, 7.3 ± 1.8 cm. taller than the average of the parents.

The F_1 plants resulting from crosses of members of the *vulgare* group and the *dicoccum* group are partially sterile. The height of these plants is however 10.5 ± 1.1. cm. greater than the average of the parent groups. 5 plants only of Alaska × *T. monococcum* were grown but though these F_1 hybrids were totally sterile, their height greatly exceeded that of their parents: 129.5 ± 2.8 cm., whereas the average height of Alaska was 102.3 ± 1.1 and that of *T. monococcum* 87.0 ± 1 cm., there being a difference of 34.8 ± 3.0 cms in favour of the hybrid.

It is thus evident that partially or completely sterile F_1 plants are often superior to the parents in vegetative vigour, even though they originate from small wrinkled seeds.

III. — LETHAL FACTORS IN WHEAT CROSSES. — The F_1 hybrids of the Bluestem × Amby cross (both members of the *vulgare* group), developed regularly till they reached the height of 15-20 cm. They then began to tiller excessively, as many as 40 or 50 primary culms being formed but in no case did a true culm develop. This unusual growth is probably due to lethal factors that prevented the development of the plant beyond a certain stage.

IV. — DEGREE OF STERILITY IN THE F_1 HYBRIDS. — This was determined by counting the pollen grains and the grains set per spikelet. With two exceptions, the grains set per spikelet on the parent plants ranged from 1.85 to 2.91. In the case of Hybrid 143, the number was unusually low, 1.49, which was due to late maturity and unfavourable climatic conditions, whereas the 0.97 of *Monococcum* represent a very high figure, as it normally sets only one grain per spikelet.

In the partially sterile crosses (*dicoccum* × *vulgare*), the number of grains set varies from 0.45 to 1.92; the hybrid *Alaska* × *monococcum* is completely sterile, producing no grain, but the fertile hybrids set more seed than their parents, viz from 2.43 to 3.64. Similar conditions are also observed as regards the percentage of the abortive pollen; from 0.3 (*monococcum*), to 1.9 (Kubanka) in the case of the parents, and from 11.5 (Kubanka × Marquis) to 21.5 (Kubanka × Bluestem) for partially sterile hybrids (97.7 for *Alaska* × *monococcum* completely sterile) whereas the amount of abortive pollen in the case of the fertile hybrids is almost the same as for their parents (0.4 for Bluestem × Hybrid 143, and 1.2 for Kubanka × Polish).

IV. — SIZE OF POLLEN GRAINS IN PARENTS AND HYBRIDS. — The size of the pollen grains differs greatly in the various species. The average volume of the pollen grains expressed in thousands of cubic microns is 72 for *T. monococcum*, 94 for Kubanka and Alaska (*dicoccum* group) and 144 for Marquis and Hybrid 143 (*vulgare* group).

TABLE II. — *Diameter of Pollen Grains in Microns*

Kubanka	55.6 µ	Alaska × *T. monococcum* (*p*)	39.7 µ
Marquis × Kubanka (*n.*)	63.1 »	*T. monococcum*	51.5 »
Marquis × Kubanka (*p.*)	48.6 »	Hybrid 143	60.1 »
Kubanka × Marquis (*n.*)	53.7 »	Alaska × Kubanka (*n.*)	57.0 »
Marquis	60.3 »	Hybrid 143 × Alaska. (*n*)	56.9 »
Alaska	57.1 »	Kubanka × Bluestem (*n.*)	57.3 »

(*n.*) = normal grains — (*p.*) = poor grains.

The variability in size of pollen grains is greater in both the fertile and partially sterile F_1, hybrids than in the parents. In the partially sterile hybrids all degrees of compatible and incompatible combinations are probably present in the pollen grains. The pollen grains of the F_1 plant contain the haploid number of chromosomes contributed by both parents. We may assume that some combinations are unable to function and the pollen grains abort at an early stage in development. Other combinations are able to function more or less favourably, resulting in apparently good pollen grains of varying sizes. In the fertile hybrids, and to some extent in the partially sterile hybrids, the increased variation in the size of the pollen grains may be attributed to differences in growth factors, resulting from various combinations of maternal and paternal chromosomes. Here we have a case of variation in the haploid generation due presumably to different combinations of non-homologous maternal and paternal chomosomes.

1209 – **White Sheath, a Transmissible Character of Maize.** — KIMPTON, J. H., in *The Journal of Heredity*, Vol. XII, No. 5, pp 224-226. 1 fig Washington, May 1921.

White sheath is a variation in which the leaf-sheaths and husks fail to develop chlorophyll and remain white.

This character appeared simultaneously in two sister progenies of the Pawnee variety obtained by self-pollinating the original strain for 2 years.

In both progenies, the number of plants with white sheaths indicated that the character was a simple Mendelian recessive, the actual numbers being respectively 29 green and 11 white: 30 green and 12 white, according to the ordinary 3: 1 ratio. When these variegated plants are crossed with others having normal sheaths, the F_2 consist exclusively of green-sheathed individuals.

1210 – **A Study of the Segregation of a Quantitative Character in a Cross Between a Pure Line of *Phaseolus* and a Mutant from it.** — LEITCH, J., in *Journal of Genetics* Vol. II, No. 2, pp 183-202, figs. 4. Cambridge, September 1921.

In 1901, Prof. JOHANNSEN obtained from seeds of a variety of *Phascolus vulgaris nana* known as Brown Princess beans, a number of pure lines, one of which, line E, is distinguished by having pure white petals and a yellow-white colour in the rest of the flower, without a tinge of violet. The other lines have a violet tinge, often weak but quite unmistakable.

Line E has twice shown a sudden change in genotypical constitution, without any alteration in the white colour of its flowers. One of the mutants, M (long mutant), is distinguished by the greater length of its seeds. Thus we have:

Original type	Length	12.459	Breadth	9.017	I	72.1
Long Mutant	»	13.564	»	9.137	I	67.4

(I is the length-breadth index).

The question being one of quantitative characters, it is a matter of great interest to determine whether they obey MENDELS' laws.

In order to settle the point, the author crossed E and M, obtaining 3 hybrids producing 62 seeds. Two only of these were discarded, the rest being sown in 6 rows and the resulting crop examined in the autumn of 1914.

In his biometrical determinations, the author used distribution curves for the length of the seeds, and also a system of dotted charts.

In plotting the curves, the lengths of the seeds were used as abscissae, and the frequency or number of cases, as the ordinates ; in this way, a curve for each of the lines sown could be plotted.

In the charts the lengths are the abscissae, and the indices of length are the ordinates. The length index is obtained by dividing the length (L) by the breadth (b) and expressing the quotient as % $\frac{(L\ \%)}{b}$. Each plant is represented by a point whose coordinates are respectively the average length and index of its seeds. The plotting was done on transparent mm. paper. This gives an immediate picture of the position of every hybrid in relation to the two parent lines.

These biometrical determinations, which were begun in 1914 and continued until 1918, prove that:

1) In the two cases examined, the hybrids between E and M showed no evidence of segregation (intermediate constant form).

2) On the other hand segregation occurred in most cases in : type M + a new type X shorter and broader than E + an intermediate type that again split, while M and X remained constant. In this case, the ratio of non-M plants (E or X) and M plants is as 3 :1.

These results show that immediately the new X type was established, the theory of mutations being due to the loss of a factor or factors cannot be applied to the present case. No system of recombination of factors (cumulative or otherwise) could explain the appearance of a new type with biometrical characters lying outside the limits of the two parents. The difference between E and M must be regarded as a case of positive actual difference, and not as a case of *presence* or *absence* of a factor or factors.

The simplest view seems to be that one factor has been modified in the original pure line, to give the mutation.

Why not more than one factor ?

1) the segregation according to the ratio of 3: 1 confirmed by the 1916 results, and 2) the fact of there being no splitting in the X and M groups seem sufficient indication that one genetic factor only has been altered in E.

1211 - **Sugar Beet Seed Growing in the Rocky Mountain States.** — TRACY, W. W. (Technologist, Office of Sugar Plant Investigations), in *Farmers Bulletin* 1152 *United States Department of Agriculture.* Washington, D. C., October 1020.

The production of sugar beet seed in the United States is now an established and apparently profitable industry in several sections of the country. Development has been most marked in the irrigated sections of Colorado, Montana, Utah and Idaho. The author gives a description of the methods employed in the Rocky Mountain States and the suggestions made refer to operations on a large scale.

Details are given as to the size of roots for seed, time to sow for stecklings (i. e. small roots used for commercial seed production), spacing, preliminary germination tests before planting, tillage, harvesting, silage, threshing and cleaning.

In addition to the commercial production of sugar beet seed the development of new and improved strains of beets is under study and experiments are being made.

1212 - **Trials of Foreign Cereals in Algeria.** — DUCELLIER, L. (Professeur d'Agriculture à l'Ecole de Maison-Carrée), in *Bulletin agricole de l'Algérie-Tunisie-Maroc*, Year 20, No. 10, pp. 218-219. Algiers, October 1921.

The trials of foreign cereals, that had been discontinued from 1915-1918, were resumed during the season 1919-1920, at the Agricultural College of Maison-Carrée (Algiers) (1). The results obtained before the War were not satisfactory as regards most of the varieties tested, which as a rule, showed less resistance to rust, drought and heat than those habitually cultivated in Algeria.

The varieties giving results most similar to those obtained by cultivating the Algerian kinds were as follows:

Red awned Winter wheat — Dubosc Farm Wheat. The latter is known in Orania under the name of "Tuzelles de Descartes"; it much resembles the Red March Bordeaux Wheat and the Provence Red Wheat.

Awned March Wheat — Late Richelle Wheat — Six-rowed Spring Barley — Six-rowed Winter Barley — Russian Barley (known in Algeria as foreign barley), little valued on account of its small, hard grains that are not digestible when fed whole to stock — Imperial Barley of Italy — Chevalier Barley — Princess of Swalöf Barley — Black Carrée Barley — Large awnless Barley of Siberia or Thibet — Small, awnless Barley, or "orge celeste" — White Ligowo Oats — Grey Winter Provence Oats — Oats of Naples, or of the Abruzzi.

The foreign cereals cultivated in Algeria usually make a very fine show when they first begin to grow, from germination until tillering, but subsequently, the effect of the environment is clearly seen in the case of certain varieties, which sometimes only succeed with the greatest trouble in producing some inflorescences, being arrested in their development by rust, or intense heat, according to district. Others continue their evolution but bear poorly-developed and sometimes wrinkled grain of no value. Finally there are a very few varieties, that bear grain suitable for sowing the following season. Amongst these, some have persisted, but they become gradually weaker, and lose all their good qualities at the end of a few years; hence it is necessary to use new seed corn. This is well-known to occur in the case of the Bel-Abbès Tuzelle, or Awnless Odessa Wheat, which is the only variety cultivated on large areas in Algeria. At Maison Carrée, the best results are obtained from Awnless Odessa Wheat after the 2nd generation. Tuzelle de Descartes is chiefly confined to the neighbourhood of Tlemcen, and Bel-Abbès where so far, it seems to have retained its good quality. The other varieties of wheat mentioned above can hardly properly be said to be cultivated, but are met with here and there generally mixed with Awnless Odessa Wheat and Tuzelle de Descartes. Manitoba wheat has been tried in different districts; its grain although almost normal, is still little in request by the corn merchants, or flour export trade of Algeria. A study of the elements composing this mixture would however be of interest

---

(1) See *R.* June 1921, pp. 711-718. Original Article by BRUNEL, entitled *L'Institut Agricole d'Algérie*. (*Ed.*)

Barley adapts itself better than the other cereals to the climate of Algeria, especially the five-rowed Russian variety, black barley and awnless barleys. The latter seem not to suffer from the climate of North Africa any more than the Algerian square barley, and they produce good grain. In spite of this, square barley only is cultivated on a large scale in Algeria. The small awnless barley, or Orge celeste, is grown by the natives, who call it " Chair en Nebi, " or Barley of the Prophet. Its grain is but little used, therefore it is cultivated on very small areas only. Amongst the square Algerian barley are to be found some heads of Russian barley (Bel-Abbès), Black barley, the Six-rowed Barley (Sétif) and Escourgeon, but only in very small proportions. The two rowed barleys soon die out owing to different causes, early-ripening, shelling, etc.

As regards oats, none of the foreign varieties have yet proved superior in yield to the Algerian red oat. The Naples variety does not differ in any way from the Algerian oats cultivated in other parts of the East Mediterranean region, Greece, the Archipelago, etc. The grey variety is little represented in Algeria, and only seen mixed with the red Algerian oats. The few grey kernels to be found in consignments of Algerian oats are less fine in quality than those grown in Provence, Poitou and Brittany.

In 1907, the author discovered among the oats of the Algerian Red variety, a white, still undetermined oat, very noticeable on account of the nodes of the culms which are covered with characteristic whitish hairs; the flowers of this variety are sometimes awnless. This oat produces a fine white kernel more slender than that borne by the Red Algerian variety; on the sea-coast, it appears more susceptible to rust than the latter.

The same conditions obtain on the High Plateaux, where however it is not rust that prevents the growth of foreign cereals, but heat and drought, for when these set in suddenly, they produce scald which affects most of the foreign crops. The possibilities of acclimatisation are greater in some of the higher, and more favourable localities such as the neighbourhood of Médéa, Tlemcen, etc.

In trials made during the year 1919-1920, wheat varieties or hybrids, from the Mediterranean region were chiefly tested. SCHRIBAUX, Director of the Seed Station at Paris, sent to the author 22 fine varieties obtained either by himself, or by STRAMPELLI, Director of the Cereal Cultivation Experiment Station at Rieti, or by F. TODARO, Professor of the University of Bologna. These wheats were sown on December 31, 1919, a little late, in the experiment field of the School of Agriculture at Maison

Carrée, in siliceous clay soil, well prepared by a crop of spring mangels, and in excellent conditions as regards moisture and temperature.

Fertilisers: 300 kg, of 16/18 superphosphate dug in by a gang plough followed by a pulveriser.

Sown in rows 33 cm apart (1).

Thanks to the temperature, which kept relatively high after sowing, and also to the moisture of the soil, the seeds came up very regularly, generally within 12 days after sowing, except in the case of one variety of wheat, Bobs, which took as long as 14 days. This is probably due to the present character of the variety, which is not homogeneous, being composed of 3 kinds of wheat, which are identical as regards shape and size of grain, but differ in growth and character of ear.

The growth of these varieties, on account of the progressive rise in temperature, was only slightly checked after the seed came up, and in the first fortnight of February, tillering was practically finished. At this time all the stools were regular and entirely covered the ground. It is stated that the leaves of these varieties were generally smaller than those of the varieties which have adapted themselves to the climate of Algeria.

Rust suddenly made its appearance on all the wheats during the second fortnight in April; in some cases the lower leaves were almost destroyed by the parasite. The sorts that suffered were chiefly:

Square-eared Wheat × Krelot — Bologna Wheat No. 38 — Rieti Wheat × Japhet A 1 — Bologna Wheat No. 96 — Rieti Wheat × Japhet A 3.

The following were also attacked, but to a less extent:

Rieti Wheat × Awned Japhet — Bologna Wheat No. 48 — Early Saunders Russian Wheat — Bologna Wheat No. 12 — Fédération Wheat — Carlotta Strampelli — Bologna Wheat, No. 33 — Aurora — Bologna No 8 — Bologna No. 1 — Bologna No. 20 — Rieti Wheat.

The effect of rust has not yet been determined as regards the Bobs and Manitoba wheats, which are populations including many varieties or kinds, some of which appear likely to be useful in Algeria.

---

(1) This space between the rows has been adopted in the case of the experiments made at Maison-Carrée as the result of various trials begun in 1908. Of all the different methods adopted (sowing in rows from 20 to 80 cm. apart), none has, so far, proved better or more practical than that of leaving a space of 25 to 35 cm. between the lines, whether as regards the utilisation of the soil by the plants, tillage, or quality and crop yield. The ground of the experiment field was hoed twice, at suitable times, between the germination of the seed and the moment when the cereals cover the soil with their leaves, thus forming a screen, after which they resist drought better. The crops are only harrowed once, the time selected being more or less suitable and before the growth period; this single operation is quite insufficient in Algeria, especially in dry years, when the rainy periods occur at long intervals, and the rainfall is very small. The same observation was made at Sétif (see: A. CHOLLET, La culture sarclée des blés, in *Revue agricole*, Sept. 3, 1920), and in other parts of Algeria (Orania). On the other hand, the spaces left between the rows must not be excessive, for DUCELLIER has found that cereals sown widely apart are more severely attacked by rust than those seeded broadcast. (*Author's Note*)

[1212]

In this experiment, it was again found that the injury caused by rust did not appear to bear any strict relation to the severity of the attacks. The size of the spots, and their position, seem to acquire special importance when these patches occur in large numbers on the sheath, lower portion of the leaf blade, or the upper part of the culm. In this last case, it seems clear that the migration of the substances elaborated by the leaves was considerably interrupted, for some patches covered nearly the whole width of the sheaths or base of the leaves Special experiments should however be made to prove this.

The rust attack was less intense during the last agricultural season, which was particularly dry, than in wet years and the upper leaves of some varieties of wheat were able partially to fulfil their functions.

As drought supervened upon rust, their combined effect hindered the development of some already very weak varieties such as:

Bologna Wheat No. 38 — Rieti Wheat Japhet A 3 — Square eared Wheat Krelof — Carlotta Strampelli — Rieti Japhet A 1 — Bologna No. 6 — Bologna No. 11 — Bologna No. 96.

The monthly rainfall at Maison-Carrée from September 1919 to June 1920, was respectively (in millimetres): 48-71-29-81-24-70-62-16-13-23; total 437. There was thus but little moisture in the soil and as a rule only the surface was damp.

The rain of September and of the first fortnight in October had no effect upon the soil moisture, evaporation being complete. The May, rains, although more plentiful, were of no benefit to the Maison-Carrée cereals on account of their stage of development. The June rains fell at the end of the harvest.

The amount of water therefore at Maison Carrée that could actually be turned to account, was only about 300 mm., a deficit of nearly 200 mm. on the mean registered rainfall, the average annual rainfall being 500 mm.

This deficit was the more serious on account of the small amount of rain that had fallen in January and April; the light falls of these months having been frequently preceded or followed by drying winds or periods of high temperature.

The hot dry period lasting from May 9-14)(25° C to 35° C), was most injurious to the varieties under trial at Maison Carrée, the growth in most cases being suddenly arrested.

Flowering took place during the second half of April, and in the case of all the varieties (except Bobs which had 3 fertile flowers) the two lower flowers of the spikelet set and produced two seeds

The varieties that did best were:

Bobs Wheat Bologna No. 12 — Early Russian Saunders Wheat — Aurora — Rieti × Awned Japhet Bologna No. 91 — Bologna No. 33 — Bologna No. 16 — Marquis.

They ripened early (end of May), for there was no great difference beween the time each variety matured, although in a normal year, it would have been at least twenty days before all the wheats reached maturity. This therefore must be regarded (except in the case of Bobs) as an abrupt cessation of growth, rather than as the normal close of the vegetative period. The grain produced by Bobs was very similar to that used for seed-corn.

The grain of Bologna No. 12 was also very like the seed planted but rather narrower.

All the other wheats gave a smaller grain, usually of slightly darker colour than the samples. Their appearance leaves much to be desired from the Algerian commercial standpoint, for preference is given to the supple, fine, white or yellow wheats which, as a rule, prove the hardiest in Algeria.

The grain and straw returns obtained are as follows (in kg. per hectare): Manitoba, 440; 3600 — Rieti, 850; 4720 — Early Russian Saunders 940; 4060 — Carlotta Strampelli 450; 3730 — Bologna No. 12, 650; 2600 — Bologna No. 11, 300; 1650 — Bologna No. 1, 800; 4300 — Bobs, 1100; 2860 — Bologna, No. 29, 850; 2450 — Fédération, 900; 3750 — Aurora 1420; 4970 — Rieti × Awned Japhet, Hyb. Station 1100; 4460 — Bologna No. 91, 1300; 4260 — Bologna No. 33, 1280; 3380 — Bologna No. 8, 250; 2050 — Marquis, 920; 4080 — Bologna, No. 48, 900; 2950 — pedigree kinds obtained at Maison-Carrée: Mahon, No. 17, 1570; 5230 — Mahon No. 49, 1920; 7320 — Mahon No. 2,2250; 8050 — Mahon No. 10, 2500; 8500 — Mahon No. 15, 2950; 9420 — Mahon, No 28, 3050; 1050. These kinds were as a rule little attacked by rust and yielded grain of average or good quality.

The wheats, Bologna No. 38, Rieti × Japhet A 3 Station, Bologna No. 90, Epi Carré × Krelof Hyb. Station, Rieti × Japhet A, Hyb. Station were not able to set any grain.

As regards rust resistance and the quality of the grain, the following observations have been made.

Manitoba: patches of rust on culms and sheaths, more numerous usually on the leaf-blades. Mixed variety: 1) with red awnless ear, kernels red, short; 2) awned red ear, grain short, very small; 3) white awnless ear, grain red, short. Small grain of marketable quality

Rieti: sheaths little affected by rust, leaf-blades more attacked. Grain wrinkled, quality inferior.

Early Russian Saunders: Numerous patches of rust in sheath and blade of upper leaves. Grain a little wrinkled, of average quality.

Carlotta Strampelli: Traces of rust on the sheaths, more on the leaf-blades. Scalded. Grain of inferior quality, much wrinkled, irregular.

Bologna No. 12: Rusted on culms, sheath and leaf-blades. Large grain of good quality, pure variety bears 6-7 infertile spikelets at the base of the ear.

Bologna No. 11: Traces of rust. Grain of inferior quality.

Bologna No. 1: Little rust on culms and sheaths, more on leaf-blade: 6-7 infertile spikelets per ear. Grain wrinkled, irregular, quality below the average.

Bobs: irregular growth. Mixture formed of several varieties: 1) ear white and yellowish, awned, grain short and yellowish; 2) ear red, semi-awned, grain short; 3) ear yellowish or reddish, awnless, grain short, yellowish. The 3rd variety is less attacked by rust than the others. Grain of good quality.

Bologna No. 29: Like Bologna No. 12, except that the quality of the grain is inferior.

Fédération: Leaf-blades much rusted. Traces of rust on the sheaths Half-scalded. Grain of inferior quality, scarcely marketable.

Aurora: Has a few patches of rust on the culms, but more at the base of the sheaths and on the leaf-blades. Grain of average quality, homogeneous.

Rieti × *Japhet*: Irregularly attacked by rust at the base of the sheath and of the leaf-blade. Large grain of average quality.

Bologna No. 91: Little rust on the sheaths, more on the leaf-blades. Large grain, quality scarcely average, homogeneous.

Bologna No. 33: Irregularly marked with rust. Grain short, homogeneous, quality below the average.

Bologna No. 8: Rust on sheaths and blades of upper leaves. Grain homogeneous, of very inferior quality. This variety suffers greatly from drought.

Marquis: blade of leaf attacked by rust, sheaths and culms little affected. Grain short, small, average quality, homogeneous.

Bologna No. 48: Much rusted at base of sheaths and leaf-blades Some individuals suffer more than others. Grain homogeneous, wrinkled, quality scarcely average.

If classified according to yield, which varies from 250 to 1250 kg. per hectare, these wheats come below the Algerian varieties grown on the same soil, the yield of the latter being between 1970 and 3050 kg. per hectare. The comparison of the yields, is however only given as a guide and to show the effect of early sowing in Algeria.

The sowing of the Algerian varieties in the experiment field belonging to the College was finished by the end of November. The difference of one month between the dates of seeding would partially explain the differences reported between the yields of the European and African wheats

Some other varieties of cereals were also tested, such as: Pétanielle de Nice, Awned Blé de Mars, Blé hybride des Alliés, Chevalier barley, Princess of Swalöf Barley, White Ligowo Oats, Grey Houdan Oats, Black Hungarian Oats. Negative results were obtained in the case of: Pétanielle de Nice; Blé Hybride des Alliés, Houdan Oats, and Black Hungarian Oats.

The condition of the European varieties during growth, their yield, and the quality of their grain justify the following conclusions.

They are less drought resistant than the local varieties.

Their period of winter repose is longer than that of the African varieties.

They grow more slowly and, as a rule, their vital processes slacken as soon as the heat begins in April or May.

Their rust resistance is inferior, owing to some extent to their mode of growth.

The grain ripens more slowly.

[1212]

These conclusions corroborate in the main those previously made at Maison-Carrée respecting the chief European and other varieties. Therefore fairly early wheats only give the best results in Algeria. The very early sorts, as for instance those from the Sahara, do not suceed better than the former, are destroyed by rust, or else by damp, which makes them shed nearly all their flowers, while the latter are checked in development by drought or rust according to district. Sahara wheats sown in December have headed in February-March, but the flowers were not fertilised. Early Lapland barley planted on December 5, continued to head from February 21 to April 15 without giving any results.

On account of the meteorological conditions of the year 1919-1920 which were unfortunately most unfavourable to cereals throughout Algeria, and prevented a complete valuation of the varieties tested, the most productive varieties will be grown again for the purpose of comparing them with the wheats that have been selected at the College.

1213 - **Experiments in Treating Wheat Grain by Immersion in Nutrient Solutions, in Italy.** — D'IPPOLITO, G. (Modena, R. Stazione agraria), in *Le Stazioni Sperimentali Agrarie Italiane*, Vol. LIV, Parts 7, 8, 9, 10, pp. 218-256 Modena, 1921

Experiments in treating wheat grain with solutions of different salts at varying degrees of concentration: some of the solutions used are known for their power as fertilizers and their effect as stimulants. These experiments were carried out in earthen boxes (29 wheat seeds being planted in parallel rows in each), they were continued until the 21st day, by which time, the seedlings were about 20 cm. high. The seeds were treated in 3 series: 1) for 6 hours with 5 % solutions of respectively calcium phosphate, potassium, sodium, ammonium, and of calcium ammonium, and potassium nitrates and subsequently wih 20 % copper sulphate and quick-lime for 20 minutes. The results were compared with those obtained by immersing the grain for 6 hours in ordinary water, and then in some anticryptogamic substance, like those mentioned above, and were also compared with the results of control experiments. 2) For 1 or 2 hours with 20 % solutions of phosphate of ammonium, calcium, potassium and a 2-5-10 % solution of sulphate of potassium, and also for 5 and 24 hours with these last solutions; they were also given the same anticryptogamic treatment. For purposes of comparison other seeds were heated with ordinary water or left untreated. 3) 1-2-5-24 hours immersion in 0.050-0.10-0.15.0.20-0.30 % solutions of sulphate of manganese (for 5 hours only in the two last solutions). These experiments in boxes were completed by others made in the open on plots of 200 square metres: 1) seed treated with a 5 % solution of calcium nitrate for 6 hours — 2) *id.* of calcium phosphate — 3) *id.* of commercial manganese 3 parts per 1000 for 24 hours. — 4) *id.* pure, 30 parts per 1000; 5) with 4 % potassium sulphate — 6) with ordinary water for 6 hours.

The results of these preliminary laboratory experiments do not justify any conclusions as to the good effect to be obtained from fertilising seed by immersing it in nutrient solutions, for not only did both the nitrates and phosphates fail to produce any noticeable improvement, but the nirates, after a certain point, proved distinctly injurious. Sulphate of potassium however though its fertilising power is inferior to that of the phosphates and nitrates appears to have been of some advantage.

Sulphate of manganese, on the other hand and to some extent ordinary water were very beneficial.

As the open air experiments proved quite satisfactory it may be supposed that the advantages accruing from the immersion of seeds in ordinary water may be due to some special stimulating effect exerted by the latter on cellular activity, manifesting itself later in the stronger development of the root system, and consequently of the whole seedling.

Further the negative results obtained by treatments with phosphates and nitrates disprove the hypothesis that the fertilising substances penetrating by absorption into the seed can afterwards affect the plant at a more advanced stage of growth. It would indeed be impossible to explain why the seedling does not at once use the nutrient elements at its disposal, during the period when it most requires them.

The field experiments finally dispelled all doubts on the subject, for the plants that continued developing with greatest vigour throughout the entire period of growth, and hence gave the best yield, were precisely those that had shown their superiority from the earliest period.

Another important fact was demonstrated by the field experiments viz., that even allowing for the experimental errors always accompanying such tests it was clear that the plots yielding the finest crops were those sown with wheat treated with sulphate of manganese. Since it cannot be supposed that the manganese had a fertilising effect, owing to the small proportions (3 in 1000) in which it was used, it is most probable that it acted as a stimulant. Thus support is given to the new theory put forward by many investigators engaged in the study of the question, namely that manganese plays the part of an active oxidising agent, not only directly but also indirectly transporting oxygen and fixing it in the soil.

In any case the results obtained naturally cannot be regarded as final, and it will be necessary to repeat the experiments under more favourable cultural conditions in the hope of reaching definitive conclusions.

1214 - **Preliminary Classification of the Wild Rices of the Central Provinces and Berar, India.** -- ROY, SUDHIR CHANDRA, in *The Agricultural Journal of India*, Vol. XVIII, Pt. IV, pp. 365-380. Calcutta, July 1921.

Report of investigations as to the character and nature of the wild rices found growing in the "nalas" and waste lands of the Central Provinces and Berar, India. Earlier results dealing with the classification of the cultivated rices are to be found in the *Memoirs of the Department of Agriculture in India* (Botanical Series), Vol. VI, No. 7, Dec. 1913 by R. J. D. GRAHAM. The economic importance of the study of wild rices is evident owing to the fact that heavy losses have been incurred through contamination of the cultivated rices through casual mixture and natural crossing and much trouble has also been caused by the spread of wild rices as a weed.

Seeds of over 100 different samples were obtained from all the districts of the Provinces in question and were sown on the College Farm, Nagpur. In most cases, except where whole ears were available, the samples were found to be mixed in varying proportions of the different types of wild and cultivated rices. By single plant selection, ears of 536 individual plants were collected separately and line cultures were easily obtained.

Occurrence. — Wild rices are to be found on the margins of tanks, rice fields or other marshy or low lying places not actually submerged, but containing enough moisture to carry them through the season.

Characteristic features. — Morphologically there is very little difference between a wild and cultivated rice, but generally speaking the former may be recognised by the spikelets having dark red grains inside, by the presence of long stout awns, red, scarlet or green in colour, and lastly by its characteristic habit of shedding the spikelets in the green stage, long before they appear to have become quite ripe. The ripe grains in many of the varieties were noticed sometimes to develop a peculiar light black or ashy colour, here refered to as " wild " type colour. This is a special feature and is not generally found in cultivated rices.

Pollination. — The glumes open out between 8 and 9 a. m. as in cultivated rices but remain open for a longer period (about 1 hour or more), and the anthers do not burst till they get slightly warmed by the heat of the sun for about 2 to 5 minutes. The stigmas come out immediately on the opening of the glumes and remain in that position for some time and in most cases fall over and assume a pendent position. Occasionally dehiscence takes place before falling, but as a rule it does not occur till about 2 to 5 minutes from the opening of the glumes. During this period the chances of cross pollination are certainly considerable and hence apparently the much higher percentage of crossing met with in the wild than in the ordinary cultivated rices when the pollination generally takes place inside the closed glumes, the anthers bursting either before the opening of the glumes or just at the time of opening and thus encouraging self-pollination.

Natural Crossing. — By single plant selection it was found that, though the majority of lines bred true, some showed distinct signs of splitting proving the selected plants to have been heterozygotes. Tables give the results of the F_2 generation of some of the natural crosses obtained in the wild rices during the years 1917 to 1919. The following characters have been found to behave as Mendelian units in the wild rices: — The green or red colouring of the leaf sheath, black or straw colour of the ripe grain and the clustering or non-clustering habit of the spikelets ; of these the characters of the coloured leaf sheath, the ripe black grain and the clustered spikelets have been found to be dominant and segregating characters.

Classification. — An artificial key to all the types collected is given, classified according to colouring of grain with leaf-sheath green and also with leaf sheath red or purple, with a description of 24 different types.

Economic Aspect — The method recommended to eliminate these wild forms from a cultivated rice field is to grow some coloured rice (preferably the purple rice) in the fields which show an abundance of wild rice. This rice, being purple all over, will allow all the green rice plants to be uprooted without any loss, and with careful weeding the land should be quite free from wild rice the following year. Another method which could be adopted as an alternative is to keep the land bare of any crop for 6 to 8 weeks after the starting of the monsoon. Seeds of cultivated rices should be sown in seedbeds known to be free from wild rice and transplanted to the fields where in the meantime the wild rice has grown and been uprooted

1215 - ***Phalaris bolbosa* in the Province of Tucumán, Argentina** (1). — SCHULTZ, E. F., in *Revista Industrial y Agricola de Tucumán*, Vol. XI, Nos 5-6 pp 63-70, 9 figs. Buenos Ayres, October-November 1920.

The Agricultural Engineer, A. Y. BOTTO, Chief of the Agricultural Division of the National University of Buenos-Ayres, has introduced *Phalaris bulbosa* into Argentina, and considers it an excellent forage plant for the coast provinces. It has spread rapidly throughout the coast and central regions where it is grown, especially in winter, as a perennial forage crop.

Phalaris bulbosa has been tested since 1915 at the Tucumán Experimental Station, and is there regarded as being not suited for growing on a large scale in the province, for it is a plant requiring a more temperate climate, free from the sudden and great changes of temperature and more particularly the excessive heat of Tucumán, where the thermometer frequently registers over 45° C. Another cause militating against the success of *Ph. bulbosa* is the drought which usually persists from May to October and is accompanied by great evaporation. Hence this plant can only be grown in the district with the assistance of irrigation, or in soil where the moisture always rises to the height of its roots. Where however irrigation is possible, and the water does not stagnate, lucerne is a more paying crop than *Phalaris bulbosa*.

On soil capable of irrigation *Phalaris bulbosa* produces a regular crop of green forage of good quality, but much inferior in quantity to the amount of lucerne which could have been obtained from the same land, even without irrigation. Thus in 1919, with irrigation and in 4 cuttings, 399 quintals of *Ph. bulbosa* were obtained per hectare, whereas the crop yielded by a contiguous, non-irrigated plot under lucerne amounted in one year to 598 quintals per hectare.

In the district of Tucumán, green forage is scarce, especially during the winter months (May to October), that is to say, at the very time when the cuttings of *Ph. bulbosa* are poorest. The usual custom of sowing from March to May, barley, oats and rye to be used as winter forage is far more profitable as these cereals seldom yield less than 2 good cuttings, with a total crop of 250 quintals per hectare, until they are dried up by the October heat.

---

(1) See *R.* Oct. 1915, No. 1036. — For information respecting other varieties of *Phalaris*, see *R* 1914, No 732; *R.* 1915, Nos. 808 and 1036; *R.* 1917, No. 517; *R.* 1919, No. 870, *R* 1920, No. 197.

Naturally, *Ph. bulbosa* produces larger crops, if frequently irrigated Thus at the Tucumán Agricultural Station, one plot of ground yielded: in 1917, with 12 irrigations and 4 cuttings, 440 quintals of grass per hectare, in 1918, with 8 irrigations and 4 cuttings, 349 quintals per hectare; in 1919, with 7 irrigations and 4 cuttings, 399 quintals per hectare, and in 1920 (up to the end of July), with 1 irrigation and 2 cuttings 466 quintals per hectare.

Ph. bulbosa is propagated either by seed, or by dividing and replanting the stools. Seeds sown in the autumn, at a depth of 1 or 2 cm. and on well-prepared soil, germinate in a few days. For the first 3 or 4 months, the seedlings are weakly, and easily suffocated by weeds, unless frequently hoed. Laying down a field of this grass is therefore an expensive undertaking and still more costly if recourse is had to propagation by tufts (replanting).

Under very favourable conditions (110 mm. of rain from Aug. 29 to Sept. 1), it has been possible to obtain a first cutting at Tucumán, 6 months after sowing or replanting. As a rule the first cutting is taken 8 months after sowing or replanting, and these operations are generally performed in March or April.

Ph. bulbosa begins to flower at Tucumán at the beginning or middle of November, and the seeds ripen at the beginning or middle of December

The plant has shown great powers of resistance to cold at the Station having borne temperatures ranging from —6° C to —8° C. without any visible effects upon its young leaves. It also enjoys complete immunity from all forms of diseases

1216 - ***Andropogon purpureo-sericeus*, and Its Importance in the Improvement of Grazing Areas in the Bombay Deccan, India.** - KULKARNI, L. B., in *The Agricultural Journal of India*, Vol. XVI, pp. 388-395, pl. 1. Calcutta, July, 1921.

After reference to foregoing trials made with the wild indigenous fodder grass, *Andropogon purpureo-sericeus* 1912-15, the author proceeds to describe in detail the experiments carried out on three plots in the Government House compounds at Ganeshkind, near Poona, 1916-18. The seed was sown indiscriminately with those of other species and comparisons were duly made, and the following facts noted.

1) *A. purpureo-sericeus* grows well on all types of soil and is therefore suitable for poor land; it grows tall and quickly and yields alone up to 5000 lb. green grass per acre; hence its usefulness for silage.

2) It suppresses *A. contortus* which hitherto has been the dominant crop on the vast area of poor land of the Bombay Deccan. It was reported that *A. purpureo-sericeus* even in its dry stage was eaten by dairy

cows and maintained the milk yield in the absence of *A. Sorghum* stalks in May, while *A. contortus* was not touched by them, a fact which proves the superiority of this species as a fodder over *A. contortus*.

3) It resists drought conditions to a great extent.

This fact was further tested by actually counting the number of seedlings from a measure of 3 × 3 ft., in the experimental area affected by drought and by re-counting those that survived. The proportion was upwards of 84 %.

In 1919, 4 oz. of seeds of each of the following species were mixed together and sown broadcast in the beginning of June in a small plot of poor soil. The following shows the composition of the different grasses in weight and the height to which they grew.

Annuals	Weight	Height
	lb.	ft.
A. purpureo-sericeus	13	6
Anthesteria ciliata	4	5
Apluda varia	2	4
Ischaemum sulcatum	1	2
Thelepogon elegans	1	1

This grass acts evidently as a nurse crop to perennial grasses which are generally slow to establish, since it entirely disappeared from the plots when the latter were more dominant. It is a pioneer grass in the artificial reseeding of grazing areas.

1217 – **Napier Grass (*Pennisetum purpureum*): Promising New Forage Plant for the Philippines** (1). — WESTER, P. J., in *The Philippine Agricultural Review*, Vol. XIII, No. 4. pp. 353-354, pl. 1. Manila, 1920.

Napier grass (*Pennisetum purpureum*) has proved greatly superior to all other forage plants now grown in the Archipelago, and in Cuba the yield reported amounts to over 550 tons of green forage per hectare per year. The author introduced this plant into the Philippines in 1918 from Honolulu and it has shown itself well adapted to the climate and soil and to be more drought resistant than any other forage plant as yet introduced into the Islands.

The food value of this grass as compared with green maize fodder is shown in the following analysis:

	Water	Protein	Carbo-hydrates	Fat	Fibre	Ash
	%	%	%	%	%	%
Napier grass .	61.81	2.92	17.29	0.29	14.77	2.92
Green maize .	79.0	1.7	12.0	0.5	5.6	1.2

---

(1) For articles on other *Pennisetum* vars. see *R.* April 1919, No. 459, and *R.* July-Aug. 1920, No. 747. (*Ed.*)

The grass is well relished by horses, cattle, etc.; in order to avoid waste in feeding because of its coarse growth the author considers it unwise to allow the plant to grow more than 80 to 100 cm. high between each cutting as otherwise the lower woody ends of the grass will be rejected by the animals.

Depending upon the quality of the soil and the distribution of the rainfall, six to nine cuttings of green fodder can be made during the year after the plants are established.

Seeds have been found difficult to germinate but cuttings grow as readily as sugar cane points and should be treated very similarly The author has found that cuttings from 15 to 20 cm. long (each cutting with one or two joints, and in cases where the internodes are long, the cutting of the canes so that the topmost joint is not more than 5 cm. below the top end of the cutting), have given the best results. Where material is abundant whole canes may be laid flat in a shallow furrow and covered with soil, but where material is scarce it is advised to plant and then push diagonally into the soil so that the top ends are about even with the surface of the land.

" Merker grass, " another variety of *P. purpureum* less coarse than Napier grass has recently been tested by the Bureau of Plant Industry, United States Department of Agriculture, and also introduced into the Philippines where it is very successful as a forage plant.

1218 – **A Good Forage Plant Suitable for Cultivation at San Salvador: "Zacate jaraguá" (*Cymbopogon rufus*).** — Renson, C., in *Revista de Agricultura Tropical, Organo de la Dirección general de Agricultura e Industrias de la República de El Salvador*, Vol I, No. 1, pp. 2-9, figs. 4. San Salvador, Jan. 1921.

The author advises the cultivation in San Salvador and in Central America generally of *Cymbopogon rufus*, a forage plant native to Brazil. He describes its botanical and cultural characters, and the methods of propagation, which consist in sowing the seed in pockets, or dividing and planting tufts or portions of tufts. He mentions that an agriculturist, of Jauyná (San Salvador), has taken great trouble to grow *Cym. rufus* for hay (to be cut in September) or for grass. It forms good pasture until the flowering season, after which it becomes too tough. Grazing should only begin the 2nd year after sowing or planting, for by that time the plant has taken full possession of the ground, after suppressing the rest of the vegetation.

The value of *Cym. rufus* lies its being unexacting as regards soil, and resistant to drought, frost, fires, and the trampling of animals.

1219 – ***Trifolium squarrosum*, a species of Clover Behaving Like Bersim and Capable of Replacing the Latter in Some Cases.** — Fiori, A. (R. Istituto Superiore forestale di Firenze), in *L'Agricoltura coloniale*, Vol. XV, No. 8, pp. 413-416. 1 Table separate from Text. Florence, August 1, 1921.

In 1918, the author collected, in the forest of Gallipoli-Cognato, (Basilicata), a small quantity of the seeds of a clover which he subsequently classified as *Trifolium squarrosum* L. It grew so well, and its vegetative development was so luxuriant when sown next spring in the experiment field of the Cascine Forestry Institute at Florence, that he considered it desirable to continue the experiment in order to fix its biological characteristics, with a view to its possible use as a forage plant. The author has noted, so far, that:

This clover is an annual, and very nearly related to bersim (*Trifolium alexandrinum* L.). Its normal growth cycle lasts from autumn to spring, although, if sown in spring, it suceeds in flowering and ripening its seed before the summer heat sets in.

The entire plant is covered with hairs, and on fertile soil attains a height of 50-60 cm. The small leaves are oblong, and measure 5 cm. or more in length. The free portion of the stipules is linear-pointed, The capitulum, at first spherical, later becomes oblong-oval. The calyx has stiff hairs, the base is inflated, forming a bulb; there are 5 triangular lanceolate teeth, of which the lowest is the widest and longest, and is directed downwards, while the others open out forming a star, especially in the fruit. The tubular part of the calyx has 10 veins, and is slightly inflated at the bottom, and its throat is closed in the fruit, by a callosity just leaving a linear fissure in the middle; the teeth of the calyx eventually become rigid and sharp The seeds are relatively large (1 mm. to 1.5 mm. × 1.5 mm.), oval, reddish-yellow and glossy; 1000 seeds weigh 5.110 gm., or about 196 000 seeds to the kg. They are thus heavier than the seeds of bersim (Alexandrian clover), of which about 395 000 go to the kg.

Trifolium squarrosum prefers an alluvial soil and especially one that is sandy and damp; it can also stand a certain amount of salt, as it grows wild near the sea. The seeds germinate in the autumn, as soon as the first rain falls, and if the winter is mild, the plants continue growing, so that very soon in the spring, they provide an excellent crop of forage. No attempt has so far been made to mow *Trif. squarrosum* to see whether like bersim, it will shoot again from the roots.

The crop obtained represented 210 quintals of fresh grass and 66 quintals of hay per hectare.

Trifolium squarrosum is a purely Mediterranean species, its area of distribution extends towards the east as far as the Crimea and the Caspian Sea, and westwards to the Canary Islands. In Italy it grows in the centre (Tuscany), the South, in the Isles, and in Istria; it has also been reported from Liguria and the Valley of the Po, where it is of occasional occurrence only.

This clover therefore is much more widely distributed than *T. Alexannum* (a native of Asia Minor), and hence would appear to be more adaptable than the latter to different climatic and soil conditions. In order to establish this fact, a series of experiments are necessary. *T. squarrosum* has however withstood very cold winters and hard white frosts in the Cascine Gardens at Florence without visible sign of injury.

The chief practical advantages to be gained by growing this clover for forage lie in its power of profiting by the autumn, winter and spring,

[1219]

rains of the dry Mediterranean zone, where the winters are mild. The author considers *T. squarrosum* is much to be recommended as a forage plant for Central and South Italy, the Isles and especially for Libya.

As regards methods of cultivation, the information given by Dr. CARRANTE in his monograph on the Alexandrian clover (1) will prove most useful.

1220 - **The Future of Cotton Growing in Brazil, Especially in the State of Sao Paulo** (2). — I. COELHO DE SOUZA W. W.; II. PEARSE A., in *Brasil Agricola*, Vol. VI, No. 11, pp. 45-58, figs. 4. Rio de Janeiro, August 1921.

A lecture given at São Paulo, at the request of the " Sociedade rural brasileira " by Arno PEARSE (representing the United States on an International Cotton Mission in Brazil), and preceded by a lecture given by Dr. William Wilson COELHO DE SOUZA, Chief of the Cotton Service at the Ministry of Agriculture of Brazil.

I. — It cannot be denied that coffee is the chief agricultural source of wealth of Brazil, and especially of the State of São Paulo, where it is principally grown. Cotton, however, is also a very important crop, and has a brilliant future before it. In fact it is easy to foresee, that when once the present crisis is past, and the cotton factories of all countries have resumed their normal work, the amount now produced will not nearly satisfy the demand. As a rapid and largely increased production on the part of the chief producing countries cannot be expected, Brazil, which possesses soils and a climate eminently suited to the cultivation of cotton, is in an excellent position to secure a new source of revenue. By means of methodical and systematic organisation this country could become in 4 or 5 years time one of the largest sources of supply of cotton.

The State of São Paulo is especially suited to cotton-growing and produces large crops. Some of the cotton plants have lint 30 mm. long, and if selected and bred, might supply the local cotton industry which would obviate the necessity for importing the raw material from North Brazil, save the expense of carriage from Recife and allow the cotton produced in the Northern States to be exported to Europe.

The Federal Decree No. 14 177 of March 27, 1920, instituted the " Serviço do Algodão » (Cotton Service) at the Brazilian Ministry of Agriculture.

The programme of this Service, to which is entrusted the organisation of Brazilian cotton production, includes the creation of establishments for seed-growing in order to insure improvement and uniformity in type, and the adoption of prophylactic measures against diseases and parasites. This organisation will be completed by a system of practical education in cotton-growing to be given by peripatetic instructors and including information respecting: the choice of seed; careful ginning in order to remove all impurities from the lint; control methods against Pink bollworm, or " lagarta rosea " (*Pectinosphora gossypiella*), and other parasites of the cotton plant, etc. In addition, the Cotton Service advocates the provision in cotton centres of: depôts of insecticides, such as Paris green, and of simple machines for cotton cultivation (to be furnished to growers at cost price), the institution of schools of practical instruction in the use of the machines; the passing of a law making compulsory the commercial grading of cottons, the reduction (by way of encouragement) of the export dues on clean, pressed cottons classified according to commercial types, and the establishment of sanitary regulations in the interest of the cotton-worker.

---

(1) A. CARRANTE, *Il Trifolio alessandrino.* Biblioteca agraria coloniale, Florence, 1916. (*Author's note.*)

(2) As regards the possible development of cotton-growing in Brazil, the report presented to the Ministry of Foreign Affairs of Brazil by Dr. Deoclecio DE CAMPOS, the Commercial attaché at the Brazilian Embassy in Rome, and Delegate of Brazil at the International Institute of Agriculture is worth studying (*Boletim do Ministerio das Relações Exteriores No.* 16, Rio de Janeiro, October 1920. (*Ed.*)

On the occasion of his tour of inspection in the district of Sorocabana (State of São Paulo), the author began to carry out the last part of this programme. He made arrangements with some of the municipalities for installing plant for the sterilisation of cotton seed by the action of heat, and for the promulgation of decrees dealing with the protection of the cotton crops against parasites and other enemies.

II. — The tour of inspection made by PEARSE through the many cotton plantations and factories of São Paulo convinced him that cotton growing might become a most successful industry in Brazil, and especially in the State he visited.

Whereas the average yield of ginned cotton per hectare is 210 kg. in United States, 110 kg. in India, 280 kg. in Egypt (where it has undergone a perceptible diminution in recent years) it is as much as 400 kg. in the State of São Paulo, and the maximum can even reach the surprising figure of 3200 kg. Further while in other countries irrigation and fertilisers are required though Egypt has the great advantage of the fertile mud deposited by the waters of the Nile, the cotton plant in São Paulo is neither irrigated nor fertilised and requires no special attention.

Some cotton plants can give staple equal to No. 36. The soil, climate, distribution of the rainfall, railway-lines and excellent harbours all contribute to render São Paulo an ideal country for the cultivation of cotton, and if it were well organised few countries could compete with it.

The area of land suitable for cotton growing in Brazil exceeds that now under the crop in the United States.

Before the War the number of jennies working in the cotton factories of the world was 140 millions; towards the middle of 1921, 60 million were standing idle. On the re-establishment of normal conditions and when all factories are in full work, demand will be greater than supply.

At the present moment, the cotton-growing industry is going through a crisis in the State of São Paulo, owing to the shortage of labour and the attacks of parasites. The first is merely a passing trouble, since there are in Europe over 20 million persons anxious to emigrate to America, and it is only necessary to attract and organise these emigrants; the second, if systematic control measures are adopted, should not prevent the production of very remunerative crops (though some losses are inevitable), as has been already proved by the example of the United States.

For cotton-growing to take its rightful place in São Paulo, it is necessary that the industry should be organised by: 1) founding Stations for the production and distribution of selected, pure healthy seed (for the cotton-plant easily becomes degenerate through natural cross-fertilisation) — 2) making demonstration plots for growing cotton and using suitable machinery for cultivating the crop; — 3) establishing experiment fields for acclimatising and testing new varieties; — 4) organising a systematic control of the parasites of the cotton plant, among which one of the most destructive in the State of São Paulo is the "curuquèrę" (*Alabama argillacea*), whose attacks can be avoided by the growth of early varieties — 5) care in gathering the crop, in order to prevent what now occurs frequently, a number of open capsules shewing fine, white lint, with the result that the warehouses are filled with bales of dirty cotton containing many impurities — 6) the institution of official regional markets in each cotton-growing municipality: such markets would insure the grading of the cotton offered for sale, and could undertake the distribution of seed (such a system has given excellent results in India and Egypt) — 7) the organisation of annual exhibitions with prizes for the best cotton shown.

Finally Pearse advises: 1) that cotton should not be picked wet, or left too long in the sun, as this spoils it; it should never be exposed for more than 3 days, dating from the opening of the boll; 2) the regular inspection of the work of the ginners, who often ruin the cotton and mix the seeds.

The introduction of the cotton plant into a systematic rotation scheme would greatly contribute to an increase in its yield, as well as in that of the crops grown in alternation with it.

1221 - **Cambodia Cotton (*Gossypium Hirsutum*): Its Deterioration and Improvement in India** (1). — Hilson, G. R. (Cotton Specialist, Madras), in *The Agricultural Journal of India*, Vol. XVI, Pt. III, pp. 235-243, pl. 1. Calcutta, May 1921.

Cambodia cotton was first brought to the notice of cultivators in the Madras Presidency in 1907 and since then its cultivation spread rapidly and the Indian Cotton Committee state in their report in 1919 that the area under this crop in the Presidency alone, was estimated at 200 000 acres.

The author traces the deterioration in quality of the lint during recent years and attributes it to the following causes:— 1) weakness and staining; bollworm, 2) shortness of staple; the first seed distributed was unselected and a mixture of types. This is followed by a description of two main lines along which crop improvement work usually proceeds which should be regarded as necessary to restore the quality of lint, etc., namely, plant selection and isolation of types and hybridisation.

---

(1) See *R.* Dec. 1918, No. 1355; *R.* Jan. 1919, No. 46; *R.* May 1919, No. 595, and *R.* Sept. 1920, No. 868. (*Ed.*)

An outline is given of the usual methods recommended for use in order to obtain satisfactory results.

The two main pests from which Cambodia cotton suffers at present are stem-weevil (*Anthonomus grandis*) and bollworm (*Heliothis armiger*) the latter is the most destructive. The two control methods recommended are: 1) growing a type of plant wholly or partially immune from attack; 2) uprooting the whole crop as early as possible each year, and leaving as long an interval as possible before sowing the next crop. This is likely to prove successful in the case of stem weevil, but a starvation method appears to be the best way of dealing with bollworm. At present the interval between the up-rooting of one crop and the sowing of the next is generally not more than 2 months. If however a type could be found which would give a full yield in the first picking and as much then as is now obtained from two pickings, there would be very little point in keeping the crop standing after the beginning of June. (The present disadvantageous system consists in cropping in the beginning of May and also in mid June; the second crop has always been inferior and badly infested with bollworm).

As regards the production of a heavier yielding type, two characters are here discussed; viz. seed weight and weight of lint per seed. BALLS working with Egyptian, and HARLAND with Sea Island cotton found a positive correlation between these two characters and it is here demonstrated that a similar correlation holds good with Cambodian cotton :—. As the weight of seed increases, the weight of lint per seed also increases. The maximum weight of fibre per seed appears to be about $^3/_4$ the weight of the seed. The ginning percentage for any given weight of seed with the maximum weight of fibre is therefore practically the same all through *i. e.* about 43 %.

1222 - **Fruits of *Heeria paniculosa* in South Africa as a Source of Oil.** — *Bulletin of the Imperial Institute*, Vol. XIX. No. 1, pp. 24-25. London, 1921.

Results of investigations conducted at the Imperial Institute, London, demonstrate that the fruit of *Heeria paniculosa*, a shrub fairly plentiful in Zululand where it is known as "isifuku", contains a yield of volatile oil amounting to 5.5 % of the weight of the entire fruits. The oil obtained was mobile and colourless and had no pronounced or characteristic odour and consisted principally of terpenes. The lack of distinctive odour is however a disadvantage from the commercial standpoint.

The crushed fruits, after the removal of the volatile oil by distillation, furnished a quantity of fixed oil from the kernels equivalent to a yield of about 30 %, from the entire fruits. The oil in this case was viscous, clear and dark brown and had an aromatic and not unpleasant odour.

The fruits are not readily separable into pericarps and seed or kernel, and it would be necessary to submit the fruit to steam distillation in order to obtain the fixed oil from the residue by expression or by extraction with solvents. Fixed oil extracted from the entire fruits would inevitably be contaminated with volatile oil and consequently would be of little or no technical value. As already indicated, however, the volatile oil is not likely to be a commercial success and the above treatment would probably not be remunerative.

1223 - **Tobacco-Growing in Belgium.** — BRICOUT, D., in *Journal de la Société Nationale des Agriculteurs de Belgique*, Year 3, No. 34, pp. 295-296. Brussels, August 20, 1921.

The tobacco grown in Belgium includes a large number of varieties and its cultivation is essentially a home-industry. In some parts (at Appelterre, and in Flanders generally), tobacco has been grown for 2 centuries. The Appelterre product is famous for its mildness, aroma and good burning properties. The yield however is small: very good crop, 1 kg. of dried leaves per 20 plants; average crop, 1 kg. per 25 plants; poor crop, 1 kg. per 30 plants.

For this reason, during the War, coarse tobaccos with heavy yield were introduced into West Flanders, which became intercrossed slightly with the old varieties. The author draws attention to the danger of this hybridisation, and urges the necessity of restoring the good pre-War type, which has in fact been done already by many planters.

1224 - **Note on Pine-Apple Growing in Mexico.** — BALME, J., in *La Revista Agricola*, Vol. VI, No. 3, pp. 147-151. 5 figs., San Jacinto, Mexico, July 1921.

The pine-apple (*Ananassa sativa*), which requires a hot, damp climate, is cultivated throughout the region of the Gulf of Mexico up to an altitude of 500-800 m. The most favourable zone extends from Minatillán (Vera Cruz) to Tampico (Talmaulipas). It grows wild in many places in the State of Vera Cruz. The author is of opinion, that the strip of land bordering the road from Cordoba to Santa Lucrecia is very well-adapted for pine-apple plantations, on account of its transport facilities with the interior and the sea-ports, and the possibility of obtaining a plentiful supply of cheap labour. In this district really valuable varieties of pine-apples are to be found, the fruit is sometimes of a surprising size and may even attain a weight of 8 kg.

In the State of Vera Cruz, pine-apples require no irrigation, on account of the abundant rainfall (about 2 m. per annum), and the dews which are very well distributed.

The most favourable soils are humiferous and light, or else sandy alluvial readily permeable by water; plantations with a southern exposure produce the finest crop. Pine-apples are planted in different ways as the object may be either to obtain large fruits for local consumption, or medium-sized products for preserving. In the first case, the suckers are planted in single rows, 2 m. apart, or in double rows 60 cm. apart, 2 m. being left between each pair. The distance between the suckers varies from 60 to 90 cm., according to the variety; thus there are 5000 to 10 000 plants per hectare. In the second case, groups of 5 rows, 60 to 80 cm. apart, are made, a space of 1.20 to 2 m. being allowed between each group.

As a rule, the crop is hoed 6 to 8 times a year and in the less thickly planted fields, this can be done by hand. The workers have to adopt adequate measures for protecting their legs and hands in order to move about between the closely growing rows if the prickly varieties are cultivated.

The first flowering period begins, according to variety, 8 to 15 months after planting; 3 or 4 months later, the fruit is ripe. After cutting, the suckers appear around the stems of the parent plants, whence they are carefully removed as soon as they attain the height of 15 to 20 cm., and are then stored until the time of planting, which is 15 to 20 days before the beginning of the rainy season.

The varieties of pine-apple grown are very numerous, but in the State of Vera Cruz, Golden Queen, Porto Rico, Smooth Cayenna and Sugar Loaf only are known. The best results have been obtained with the spineless Cayenna variety. According to the author, Mexican pine-apples are superior in sweetness aroma, size and absence of fibre, to all others, the Hawaïan product, of which the number grown is very small, alone excepted.

The crop varies from 20 to 80 tons per hectare; the price of fruit sold on the field may be estimated at 60 dollars per ton for pine-apples in bulk and at 100-150 dollars per ton of selected fruit.

The " Sección de Horticultura " of the " Dirección general de Agricultura " of the United States of Mexico will furnish, on request, the fullest details regarding pine-apple growing.

1225 - The Curuba, *Tacsonia mollissima*, Edible Fruit in the Colombian Andes. — POPENOE, W., in *The Colombian Review*, Vol. I, No. 9, pp. 204-205, pl. 2 New York, Aug. 1921.

Among numerous fruits which are grown in the northern Colombian Andes, and are little known in other regions, the " curuba " (*Tacsonia mollissima*) is one of the most interesting. In Bogotá the fruit has a great reputation for edible purposes and for the preparation of refreshing drinks.

Apparently this fruit is not properly appreciated in other countries where it has been planted (southern France, southern California, Algeria) owing to a lack of knowledge as to the mode of preparation for consumption a secret which seems to be confined to the inhabitants of the Andean region. Although the plants are sub-tropical in their requirements and cannot withstand severe winters, they are sufficiently hardy for cultivation in California, Florida, along the Mediterranean coast of southern Europe, in northern India, southern Japan, South Africa and in many other parts of South America where it is up till now not grown. The author recommends the introduction of this fruit into the above mentioned countries and adds that the culture is simple and the yield usually heavy, and in addition to its value as a fruit, the curuba is an ornamental plant of a most attractive nature (genus Passiflorae).

The fruit is oblong, 3 to 4 inches in length, cream coloured or pale green externally; within its easily broken leathery skin, are numerous small black seeds, each surrounded by translucent, orange coloured juicy pulp; the flavour is somewhat acid.

1226 - **The Giant Blackberry of Colombia.** — POPENOE, W., in *The Colombian Review*, No. 8, pp. 179-181, fig. 1. New York, July 1921

The giant blackberry of Colombia with very large fruits 1 to 2 ½ in. in length and ¾ to 1 in. in breadth was noticed by Dr. F. M. CHAPMAN of the American Museum of Natural History, when travelling in Colombia several years ago.

In its native country (4° N. lat.) this plant grows at elevations 10 000 ft. above sea level, and it seems reasonable to expect that it would be a success in southern Europe and the southern United States. The author states that it is most abundant in the region of Cundinamarca where the largest fruits are produced. Its habitat, which appears to be fairly limited, is characterised by a cool and moist climate during the greater part of the year.

The fruits, almost heart shaped, are light crimson in colour, tending to become wine coloured when over ripe. They are firm in texture, of a pleasant subacid flavour when ripe, and quite acid when still green. The ripening season is said to extend through practically the whole year, but the greater number of fruits ripen from October to December. The moister soils produce the largest fruits and the poorer, more arid land the smallest fruits.

The fruits are sold in the Bogotá market and are eaten fresh or stewed.

Attention is drawn to the possibilities of improving this species by cultivation and especially by proper pruning, an important operation with all fruits of the *Rubus* family. Doubtless also this plant lends itself readily to selection and plant breeding.

It seems that this new fruit has chances of success particularly on the sandy loams of the Gulf States, Pacific Coast region (U. S.), in southern Europe, in northern India, in southern Japan and in South Africa.

1227 - **Descriptive List of Mango Varieties in India.** — WESTER, P. J., in *The Philippine Agricultural Review*, Vol. XIII, No. 4, pp. 265-352, figs. 71. Manila, 1920.

There are numerous mango varieties in India that are of a very superior quality and could advantageously be imported into other countries, but there are also a large number of sorts that are of very little if any value to fruit growers from the commercial point of view. To aid in discrimination between the different varieties, this descriptive list has been drawn up with the aid of a series of notes sent to the author by A. C. HARTLESS, Superintendent of the Government Botanical Gardens, Saharanpur, United Provinces, accompanied by a large series of line drawings most of which are reproduced. Other descriptions, based upon fruits grown in Florida are republished from a preceding Bulletin (*Bureau of Agriculture Bulletin* No. 18, 1911, Government of Philippine Islands, Department of Agriculture and Natural Resources) and a very large number of descriptions have been adapted from "*A treatise on Mango*" by P. C. DE, "*Gardening in India*" by WOODROW (Edition 3), "*Dictionary of Economic products in India,*" by WATTS and "*The Mango in Porto Rico*" by F. C. KINMAN.

Because of the localisation of many of the Indian mango varieties, the name of the locality from which a variety is described has been given for the convenience of prospective importers. For full details of each variety it is necessary to refer readers to the original article. Lists are limited here to varieties either useful or of no value commercially. (*Asterisks denote special quality varieties*).

I. — USEFUL VARIETIES AND WORTH IMPORTATION. — Alfonso (most celebrated and commonly grown mango in the Bombay region), Amini, Amirgola, Benazir, Bombay (Calcutta Garden), Bombay (Dr. KING), Bombay Green, Bombay Yellow (two varieties recommended for high elevations), * Cambodiana, Chakla, Dadh mungo, Dhurgo-bhog, * Fajri Long, Faqirwala, Fernandez (similar to Alfonso but later fruiting), * Gopalbogh, Haden, * Hathijuhl, * Jaffna, Kachamitha, Karelia, Kishenbhog, * Kohitur (premier mango in Mushodabad), Kumrajah, Kurpura-dagi, * Lamba Bhadra, * Langra, Langra Benarsi, Langra Hardoi, Miskirund, Mohun Thakur, Pairi (Paheri, Pirie, Peary, recommended for home consumption but not for long distance shipment), Pansera, * Sandersha, Sharbati Black, Sha-pusund, * Singa puri (Singapore), Singra, Souria (Souria budaya, * Durbhanga budaya), Stalkait, * Sufaida No. 1, Sufaida No. 2, Surkha.

MEDIUM QUALITY BUT WORTH IMPORTATION. — Amiri (too acid for a good dessert fruit but might prove acceptable for preserves), Bennett, Bulbulchasm, Fajri Round, Faizan, Fasli, Gola, Gordon, Kachmahua Seedling, Kakria Stud, Karenia, Khaparia, Kistapal, Mombosa, Mullgoa, Mulgoba (for private collection only), Salibunda, Sunahra, Zarda.

INFERIOR QUALITY NOT RECOMMENDED FOR IMPORTATION AND OF NO VALUE FOR GENERAL PLANTING. — Ajwanea, Arbuthnot, Baramasi (of little value except to the plant breeder), Batasa, Belua, Bhaduria, Bhaisht, Bhurdas, Brindabani, Charkichampa (no pomological merit), Chickna, Davys (Davy's Favorite), Divine, Gajria, Kachmahua, Kala, Khajya, Krishnabogh, Kutna, Langra Large, Langra Stud, Madras, Martinique, Najibabadi, Nayab, Nucka, Payasi, Père Louis, Peters, Punia, Romani, Rupee, Sanduria, Sans Pareille, Sharbati Brown, Strawberry, Sufaida Malihabad, Sundershah, Tamancha, .

OTHER VARIETIES INCLUDED IN THE LISTS AND OPEN TO TRIAL. — Amergola, Amrita-bhog, Amrita-pal. Amrita-monda, Anarua, Antochat, Aswina, Atai, Bherwa (Chapra), Bhupali, Bijnour Safeda, Bira, Bonkhaja, Borsha, Budaga (Bhadai), Champa-daghi, Chandani (Sundali), Chini sukker, Chonga, Choursa, Chutra, Darika, Darma, Daudbogh, Dayal Singh, Derrima (Durma), Dhumo, Dilsaj, Doanti, Dudia, Dula, Durga-bhog, Durgilal, Enuria, Fernandez, Fuzli (Fuzlee Bewa), Ganeshbhog, Golabbash, Gopal-dhoba, Gopinath-bhog, Gulsukri, Guria, Himsager, Hsapeti, Ithada, Jalibandha, Kala-Alphonse, Kalachand-bhog, Kalapahar, Kalua, Kanchan-Kasha, Kancha-Mitia, Karbuza, Karpuria (Maharaj Pasand), Kartika (Kartika Jaffer Shah), Kathambi (Kathambi Sobhan Ali Khan), Katki, Kerowa, Khari (Khari Budaya), Kharmuza, Khoont (Banchore), Knapaharia, Kumukt, Ladua (Maharaji-ladua), Laldarma, Laljan-banka, Larua, Latkampi, Lerrua, Madhua, Madkupia, Maharaj-pasand, Mahbub, Mahudinagar, Majgaon, Malabar Bombay, Mejidi, Mithua, Misribhog, Miscrikund, Mohun-bhog, Mohun Thakur, Munshiwala, Nakua-laghi, Nazim-pasand, Nazirbhog, Nazuk-badan, Nim, Nowaroa, Nur-Fuzli, Nusingbhog, Ogee, Paddojola, Pakria, Patel (Cowasjee patel), Phaykalbayan, Phulia, Pirgachia, Polla, Putu, Raj-Bhog, Raja-pasand, Rarhi, Rungbahar, Sabza, Safeda, Sarat-bhog, Sarda, Sarvati, Sauna, Seha, Shahpasand, Seohind (Gopal Larooa), Shridahan, Sinduria, Sokhta, Subja, Sukul, Tars, Tehfaringa, Terha Kellua, Tisiphool, Tota, Tota pari.

Since the foregoing article was written the author has completed these lists by additional descriptions of mangos in accordance with "*The Mango in Southern California*" by F. W. POPENOE.

The experience in Florida, Hawaii, and Porto Rico with a large number of the imported grafted Indian varieties has led to disappointing results, hence the evident importance of discrimination.

1228 - **Varieties of Date Palm in the Oasis of Derna, Cyrenaica.** — BROGLIO, E. (Nursery-Gardener of the Royal Agricultural Bureau of Derna), in *L'Agricoltura Coloniale*, Vol. XV, No. 8, pp. 401-406, 14 figs. and 2 Tables separate from the text. Florence, August 1921.

The Oasis of Derna, of which the chief crops are citrus-fruits and dates, possesses some 8200 palms yielding annually from 4500 to 5000 quintals of dates. The author mentions 22 varieties, and describes 14 under their native names: 1) brelsi — 2) meccani (i. e. from Mecca) — 3) becrèri — 4) hâmra (red) — 5) abita — 6) carcàbi — 7) lemsi — 8) bella Phya — 9) tabuni — 10) hàdduri) — 11) sicàba ârus (bride's finger) — 12) elgi — 13) nuà hàmmuri — 14) nuà asfar.

The first is the most prized and most commonly grown variety; the bunches of dates weigh 25 to 35 kg. and in a good season, a tree will produce as many as 10 to 14: the fruits of the 2nd, 5th, and 6th varieties are extremely sweet; a kind of paste is made from the meccani variety. Nos. 3, 13 and 14 are valued for the laghbi (palm-tree wine) extracted from them (1). The 4th variety is used, together with its fruits in the preparation of compressed loaves for winter consumption. The fruit of the 6th variety is good for transport while the 8th is very resistant to winds.

1229 - **Yield, Preservation and Utilisation of Stones of Table Fruits Regarded as Waste Products.** — See No. 1275 of this *Review*.

1230 - **Vine-Growing and Wine-Making in Peru.** - MOLINARI, P. (Oenological Expert, Delegate of Peru, at the International Institute of Agriculture, Rome), in *I. I. I., Rassegna settimanale illustrata della produzione italiana e dei traffici del Mediterraneo e dell'Oriente*, Vol. V, General series, No. 33, Section D. Agriculture No. 8, pp. [illegible], figs 5. Milan, August 1921.

ZONE OF CULTIVATION. — From its latitude, the Republic of Peru should have the climate of the torrid zone, but on account of the cold current of the Pacific Ocean the climate of a large portion of the coast area is similar to that of Sicily.

---

(1) Also called "laghmi," see *R.* June 1921, No. 672. (*Ed.*)

The vine is grown on this coast zone of which the characteristic feature is the almost absolute lack of rain.

In Peru, there are inhabited places at an altitude of 5000 m., thus differences of climate are very great and allow for the cultivation of every kind of crop. The vine grows in many localities differing much from one another in general character, some being so cold that the grapes never set, whereas in others, it is necessary to prune the vines at the vintage time, in order to insure a short period of rest. This occurs for instance, at La Merced, in Chancamayo, a damp hot, distinctly tropical zone in the interior of the country. Hence the dates of vintage, pruning and other processes vary considerably from one place to another. If however, cases of purely botanical interest when, as occurs sometimes in the case of citrus trees, buds, flowers and fruits are met with at the same time, are left out of account and the vine is regarded merely as an industrial factor, it must be recognised, that it occupies but a small place in the " Departamento " of Ica, the principal centres being Ica and Chincha.

This region is 300 km. south-east of Lima, and the vine is cultivated in a zone that almost reaches to the sea near Chincha (Tambo de Mora), and is only 80 km. distant from the coast in the vicinity of Ica. Cotton, lucerne etc., are also grown.

The vineyards of Moquegua, Locumba, Cuzco, Arequipa, Nazca and other places are of less importance. In the neighbourhood of Lima, the vine is widely grown.

It is usually not associated with other crops, but frequently " pallares " (white Lima beans), are planted between the rows, as their roots contribute a little organic matter and nitrogen to the soil. Vines are cultivated on small, average-sized and large properties.

It was mentioned above, that rain never falls in the vine zone, and it should be added that the irrigation water comes, at intervals and in small quantities, from the chain of the Andes in the summer months, that is to say from November to April. Where the supply is scantiest, as at Inca, recourse is had to irrigation by submersion. Each plot is surrounded by a kind of dyke varying in height according to the slope of the ground, which is however nearly always flat, for, with the exception of some stony slopes where the vines are allowed to creep along the soil, the vineyards are situated on the level. At whatever time the water arrives, even if it be most unseasonable, the whole vineyard is submerged once, twice or even thrice, having regard to the possibility of drought for 2 successive years. On account of the mildness of the climate, the eyes are so strongly developed that sometimes the vines bear a small second crop of grapes out of season, an anomaly usually causing small but seldom important losses.

SOIL. — The soil is as a rule alluvial, consisting chiefly (at all events as regards the upper strata) of mud transported by the irrigation water.

An examination of the soil gave the following results :

Physical Analysis:	6 to 10	per thousand	gravel.
	500 » 700	» »	coarse sand
	250 » 450	» »	fine sand.
	4.5	» »	clay.
	0.5	» »	humus
Chemical Analysis:	0.50 to 1.25	per thousand	nitrogen.
	1.80 » 2.80	» »	phosphorus.
	2.80 » 3.80	» »	potassium.

The general structure of the region is formed by the great Pacific fault which has exposed strata formerly lying at great depths, and also ancient sea-bottoms, as shewn by the remains of whales that are not infrequently found in the belt of sand dunes stretching between the river Ica and the sea (Ocucaje farm), as well as from the phosphatic nodules with which the region is thickly strewn. The analysis of these nodules has shown them to contain 10.04 % of phosphoric acid and 41.06 % tricalcic phosphate.

The vines are little fertilised. Dung is not used for manuring, and chemical fertilisers as well as guano are reserved for the great industrial crops of sugar cane in the north of Peru.

Where the vine is not fertilised, and little trouble is taken to work the soil, or adopt prophylactic measures against disease, the average amount of must obtained never exceeds 25 hectolitres per hectare.

The regions named above would be very suitable for vine-growing, as is sufficiently proved by the fact that the vineyard of Ocucaja, at the present time the largest in Peru, having 75 specialised hectares in one plot, can produce 80 hectolitres of must per hectare. This figure could be much exceeded in the new vineyards, for the vine grows well, and is little subjected to adverse conditions. The author attained this result from an old vineyard, without any replanting, after only 4-5 years of systematic treatment; thus proving the fertility of the vine-growing regions of Peru, which is far greater than has hitherto been supposed.

ADVERSE CIRCUMSTANCES. — These are much fewer than in Europe. Hail never falls; no phylloxera exist, except at Moquegua, where it has little opportunity of spreading, owing to the sandy character of the soil, and the system of irrigation by submersion. Eel-worms are found in some places only (the regions of Chincha and Lima), and can easily be controlled. Mildew and oidium rarely attack the native stocks, and would continue to be of little importance, except in the district of Lima, even if more attention were paid to the vine. Italian and French stocks are the chief sufferers from oidium, and in localities subject to sea-fogs are attacked also by moulds. All that is needed, in order to obtain a good crop of grapes, is to give the vines normal care and attention. " Rebrote, " or secondary and unseasonable vegetation, rarely does any serious injury and any bad effect could be remedied in a great measure by improving the present methods of cultivation. In these regions, snow is unknown and no true frosts occur. The minimum temperature (which is exceptional), may be fixed at +5° C. A rapid fall of the thermometer, below the daily morning and evening temperatures at the time of flowering may occasion a certain amount of injury, but such meteorological changes are of rare occurrence. Grasshoppers and wasps can also do some mischief, but in certain regions only.

It is a fact that in the district of Ica, which is the most suited to the vine, the local stocks may be said to need no special treatment, while the Italian and French varieties can be protected perfectly by two sprayings with permanganate of potassium (125 to 150 gm. per hectolitre of water). Sulphur is also applied, but is of little use, for as a rule, it comes from California, and is badly ground, and also, owing to the very slight viscosity of the leaves and the dryness of the air, it soon falls to the ground.

VITICULTURAL PRACTICE. — This continues to improve, and present defects must be attributed to the comparatively recent introduction of the vine into S. America. This is said to be due to Francisco CARAVANTES, who in the first years of the conquest transplanted some Spanish vines from the Canary Isles, which had been the first stage on their journey from Europe. The first mention of the vine in Peru dates from 1555; it was brought to the country by Capt. Barthélemy TERRACAS, and it appears, that already in 1560 a certain LOPEZ DE CASALLES began wine-making in the neighbourhood of Cuzco, a town which had shortly before been the residence of the Inca, Emperor of Peru.

The training of the vine has not been brought to perfection, the two most commonly adopted methods are the Roman "jugum" and the low tunnel with props of dead "algarrobo" (a kind of very resistant, wild carob); in some regions, little pillars of unbaked bricks are used. These supports are not economical, and wire is now being increasingly employed. In places where irrigation without submersion is impossible, the vines are also trained in vase-shape with props.

The vines are nearly always cut back to 2 or 3 eyes, this method of pruning being suitable to arid districts; too severe pruning is however injurious in the case of Italian varieties such as Barbera and some French vines as it shortens the duration of the productive period. The stocks are as a rule, very vigorous, and in 1915, the author saw vines over 20 cm. in circumference in the vicinity of Ica (Hacienda José), some of which could well stand cleft-grafting. The vintage begins at the end of February and finishes in April.

VINES CULTIVATED. — The chief and most widely grown indigenous stocks which are descended from the vines originally imported are: — 1) "Quebranta" (a word meaning "breaks"), it is certainly near akin to the Piedmontese Barolo, a variety that has now almost entirely disappeared but was formerly known in the Piedmontese dialect by the name of "sciapa duye" ("casse-bocal"). "Quebranta" is a hardy, vigorous vine, bunches and fruit well-developed; rich in must; skin slightly coloured: 2) Neyra and 3) Moscatel, also hardy and vigorous, but with smaller berries containing less must than the grapes of the preceding variety. The third, in spite of its name, has no connection with the Muscat; perhaps it is the Blue Moscatel of Spain which when ripe takes the colour of Cordovan leather.

Next come : Rosada, the same as the Italian " Somarello ", and also very widely grown in California ; Moyar, Albilla and other less important varieties. Albilla bears long bunches of small, white grapes, the fruit of Moyar is larger, but also colourless. Albilla produces an excellent dry white wine equal in value to some of the European vintages Its fruit is made into wine separately and without any admixture of other grapes.

The other grapes, when mixed, are used to make ordinary white wines, being added to the first pressure musts (forming about ¼ of the total), and also ordinary red wines, which ferment with the pomace. The socalled " special" table-vintages are made from the vines of the French group and with Barbera ; these are not, however, well identified, but chiefly serve to improve the colour, alcoholic taste and flavour of the wines manufactured from common grapes. To obtain a good colour, recourse is also had to grapes like the " tintorera " with coloured must, for even the varieties with coloured skins produce a very pale must that afterwards assumes indefinite tints in the wine, the colouring matter being easily precipitated, thus causing much anxiety to the oenologist.

The vine most grown is " Italia " (Moscatellone), a variety that from its name must have been brought from Italy at some undetermined date. Its fruit is used for the table and is dried for raisins. These grapes are also employed in the manufacture of sweet wines (" moscato piemontese " type), liqueur wines (Lipari and Syracuse type) the better class of dry white wines, and finally in making " Italia " brandy. This liqueur is absolutely unrivalled, and is greatly in request in Peru and the neighbouring Republics, where the typical drink, if it may be so termed, is " aguardiente " (brandy), and not wine.

Peruvian brandies are often known under the general name of " Pisco, " from the shipping port, or " puro de Ica, " but are sometimes called by the name of the vine, " Moscatel Italia, " etc.

UTILISATION OF THE CROP. — It should be mentioned, that on account of the hot climate and the careless habits of the natives, the Spanish conquerors distilled their wines and brandies on the spot, thus obtaining a product that was both stable and easy of transport. As they used new wine and not pomace (which was thrown away after it had been slightly pressed), in the manufacture of " aguardiente, " the latter was a very fine brandy, greatly superior to " grappa " (pomace brandy). Peruvian " aguardiente " contains 46 % of alcohol when sold.

Wine production has progressively increased during the last few decades only. No exact statistics are available, but it may be estimated that in Peru, there are not more than 7500 hectares under vines. At the present time, half the grapes (the total being 190 000 hectolitres at the rate of 25 hectolitres per hectare), are made into brandy, the other half being used for wine, or else eaten fresh or dried, some of the dried raisins being secretly used for the manufacture of wine in the large towns.

Thus the yield is less than 100 000 hectolitres which is insufficient to supply the constantly increasing demand, and also insufficient from the hygienic point of view, for it is most desirable that less spirits (especially the deleterious brandies made from imported cereals), should be consumed, and that wine, beer and " chicha " (a local incompletely prepared beer) should be substituted.

The wine making expert has not only to contend with difficulties connected with colour, which is one of his chief troubles, but also with the excessive heat, (at the time of the vintage the thermometer registers about 32° C.) and with the defective character of the must, the glucose content of which as soon as the grapes happen to be a little over-ripe, varies from 25 % to 30 %, whereas the amount of acid is very low, seldom exceeding 3.5 parts per thousand. As the temperature of the water is about 20° C., the cooling process is both difficult and costly.

The true solution of these problems consists in the use of pure yeasts and of selected ferments accustomed to strong doses of sulphite and alcohol, and in rapid fermentation etc. This would however necessitate working on a large scale, and the employment of a technique better than is at present possible except in very rare cases. Hence most of the winemakers content themselves with using receptacles having a capacity of a few hectolitres only so that the mass cools rapidly, the must is easily handled and the tunning etc. can be carried out quickly. It is certain that the ordinary products are deficient in alcohol, but an expert, having at his disposal all the appliances generally used in the best cellars of Europe, could at once obtain fairly good wines, which he could gradually improve.

The Ica wines are the most valued, the products of Chincha, being weaker and more doctored, are more suitable for general trade, although the cellars of the district are the better equipped.

The most characteristic wines are the liqueur types, such as " Lipari " and " Muscat de Syracusa " of 8 to 10°; a small portion of the alcohol is produced by the must itself at the beginning of fermentation, later more is added and the alcohol content is raised to 16-17 %. For this vintage, a 60-65 % redistilled brandy should always be used, and never rectified alcohol. The type is subsequently obtained by the addition of " arrope, " must reduced over the fire to about ¼ its volume. If these wines are left to mature for 2 years in 4-hectolitre vats, an excellent product is obtained.

The Ica district, owing to the type of grapes and especially to the large quantity of the Italia variety grown, is an ideal region for the manufacture, of these wines, which find a ready market in Peru and the neighbouring Republics.

1231 - **Re-Afforestation of the State of Rio de Janeiro, Brazil.** — SAMPAIO A. J., in *Boletim do Ministerio da Agricultura Industria e Commercio*, Vol. IX, No. III, July September, 1920, pp. 29-30. Rio de Janeiro, 1921.

A report sent by the author to the Director of the National Museum at Rio de Janeiro, giving an account of his work on the occasion of the botanical exploration of the riverine district of Rio Itabapoana, within the frontiers of Rio de Janeiro and Espirito Santo.

Many valuable types of trees mentioned by Caminhoa in his " Tratado de Botanica," once forming a source of wealth to the district, have now disappeared owing to reckless felling. Even wood for fuel has become dear, and is very scarce in certain places. The author urges strongly that this state of affairs should be remedied, and suggests the adoption of the following measures:

1) The preservation of any woods and nuclei of young tree growth still remaining on all agricultural land, together with the manuring of impoverished soil, instead of tree-felling for the purpose of obtaining fertile land;

2) the plantation of young trees in the pastures used for cattle-rearing. When the trees are grown, they will afford a grateful shade to the stock;

3) the plantation of clumps of trees on high ground and declivities;

4) the cultivation of water-loving species (eucalyptus), on low-lying, damp land, which will thus be naturally drained. If the soil is first limed, the hydrophilous, herbaceous plants will be destroyed, and the ground rendered suitable for tree growth;

5) the afforestation of the coast zone.

1232 - **The Black Walnut (Juglans nigra): Its Growth, Distribution, Management and Utilisation.** — I. BAKER, F. S. (Forest Examiner). Black Walnut: Its Growth and Management, *U. S. Department of Agriculture, Bulletin* No. 933 (Contribution from the Forest Service. Professional Paper), pp. 1-43, figs. 4, pl. 7, tables 18. Washington D. C., March 8, 1921. — II. BRUSH, W. D. (Scientific Assistant). Utilisation of Black Walnut. *Ibid. Bulletin* No. 909, pp. 1-89, tables 27, pl. 14. Washington, D. C., Jan. 17, 1921.

I. — The importance of black walnut (*Juglans nigra* Linn.) was evidenced during the war in the demands made to secure this wood for gunstocks and aeroplane propellors. The demand since then has continued to be heavy, owing to the high value of walnut for its seasoning, easy working and gluing qualities, etc. and its consequent adaptability to various uses. Great importance may therefore, be attached to the questions of available supply, growth and management of this tree, and to the financial possibilities of growing it for the timber market. It is with this in view that the author here presents such information as is available on these subjects.

DISTRIBUTION. — The botanical range is from southern New England and Ontario to Minnesota, South Dakota, and Nebraska, south into Texas and east to Georgia, and extending to the coast of South Carolina. The commercial range is wide, but the best natural development is to be found probably in the Ohio River Basin, in the southern Appalachians or in Arkansas.

The estimated stands for 28 States is given as 821 000 000 board feet (taken from the point of view of production of timber), but probably 50 % is inaccessible to manufacturers.

The author gives a detailed description of the tree, including size, form, branches, roots, bark, leaves, flowers and nuts, and outlines the sylvical characteristics concerning soil and moisture requirements, reproduction, diseases, etc.

As regards the growth of individual trees, selected measurements are given illustrating the rate of diametric and volumetric growth under specific conditions, and comparisons are made in tabular form between the rate of growth in diameter and the formation of sapwood.

As regards the growth of stands (yield per acre), taking 55.6 as the number of trees per acre, the estimated yield is 4 660 board feet. Data concerning other groves are also given.

The DOYLE rule is in general use for measuring logs and estimating standing timber. Computations were made on approximately 12 000 000 board feet of logs purchased towards the close of the War to show the average size of logs from different States. Michigan, Illinois, Iowa and Nebraska show the highest average varying from 106.63 to 79.43 board feet per log., and Maryland and Alabama showed the lowest average 55.10 and 51.88. The average for all logs from the States taken as a whole amounts to 76.38 board feet per log.

ESTABLISHMENT OF PLANTATIONS. — A comparison between artificial and natural stands has been made, the figures being based dupon measurements for 90 plantations. After the planted trees reached 50 years of age the growth was slower than that of the slowest observed in natural stands and the quality was very inferior to the clean straight tall boles of the forest grown trees. The diameter, breast high, in plantations at the age of 50 was 10.9 in. compared with 15.7 average growth in natural stands. The best criterion for determining a planting site is thus evidently the notification of areas on which the tree flourishes naturally. Nuts may be planted in the autumn 2 or 3 in. apart (2 nuts per hole) in rows 6 in. apart and the seedlings transplanted the following spring to their permanent quarters; the final spacing should be 4 × 4 feet, or where space is not limited, 6 × 16 ft. If the trees are grown for the production of nuts, a spacing of 50 to 60 ft. is considered advisable. Whenever planting is done the aim should be to provide for the maturing at one time of 40 trees at least. In a close plantation 80 % of the trees will be cut in thinnings before maturity.

II. — UTILISATION. — This bulletin deals with the characteristics, properties, uses, manufacture and market values of black walnut wood, and the uses to which it is best adapted.

The properties of black walnut wood, actual, comparative, tested green are given with diagrams and may be summarised as follows:—

Weight per cub. ft.: green. 58 lb., air-dry 39 lb., kiln dry 37 lb. *Specific gravity*, when dry, based on volume when green, 0.51. *Shrinkage from green to oven dry condition* % in volume 11.3, radial 5.2, tangential 7.1. *Strength in bending*: Modulus of rupture 9500 lb. per sq. inch., relative strength compared with oak (oak = 100), 114. *Strength in compression parallel to grain*: maximum crushing strength 4 300 lb. per sq. inch.; relative strength compared with oak (oak = 100) 121. *Strength in compression perpendicular to grain*: fibre stress at elastic limit 600 lb. per sq. inch.; Relative strength compared with oak (oak = 100) 72. *Stiffness*: Modulus of elasticity in bending, 1420 (1000 lb. per sq. inch); relative stiffness compared with oak (oak = 100) 114. *Hardness*: Load required to embed a 0.44

inch ball 1/2 its diameter, 900 lb., relative hardness compared with oak, (oak = 100) 85. *Shock resisting ability*; work to maximum load in bending, inch lb. per cub. inches 14.6; relative shock resisting ability compared with oak (oak = 100) 127. *Shearing strength parallel to grain*: shearing strength 1220 lb per sq. inch.; Relative shearing strength compared with oak (oak = 100) 98.

Walnut veneer is cut by the straight rotary, stay log rotary or straight-slice process. Manufacturers get about 20 sq. ft. of veneer from each board foot of logs, log scale, with a waste of about 55 %. This waste is unavoidable, and includes the sap-wood (the defective veneer of which is not marketable) the wood trimmed off before a sheet of saleable width is obtained, the waste due to defects, and the " dogboard. " Owing to the fact that walnut veneer logs run comparatively small in size, wide walnut veneer is much in demand.

Apart from the above mentioned uses, walnut has been found a suitable wood for railway sleepers, fences and firewood, but only small and defective material is ordinarily converted into these products. In the appendix is given a detailed list of the various uses of black walnut reported by factories, including boxes and crates, brooms and carpet sweepers, cars, caskets and coffins, chairs, clocks, firearms, fixtures, frames, handles, professional and scientific instruments machines, planing mill products, printers' materials, refrigerators, doors, sashes, etc., ships, vehicles, canes, rackets, etc. The author gives a brief survey of the adaptability of the wood to these various branches of industry, and also gives the data referring to the amounts and values of walnut logs exported from the United States 1912-17. Data are not available on the export of walnut veneer.

Although the present very high market price of the timber may not be maintained, walnut will always be in demand and will bring good prices because of the intrinsic value of the wood. Owners of timber tracts containing walnut will generally find it profitable to give preference to the young growth of this timber rather than to that of the less valuable species. Owners can dispose of their trees to best advantage to walnut lumber and veneer manufacturers and to factories that purchase walnut in the log form; figured walnut is more valuable than plain. Walnut firms do not, as a rule, publish a fixed scale of prices and log grades, the prices being usually set by the log buyer.

Tables show the amount and values of walnut logs exported from the United States during the fiscal years ending June 30, 1912 to 1917. In 1912 the value per 1000 board feet amounted to $62.35; in 1913, to $54.49 and from then onwards there has been an increase in value, amounting in 1917 to as much as $104.33. None was exported for the year 1918.

1233 - **New Zealand Waste Timber for Paper Making.** — *Bulletin of the Imperial Institute* Vol. XIX, No. 1, pp. 1-10. London, 1921.

Results of examination of eight New Zealand timbers submitted for inspection to the Imperial Institute with reference to the possibilities of utilising the waste wood produced in the manufacture of paper pulp The chemical examination and paper making trials were carried out on wood freed from bark and the results refer throughout to the air dried wood.

The species examined were as follows :—

I. — *Fagus* (*Nothofagus*) *Solandri.* — Results show that the wood gives a fairly good yield of pulp (41.5 to 42.5 %) which bleaches almost white and furnishes an opaque paper of satisfactory quality.

II. — *Fagus* (*Nothofagus*) *cliffortioides.* — A very abundant species with yield equal to that from the above mentioned sample, but the pulp is more readily bleached.

III. — *Fagus* (*Nothofagus*) *Menziesii.* — Yield equal to the two preceding species and the pulp of similar quality.

IV. — *Weinmannia racemosa.* — Yield rather low (36.5 to 40.0 %), but the pulp bleaches satisfactorily, has good felting properties and furnishes paper of fairly good strength.

V. — *Fagus* (*Nothofagus*) *fusca.* — Fairly good yield of pulp (44.0 to 47.5 % dry pulp), bleaches well and gives a paper of satisfactory quality.

VI. — *Beilschmiedia Tawa.* — Very abundant species ; fairly good yield of pulp (43.5 to 44.0 % dry pulp), and furnishes paper of good quality and fair strength.

VIII. — *Pinus Laricio.* — Wood difficult to disintegrate probably on account of the presence of knots. Yield of pulp not very high (39 to 45 %) and bleaches to a cream colour.

VIII. — *Pinus radiata.* — As in the preceding case the numerous knots in this material rendered it difficult to disintegrate and necessary to employ a high percentage of caustic soda. The pulp produced is similar to that obtained from the *P. Laricio* wood both in quantity and yield. Strong papers were obtained from both these woods.

The first six species are indigenous to New Zealand and the last two are introduced trees, now being planted on a large scale throughout the Dominion.

All these timbers would be suitable for the manufacture of paper pulp in New Zealand if available in sufficient quantities, but attention is called to the fact that before the manufacture of pulp can be undertaken on a commercial scale a number of factors will need careful consideration. Amongst these it is notified that from the results of the trials described above, the woods of the four species of *Fagus* (*Nothofagus*) and those of *Beilschmiedia Tawa* and *Weinmannia racemosa* might be used in admixture where the quantity of waste wood of one kind is limited. The woods of *Pinus Laricio* and *P. radiata*, however, should not be mixed with the others, owing to the more drastic treatment required.

LIVE STOCK AND BREEDING

1234 - **Experiments Made in the United States on the Efficacy of Carbon Tetrachloride as an Anthelminthic, Especially against Hookworm** (1). — HALL, M. C. (Bureau of Animal Industry, United States Department of Agriculture), in *The Journal of Agricultural Research*, Vol. XXI, No. 2, pp. 157-175, bibliography of 22 works. Washington, April 1921.

After reviewing the experiments hitherto carried out with regard to the use of carbon tetrachloride in medicine, the author describes his own investigations as to the relative efficacy of this substance and other drugs commonly used to remove hookworms.

Experiments on dogs showed that carbon tetrachloride in doses of 0.3 cm^3 per kg. of live weight is more effective (efficacy 100 %), than any of the other anthelminthics used.

Chloroform, in doses of 0.1 cm^3 to 0.2 cm^3 per kg. of live weight, when given in castor oil, was only 54 % effective against hookworms, while a single dose or even repeated doses of oil of chenopodium, had only an efficacy of 20 %. The best results (average efficacy 69 %), were obtained with repeated doses of oil of chenopodium followed by chloroform. The maximum efficacy (89 %), was obtained by giving 3 doses (of 0.33 to 0.65 gm.) of oil of chenopodium at 1 hour intervals, each dose being accompanied by 14.18 gm. of castor oil, and followed half an hour later, by 0.4 cm^3 of chloroform in 14.18 gm. of castor oil.

Thymol proved to have an efficacy of 15 % only. The experiments further showed that carbon tetrachloride is a very safe drug, as it was apparently quite harmless even in doses 5 times as large as was necessary to insure complete efficacy.

It is also very effective in removing Ascarids, though somewhat inferior to oil of chenopodium in this respect. Carbon tetrachloride will, like other anthelminthics, expel whipworms (*Trichuris depressiuscula*) when they get into the caecum. It is however of no value against tapeworms (cestodes).

1235 - **Intrapalpebral Reaction for the Diagnosis of Dourine** (2). — LANFRANCHI, A. and SANI, L. (Istituto di Patologia Speciale e Clinica medica veterinaria della R. Università di Bologna), in *Bulletin de la Société de Pathologie exotique*, Vol. XIV, No. 7, pp. 374-378, 1 Plate. Paris, July 1921.

The technique of the intrapalpebral reaction has been tried in the diagnosis of dourine.

The authors used as an antigene some trypanosomes (*Trypanosoma brucei* and virus LANFRANCHI) in the pure state; they were freed of blood means of a haemolytic serum, and then emulsified. either with pure glycerine (1 : 3), or with glycerine in a physiological solution, or in distilled water.

---

(2) See *R.* May 1921, N. 519. (*Ed.*)

In the case of infected animals, the reactions are almost the same as the positive reaction to mallein. Swelling of the eyelids shows itself from the 3rd or 4th hour, and reaches its maximum between the 12th and 18th then the oedema is slowly reabsorbed, though perceptible until the 36th hour.

There is usually a slight thermic reaction, as well as more or less noticeable local symptoms (photophobia, lachrymation). After the application of the treatment, or even during its course, the local oedema was found to develop more rapidly, attaining its maximum about the 10th or 11th hour, and disappearing between the 20th and 24th. The thermic reaction was also weaker.

The local reaction is much the same in healthy as in infected animals, the thermic reaction and other general symptoms do not appear.

There is no doubt, that results of practical utility would be obtained by using *Trypanosoma equiperdum* as an antigene.

1236 – **Transmission of Rinderpest to Pigs of the Celtic Breed.** — NICHOLAS, E., and RINJARD, P., in *Comptes rendus des séances de la Société de Biologie*, Meeting of June 25, 1921, pp. 168-170. Paris, June 1921.

Experiments carried out by the authors at the Cureghem central Station for the preparation of serum, during the recent outbreak of Rinderpest in Belgium, with a view to obtaining more exact information respecting the important question, whether Celtic pigs are susceptible to the disease. Adult as well as young animals were experimented upon, being infected artificially through the mouth and by means of subcutaneous injections. The pigs reacted and became ill, some even died (occasionally after a considerable time had elapsed) from lesions similar to those induced by Rinderpest.

Scientific proof was obtained by the re-infection of 2 cows kept under conditions excluding all possibility of accidental contagion. These animals contracted the disease after an incubation period of 3 to 3 ½ days, and died in 4 days with the characteristic pest lesions.

It is thus quite certain, that pigs of the Celtic breed are susceptible to Rinderpest, though the disease in their case is far from assuming such a serious character as in cattle. It occurs sometimes in so light a form, as hardly to affect the victims, and thus passes unobserved. For this reason, pigs in Belgium have hitherto always been regarded as immune to the malady. It is most necessary therefore, in times of an outbreak of Rinderpest that all swine should be carefully watched.

1237 – **Coccidiosis of Ruminants in South Anam.** — SCHEIN, H., in *Bulletin de la Société de Pathologie exotique*, Vol. XIV, No. 7, pp. 380-382. Paris, July 1921.

The goats of the district of Nhatrang are very often attacked by a coccid, probably *Eimeria arloingi*, the same species that VELU has recorded as occuring in Morocco (1).

---

(1) See *R.* July-Sept. 1919, No. 927. (*Ed.*)

Nearly all the goats are infected, but as a rule the parasite causes the death of young animals only which happen to be in a weak condition owing to weaning, eating damp forage during the rainy season, the effect of intercurrent diseases, etc.

Adult animals, except after inoculation for Rinderpest, do not appear to suffer to any great extent, from *Eimeria arloingi* and harbour but few of this coccid.

The disease usually manifests itself by intestinal disturbances resulting in diarrhoea (the evacuations contain mucus which is sometimes tinged with blood), and causes anaemia and rapid cachexy, the parasites being present in large numbers.

Occasionally only, coccids about to form spores are found in the excreta. If the latter is placed in a moist chamber for some days, the proportion of segmented parasites becomes larger.

The results of post-mortem examination are given and also some notes upon the shape and dimensions of the cysts and sporoblasts. The goats of Nhatrang are reared near the sea, on sandy and very dry ground where the conditions would appear *a priori* to be unfavourable to the spread of the disease; even adult animals however brought from the dampest mountain regions often catch the malady in a severe and fatal form, although arriving at the coast in the summer. It would thus appear that exposure to infection from youth confers immunity from this intestinal parasite.

There are very few sheep in this part of the country, and those the author has hitherto been able to examine showed no signs of coccidiosis.

He found however a coccid in calves and buffaloes that was so similar to the microrganism present in the goats as to be in all probability the same. It however occurred only in cattle during Rinderpest reaction and amongst these the intestinal disturbance was especially severe. There was no sign of it in healthy individuals, but the author thinks it probable that some of the latter act as coccidiosis carriers.

SCHUTZ has already observed in India that Rinderpest appears to have the effect of aggravating the symptoms of coccidiosis. This appears most likely, and therefore in regions where coccids abound, it would be well, when combating Rinderpest, to increase the dose of the specific serum, and at the same time, to apply the remedies used in cases of coccidiosis.

1238 – **Note on Canine Rabies in the French Sudan.** — ARLO, I., in *Bulletin de la Société de Pathologie exotique*, Meeting of July 13, 1921, Vol. XIV, No. 7, pp. 368-373. Paris, July 1921.

In the course of his study of Sudanese rabies, the author has come to the conclusion, that it has not been imported into the Sudan, and does not appear transmissible to man.

The natural virus seems very easily destroyed, and not very toxic. All attempts to obtain a fixed virus for laboratory purposes proved unsuccessful.

1239 - **Note on Some Bird Parasites of the Belgian Congo.** — Ghesquière, M. I. (Entomologist of the Congo Government), in *Annales de Gembloux*, Year XXVII, No. 7, pp 239-242, Brussels, July 1921.

The author has made a study of the parasites attacking poultry in the Belgian Congo, and drawn up a list of those which he believes to cause a relatively high rate of mortality. The parasites mentioned are as follows:

In fowls: the nematode *Filaria gallinarum* — Cestoda — the Mites, *Cnemidocoptes mutans, Argas persicus, Sarcoptes laevis* (causing feather-eating), and *Dermanyssus gallinae* — the Mallophaga, *Geniottes gigas, Lipeurus meleagridis* and *Menopon staminarum* — the Siphonapteron *Sarcopsylla gallicanea.*

In turkeys: the Mite, *Amblyomma hebraeum* and the Malophagos, *Lipeurus meleagridis.*

In pigeons: the Dipteron, *Lyncha maura.*

As regards *Filaria gallinarum,* it may be said that 80 % of the fowls suffer from intestinal filariosis. The native birds seem to resist the disease better than fowls imported from Europe; severe cases are relatively rare. This parasite causes different gastro-intestinal disturbances (colic, dysenteric enteritis), which are followed by loss of flesh and by anaemia, which produce a cachectic condition terminating in death. The intermediate host of *Filaria* is *Hoolotermos pretoriensis* Ful., a fairly common species of termite.

Cestodes and nematodes are often found in association, and a *post mortem* examination has not only revealed complicated intestinal helminthiasis, but has further shown the walls of the intestines to be covered with haemorrhagic pustules. Microscopic investigation of a portion of the contents of the intestines also manifested the presence of large bacteria invading the dead tissues, and of an abnormal number of *Bacillus coli communis.*

The author in conclusion mentions a severe chronic form of diphtheria that occurred at Nyangwé and Barumbu in 1920, and at Eala, in 1921.

He proposes to give in a supplementary note, the control measures that have been successfully adopted against these parasites in the Belgian Congo.

1240 - **Research on the Bacilli of Avian Tuberculosis.** — Jousset, A., in *Annales de l'Institut Pasteur,* Vol. XXXV, No. 9, pp. 603-620. Paris, 1921.

The author, in the course of his researches on antituberculosis inoculation, and serotherapeutics, had occasion to study numerous types of bacteria. After trying many other species, he made some immunisation experiments with the bacillus of bird tuberculosis. The negative results obtained, together with the discovery of a series of hitherto unpublished, but very marked characters belonging to this type of micro-organis gradually led him to doubt the identity of the bacilli of the mammalian and avian forms of tuberculosis. He then carried out a series of test experiments, the results of which are given in the article analysed and summarised as follows:

Certain avian bacilli have a number of well-marked natural characters which entitle them to be regarded as a distinct form, and not to be identified with the bacillus described by KOCH as occurring in man and cattle.

These characters, which are of very different significance are as follows:

Absence of any uniting substance.

Invariability of reaction to the culture medium.

Longevity on artificial media as opposed to the susceptible character of the virus.

Inferior local power of producing casein.

Intense toxic action on horses.

Weak and negligible local or general effects upon a tuberculous organism caused by the tuberculin obtained from these bacilli.

Absence of all power of conferring specific immunity against the bacillus of human or bovine tuberculosis.

Of all these characters, two deserve special notice as clearly differentiating the types of bacillus studied from the bacilli present in mammals: these are the necrotic and the immunity reactions respectively, all the others being of relative importance only.

The question arises whether bacilli with such characters are of exceptional occurrence. Everything points to their being very frequently, if not invariably, present in cases of bird tuberculosis.

This view is based upon the analogy between the above mentioned characters and the properties recorded in all descriptions of the pathogenetic agent of avian tuberculosis which led VILLEMIN, and afterwards STRAUS, to entertain serious doubts as to the relationship between avian and mammalian tuberculosis. " It would however be very rash, and still more dangerous, to make this question subordinate to the merely speculative and philosophical theory of the single origin of the various forms of tuberculosis bacteria, an idea, which has but served to spread confusion, and should never have been introduced into the discussion ".

The author, considering the question simply from the practical standpoint, concludes as follows:

1) Bird tuberculosis is due to different causes amongst which occur: *a*) very exceptionally, the bacillus of mammalian tuberculosis; *b*) very frequently, acid-resistant bacilli, occasionally endowed with a certain power of inducing tuberculosis.

2) This property of producing tuberculosis, which is as regular and complete (power of causing necrosis) in the first type of bacilli, as it is irregular and incomplete in the second, in no wise justifies the identification of the two groups.

3) The two types of bacilli are sometimes clearly distinguished by their immunity reactions.

1241 – **The Distribution of Non-Proteic Nitrogen in the Organism.** — DELAUNAY, H., in *Comptes rendus des Séances de la Société de Biologie*, Vol. LXXXV, No. 26 (Meeting of July 16, 192[illegible]), pp. 360-362. Paris, 1921.

The author's experiments carried out on adult, or recently-born mammals of different species (dogs, cats, rabbits and guinea-pigs), both when fasting and after food in the first place confirmed the already well known fact, that considerable quantities of amino-acids are present in the blood and tissues of vertebrates. They also give further information as to the ratio between the various forms of nitrogen present and the total non-protein nitrogen. The following is a summary of the results obtained:

1) PROPORTION OF UNDETERMINED NITROGEN TO THE TOTAL NON PROTEIC NITROGEN. — The undetermined nitrogen, which includes all the nitrogen present in the different organs that has not been estimated (urea, amino acids, ammonia and polypeptids), forms in the case of the urine, from 10 to 15 % only of the total nitrogen. The proportion in the blood is higher (30 to 50 %). For the organs of any individual animal, there is a kind of average figure, usually below that for the blood. Little variation is observed in this respect between the different organs in the same individual. On the other hand, the physical condition causes the mean of the undetermined nitrogen in the organs to vary considerably, but the amount present is always large (40 to 70 %).

2) AMOUNT OF AMINO NITROGEN. — As is seen on referring to the graph given in the text, the various organs can be classified according to their amino nitrogen content. Some parts of the body (the spleen, liver and mucous lining of the intestine) take the first place, whether the animal is fasting or after feeding, and have clearly a larger amount of amino-nitrogen than others. Then come in descending order, subject however to variation, the lungs, brain, muscles, kidneys and finally, the blood.

3) AMOUNT OF AMMONIAL NITROGEN. — The percentage of this form of nitrogen is always low, and varies from 1 to 6, whereas that of amino nitrogen is between 15 and 35. The muscles and liver appear to contain slightly more ammoniacal nitrogen than the other organs.

Contrary to what might have been expected, there is no parallelism between the amount of amino nitrogen and that of ammoniacal nitrogen.

4) AMOUNT OF URIC NITROGEN. — The blood has always proved to be richer in urea than the other organs studied, though it is frequently poorer in amino nitrogen. After the blood, the kidney contains most urea. The percentage of uric nitrogen in the other organs varies around a mean which is below the figures given for the kidneys and blood.

5) AMOUNT OF NITROGEN THAT CAN BE ESTIMATED BY THE TANRET REACTION. — Very little only of this nitrogen is to be found, the amount present being below 2 % of the total non-proteic nitrogen. The spleen gives the strongest reaction and seems to be the organ containing most albuminoids and peptones. Next come the mucous linings of the intestines and the liver. The muscles give a very weak reaction. The kidneys, lungs and brain give a stronger reaction than the muscles, but one far less distinct than the digestive organs.

From these preliminary researches, it is abundantly clear that during fasting and digestion alike, the maximum amount of amino acids, albuminoids, and peptones is present in certain organs that play an important part in the digestive process (intestines, liver, spleen). The latter organs, which while digestion is in progress, have the greatest capacity of fixing the amino acids in circulation, would also appear, even during fasting, to be able to form the largest quantity. They seem thus to play an important part also in the regulation of nitrogenous metabolism.

1242 - **Physiology of Phosphorus and Calcium Metabolism of Dairy Cows** (1). — Meigs, E. B., Blatherwick, N. R., Cary, C. A., and Woodward T. E. (Research Laboratories of the Dairy Division, Bureau of Animal Industry, U. S. Department of Agriculture), in *The Journal of Biological Chemistry*, Vol. XL, No. 2, pp. 460-500. Baltimore, December 1919.

Recent work has made it seem probable that the amount of calcium and phosphorus contained in the rations of dairy cows is a matter of great practical importance. In a comprehensive series of experiments on good milking cows, Forbes and his fellow-workers (*Ohio Agricultural Experiment Station Bulletin* No. 295, 1916; No. 308, 1917; No. 330, 1918), have found that the calcium balances were always negative, and the phosphorus balances usually negative, though the rations were liberal, and in many cases contained more calcium and phosphorus than is ordinarily fed to cows yielding a large amount of milk.

When cows are fed according to their milk production, the feed — particularly the grain — is reduced with the progress of lactation, and reaches its lowest point when the cow becomes entirely dry, generally a few weeks before the next calf is born. The authors proposed to determine whether this method insures that the cows receive enough phosphorus to provide for the optimum milk yield in the next lactation period, if enough grain has been fed to provide sufficient phosphate for the maintenance of the cow and the growth of the unborn calf, as calculated from the figures given in the standard text-books.

From another series of experiments the authors have discovered that in the case of dry, pregnant cows, even if fed a much higher grain ration than usual, there is a decided tendency for the concentration of phosphorus in the blood plasm (2) to decrease towards the end of pregnancy. This tendency is more marked when the grain ration is lower. On the other hand, if the animals are given phosphates, the amount of phosphorus in the blood is increased. The authors are at present engaged in trying the effect of the addition of sodium phosphate to the ration, and intend to study the triple relationship between phosphorus in the ration, in the blood and in the urine. The results of the experiments described in the article analysed are given in 12 tables, and summarised as follows:

---

(1) See *R.* July 1917, No. 648; *R.* April 1920, No. 440. (*Ed.*)

(2) See also: P. Mazzocco "Dosage du calcium du sang," in *Comptes rendus de la Société de Biologie*, Vol. LXXXV, No. 28, pp. 689-690. Paris, October 15, 1921. — P. Maz- "Le calcium sanguin chez diverses espèces", *Ibidem*, pp. 690-691. — P. Mazzocco, and R. Bustos Moron, "Le calcium sérique dans les états gravidique et puerperal", *Ibidem*, p. 692.

Prof. Mazzocco, of the Physiological Institute of the Faculty of Medicine of the University of Buenos-Ayres, states that most of the calcium is contained in the liquid portion of the blood, and is present in almost the same proportion in the serum and the plasma. The

1) The separate collection of urine and faeces by attendants, as practised in metabolism experiments on cows, produces a nervous disturbance in the animals which interferes markedly with the assimilation of calcium and to a less degree, with that of nitrogen and phosphorus. A critical examination of metabolism experiments carried out in the past indicates that, in the great majority of instances, the experimental procedure has interfered with calcium assimilation.

2) In the case of pregnant cows, the assimilation of phosphorus, and probably of calcium also, is favoured by adding bi-sodium phosphate to the grain, and by feeding the grain and hay of the ration on alternate days.

3) The urinary excretion of phosphorus is markedly influenced by the concentration of inorganic phosphorus in the blood plasma, but it is also affected by another factor, which may be connected with the acid base equilibrium of the body.

4) The authors found in their experiments, that there was an inverse relation between tne amounts of calcium and phosphorus excreted in the urine. There is however no doubt that this relation is easily disturbed by the other influences, particularly the relation between the acids and bases of the ration.

1243 - **Variations in the Fecundity of Poultry Based on Anatomical Differences in the Ovary. Experiments in the United States.** — PEARL, R., and SCHOPPE, W. J., in *The Journal of Experimental Zoology*, Vol. XXXIV, No. 1, pp. 101-108, 2 figs. 7 tables, bibliography of 9 works. Philadelphia, August 1921.

Very detailed descriptions of the ovaries of 36 birds including various breeds of domestic fowls, water-fowl and wild birds. The object of the

---

red blood corpuscles always contain a little calcium. The following figures give the milligrams of Calcium (Ca) found per 100 cm³ of the blood examined (citrated blood).

Species	Entire blood	Plasma	Serum	Red corpuscles
Man	7.15	9.34	9.39	1.23
Dog.	7.57	10.12	10.57	1.13
Horse	7.71	10.57	10.57	0.97
White rat	6.77	8.60	8.66	1.11
Fowl	7.30	9.19	9.23	1.60
Rabbit	8.43	9.92	10.01	1.14
Cat	7.15	9.83	9.31	0.83
Goat	8.07	10.13	10.63	1.09
Guinea-pig.	6.02	7.68	7.84	0.98
Sheep	8.10	10.80	10.97	1.23
Ox	6.43	8.31	8.37	1.13
Pig	7.12	9.22	9.30	1.44

MAZZOCCO and BUSTOS MORON have found that there is a real, though slight decrease in the serum calcium during the pregnant or puerperal condition. The amount of calcium is no proof of pregnancy, nor does it give any information as to the existence or gravity of accidents occurring during pregnancy. (*Ed.*)

researches was to determine whether the ovary of a very productive hen, with a winter record of from 75 to 115 eggs, contains a larger number of oöcytes than that of a hen laying only 10 to 15 eggs a year, and none in the winter.

TABLE I. — *Variation in Fecundity of the Birds in Relation to the Number of Visible Oöcytes.*
(Biometric Constants).

	Breed or species	Mean number of visible oöcytes	Standard deviation	Coefficient of variation
owls	White Leghorn	2476	705	28.5
	F_1 Cross breed fowls	2415	274	11.4
	Barred Plymouth Rock fowls	1615	433	26.8
	For all the fowls av.	**1906**	**615**	**32.3**
We fc	Toulouse geese	1489	432	29.0
	Pekin ducks .	1068	129	12.1
	For all the domestic water-fowls av.	**1279**	**382**	**29.9**
	Guinea-hens	676	90	13.3
Wild birds	Crows . . .	764	41	5.8
	Kingfishers	376	129	34.3
	For all the wild birds av. . .	**504**	**235**	**46.7**
	Id., including guinea hens . . .	**553**	**219**	**39.6**

It has been found, as is shown by Table I, that in general, the mean number of visible oöcytes in the ovaries of different kinds of birds reflects the normal fecundity or laying activity of the same species of birds. This relation does not hold with any exactitude or regularity for differences in fecundity between individual birds.

TABLE II. — *Constants From Regeneration Experiments.*

Group	Total visible oöcytes		
	Mean	Standard deviation	Coefficient of variation
Barred Plymouth Rock (portion of ovary removed)	663 ± 83	246	37.1
Barred Plymouth Rock (regenerated ovary) . . .	1487 ± 110	348	22.1
Total . . .	**2150 ± 183**	**543**	**25.2**
Barred Plymouth Rock (normal)	1615 ± 81	433	26.8
Cornish Indian Game (portion of ovary removed)	1088 ± 79	234	21.5
Cornish Indian Game (regenerated ovary)	1523 ± 146	432	28.3
Total . . .	**2611 ± 189**	**561**	**21.5**
Cornish Indian Game (normal)	1550	—	—

In Barred Plymouth Rocks, the number of visible oöcytes increases with the advancing age of the bird within the limits of 6 months and 36 months.

In another series of experiments on ovarian regeneration it was discovered, that by removing a portion of the ovary and causing it to regenerate, the total number of oöcytes developing to visible size is increased from 33 to 68 % over the number which develop in the normal unoperated bird. Table II gives data showing this increase in the oöcytes produced by the removal of a portion of the ovary.

1244 - **Estimation of the Digestibility of Foods Containing Cellulose: Experiments Made in Germany.** — SEMMLER, F. W. and ARINGSHEIM, H., in *Die Landwirtschaftlichen Versuchs-Stationen*, Vol. XCIV, Parts, 1-2, pp. 85-96, 4 Tables. Berlin, August 1919; Summarised in *Biedermanns Zentralblatt*, Year I, Part 7, pp. 270-272. Leipzig, July 1921.

The authors in the course of their researches on the digestibility of a food containing cellulose, came to the conclusion that WEENDE's method (1) which is customarily used for the quantitative estimation of the crude cellulose content of a food, cannot serve as the sole basis for the determination of its digestibility.

Good results have been obtained by direct and indirect estimation of the lignin.

The direct method, according to WILLSTAEDTER, consists in determining the water, ash, crude protein, pentosans, cellulose and lignin (total analysis). The samples of the foods containing cellulose are treated repeatedly with 40 % hydrochloric acid at low temperatures (in freezing chamber). They are then left to digest for 2 × 24 hours, and the residue, soaked in water until a neutral reaction is obtained; by this means the lignin content can readily be estimated.

It can also be determined indirectly by WAENTIG and GIERSCH's method of finding the chlorine index (" Chlorzahl "): 10 gm. of the substance the digestibility of which is to be determined are placed in a chloridising vessel with 25 cm^3 of water. The weight of the receptacle having been found, chlorine is introduced until the right weight is reached.

The increased weight, minus the amount of chlorine absorbed by the water used to moisten the substance (100 cm^3 representing 0.70 of chlorine), when multiplied by 10, gives the chlorine index: by subtracting 1.34, the exact lignin content of the cellulose food is then obtained.

The comparative analyses made by the authors agreed in general very well, except in the case of straw disintegrated by the BECKMANN method, and this discrepancy they are unable to explain.

When it is a question of a total analysis (" Gesamtanalyse "), a high lignin content (e. g. 20 %), in a natural product (" Naturprodukt ") indicates low digestibility not exceeding 50 %, whereas in the case of a product treated with alkalis (" Kunstprodukt, ") a high lignin content does not prevent a greater digestibility (up to 75 %) for the crude cellulose. It must be remembered always that the digestibility of the organic matter is in inverse proportion to the amount of lignin contained in the food.

---

(1) See *R.* March 1921, No. 314. (*Ed.*)

From the total analysis, and by comparison with other foods of known nutritive value, certain conclusions can be reached as to the digestibility and starch value of a cellulose food, especially one that has been disintegrated by alkalis, which will suffice at all events to settle the preliminary question whether a feeding experiment is necessary.

1245 — **Experiments Carried Out in Germany on Sheep and Pigs to Determine the Food Value of Some Dried Beer Yeasts** (1). — HONCAMP F., in *Die Landwirtschaftlichen Versuchs-Stationen*, Vol XCVI, Parts 3-4, pp 143-206. Berlin, 1920.

The author has analysed and used in feeding experiments dried beer yeasts obtained by 4 different processes of manufacture namely: 1) the Max OSCHATZ system, Dresden — 2) BUTTNER and MEYER's system, Urdingen near Duisbourg (Rhineland) — 3) TATOSIN's system (Trocknungsanlagengesellschaft), Berlin. — 4) Vacuum process ("Vacuumverfahren") of Emile PASSBURG, builder, Berlin. Experiments were made also in the utilisation of "Hefetrub" (the deposit formed in beer vats and coolers) as a food for sheep and pigs.

The content in crude nutritive substance of the dry yeasts, and of "Hefetrub" were as given in the following table.

Content in crude nutritive matter of the 4 kinds of dried yeast and of "Hefetrub".

	Organic matter	Crude protein	Refined protein	Nitrogen free extracts	Crude fats	Ash
	%	%	%	%	%	%
Yeasts:						
Oschatz system .	99.65	48.07	41.61	13.59	0.99	7.35
Tatosin »	92.35	57.65	51.18	33.10	1.60	7.65
Büttner » . .						
and Meyer	92,58	55.52	50.30	35.72	1.34	7.42
Passburg system . .	89,41	55.24	17.50	32.42	1.75	10.59
« *Hefetrub* »	91,39	55.45	39.63	31.17	4.17	8.61

In the experiments with sheep fed with a supplementary ration of lucerne hay no difference in favour of any of the drying methods was observed. The protein digestibility of the various system was as follows:— Oschatz 88.8 % — Büttner 91.7 % — Tatosin 93 % — Passburg 91.5 %. — "Hefetrub" 72.9 %. Similar results as regards protein were obtained in the pig-feeding experiments, but the nitrogen free substances were turned to better account by the pigs than by the sheep. A considerable difference was noticed in the case of "Hefetrub" only, its digestibility coefficients being as follows for sheep and pigs respectively: crude protein, 79.9 and 62.7 % — nitrogen free extracts, 71.4 and 54.5 % — Organic matter, 66.4 and 53 %.

---

(1) See *R.* Feb. 1915, No. 204. (*Ed*)

In the sheep fattening experiments, it was found as a rule, that given an equal quantity of digestible protein and starch values in the basal ration, dried yeast fed as a supplementary ration, though rich in protein, did not have the same effect upon the live weight and quality of meat and fat as a mixture of sesame cake and ground cotton-seed cake.

Since, however, the differences were but slight, it must be admitted that they should be attributed to the better or worse digestive capacity of some of the animals, composing the various groups fed with dried yeast This view is confirmed by the fact that in the group given dried yeast as a supplementary ration, the results of the experiments were almost equal to those in the case of the two groups fed with a mixture of sesame cake and cotton seed cake.

In a second experiment in fattening sheep, dried yeast proved equivalent to soy-bean flour as regards increase in the live-weight.

In a pig fattening experiment, the effects of dried yeast and fish meal were compared. The latter proved superior as regards live weight, producing a daily increase of 0.663 kg. per head as against 0.637 kg. with dried yeast. No difference was observed in the quality of the meat.

1246 - **Effect of Degerming on the Fattening Value of Maize; Experiments Made in Hungary.** — WEISER St, in *Die Landwirtschaftlichen Versuchs-Stationen*, Vol XCVII, Parts 1 and 2, pp. 93-110. Berlin, November 1920.

The output of maize oil in Hungary which was very small before the War, assumed considerable proportions during the War, on account of the scarcity of animal and vegetable fats.

As the extracted germ is richer in nitrogenous substances, crude fats and mineral matters than the whole seed, degerming causes a loss in these materials

The authors with the object of determining how far these losses affected the value of degermed maize in fattening stock, calculated first the deficiency produced by abstracting from 1 quintal of maize 10 kg. of germs containing 24 % of oil, and then proceeded to make feeding experiments on pigs on the Bábolna and Kisbér estates.

These experiments showed, that degerming has but little influence upon the fattening properties of maize (1). The same results were obtained as regards increase in live weight and quality of fat, when 103-104 kg. of degermed maize were fed instead of 100 kg. of entire maize the basal ration being maintained.

1247 - **The Chemical Composition and Food Value of *Monilia coerulea* Hay. Experiments Made in Germany.** — HONCAMP F. and NOLTE O., in *Die Landwirtschaftlichen Versuchs-Stationen*, Vol. XVIII, pp. 91-95. Berlin, 1919; Summarised in *Biedermanns Zentralblatt*, Year 1, Part 3, p. 105. Leipzig, March 1921.

Molinia coerulea flourishes on damp sandy soils, as well as on the peaty soils of high-moors and meadow-moors.

---

(1) The author was able to estimate the maximum decrease in nutritive value at only 3.5 %. (*Ed.*)

The hay is regarded as of inferior quality, and has hitherto been used for litter only.

In the authors' feeding experiments, the first sample of this hay was so much lignified, that the sheep tested refused to touch it, even after fasting for several days, whereas a Russian native horse (Panjepferd) ate it readily.

Molinia coerulea when cut very young, and at once dried was eaten without the slightest hesitation. Its crude nutritive content regarded as percentage of dry matter is as follows: organic matter 94.58 — crude protein 15.34 — refined protein 15.11 — nitrogen-free extracts 50.67 — crude fats 2.33 — crude cellulose 26.24 — refined ash 5.42. The following percentages of these substances were digested on an average : organic matter 65.5 — crude protein 71.8 — nitrogen-free extracts 64.9 — crude fats 27.9 — crude cellulose 66.3. *Molinia coerulea* hay is thus very rich in protein, but poor in crude cellulose. From the above coefficients of digestibility, the starch value of this forage is 30.6, which is equal to that of good quality meadow hay with a high protein content. When lignified, it should be used for litter only.

1248 - **Variability in Domestic Animals and the Value of Statistics to Biological Researches Applied to Animal Breeding; Researches Made in Germany** (1). — FEIZE, E., in *Fühlings Landwirtschaftliche Zeitung*, Year LXX, Parts 13 14, pp. 259-271, 3 diagrams, 3 tables. Stuttgart, July 1921.

Researches on biological genetics hitherto made have been chiefly concerned with Mendel's theory as applied to the heredity of characters of little importance from the standpoint of scientific stock-breeding. The greatest progress has been made in the study of the transmission of coat colour, whereas morphological characters, which are much more important to the breeder, have been neglected.

In a study on the transmission of the character, power of performance ("Vererbung von Leistungseigenschaften," in *Fühlings Landwirtschaftliche Zeitung*, 1914, part 8), ROEMER has already pointed out certain limitations affecting researches based on Mendel's laws. On the other hand, the theory that power of performance cannot be correlated with body measurements (2), is still the subject of much discussion. The author hopes that analysis based on statistics of variations will throw some light on the question. Attention should be directed to the behaviour of certain groups of biotypes or "elementary races" (GOLDSCHMIDT), rather than to a supposed correlation existing between shape and power of performance.

---

(1) An exhaustive bibliography on this question is to be found in the work of the same author entitled "Über korrelative Variabilität bei Haustieren" in *Fühlings Landwirtschaftliche Zeitung* Year LXX, Nos 3-4, pp. 61-69, February 1921, summarised in *R.* July 1921, No. 739. (*Ed.*)

(2) See *R.* July 1921, No. 739. (*Ed.*)

In analysing the old conception of selection, the author remarks that the strong predilection shewn by practical breeders is founded on the everyday experience, that by means of systematic breeding, the progeny generally become superior to the original stock. This is easily understood, seeing that most stock-breeders have not the opportunity of observing a large mass of material, and hence are not able to understand that progress from the ordinary stock-raiser's standpoint in no wise signifies a displacement of the typical characters of a form, but merely a segregation of lines.

On the other hand, very little is yet known as to the number and extent of the mutations occurring in stock, especially as regards most morphological characters. It is probable that many mutations of this class are part of the typical deviation of the form as a whole, and therefore should not be regarded as extreme variations. Only a succession of generations can show if they really constitute a new line distinct from the genotypic point of view, and capable of transmitting the recently-acquired character to their progeny.

The author with the object of obtaining information regarding the general behaviour of the forms, has made an exhaustive study of the variability of horses from Hanover and Westphalia. He does not take into account questions of heredity, but bases his work on statistics of variation, a method already adopted by WALTHER (1), SCHMIDT B. (2), STROEVER (3) and other authors.

The data respecting the height at withers given in the appended tables are taken from the Hanover Horse Stud Book (Vols. 2-3) and the First-Register of the Westphalian Horse (Vol. 8).

The author gives the distribution curves of the 3 types of horse (4) in the various classes established according to the height at withers; he has also determined the mean value (M), the typical variation (σ), as well as the coefficients of variation. The method of calculation is given in detail tail (5).

When M and σ are known, it is possible to calculate the probability of the occurrence of the different classes of height.

In the case of fluctuating variations, the limits $M + \sigma$ and $M - \sigma$ represent the points where the largest number of variations occur.

The values determined are as follows:

	Mean value	Typical deviation	Coefficient of variation
Hanover horses.	161.143 cm ± 0.071	± 3.936 cm	2.443
Westphalian horses			
a) Trotters.	158.812 cm ± 0.134	± 4.396 cm	2.768
b) Draught horses. . . .	159.219 cm ± 0.129	± 3.953 cm	2.264

Outside the limits $M + \sigma$ (157.207 to 165.079 cm.), there are in the Hanover horses about 750 variations, that is to say, only ¼ of the whole number. This fact proves the importance of the calculation of the typical deviation in estimating the different measurements of animals. This is the only method that makes it possible to predict the transmission of quantitative characters, though it does not exclude hereditary analysis extending through several generations.

(2) SCHMID B., Vererbungsstudien im Hauptgestüt Trakehnen. Hanover, 1913.

(3) STROEVERR, Die Vererbung der Haarfarbe beim Vollblut. Berlin, 1917.

(4) Whereas the type of Hanover horse is already fairly fixed (in the zootechnical-biological sense), the Westphalian breeders have a good deal to do before obtaining uniformity of type. Both among trotters and draught-horses, stock animals are still found which have come from the most different countries (Hanover, Great Britain, United States, France, East Prussia, Belgium, the Rhineland and East Frisia). As the author only wished to study individuals of pure Westphalian descent, the number of animals available was reduced to about 1000. The author has however been able to prove that the typical formation of the series has not been modified in any way. (*Ed.*)

(5) σ indicates the variations within the group. As regards its calculation see also *R.* July 1921, No. 739, and *R.* August 1921, No. 836. (*Ed.*)

[1248]

From a curve showing the distribution of Westphalian trotters (both as observed and calculated), the author found, that the horses used by him in these researches were very suitable subjects for theoretical calculations.

Conclusions. — What do the curves plotted and the statistical data collected show from the stock-breeding and biological standpoints ? There is no doubt that in the three cases there is a mixture of forms. This can be explained in the Westphalian horses by the their mixed descent. This explanation does not hold good for the Hanover horses, which from the stock-breeders' point of view, are already more homogeneous. If the probable influence of age and environment are left out of account, the most perfect zootechnical homogeneity does not in any way imply biological homogeneity of form. This fact is clearly demonstrated by the curves reproduced in the text. The asymmetry of the curves depends upon the presence of very different hereditary units (genotypes) whereas the breed (" race ") from the zoo-technical standpoint may appear homogeneous. The different genotypes (races, lines, populations) themselves again represent a fusion of various ancestral forms of which the number and prepotency cannot be exactly determined in the case of the Hanoverian or of the Westphalian horses.

It would be possible to decide, by means of special researches based on Mendel's theory whether the different sectors of the curves correspond, as regards genotypic constitution, to constant forms (D and R respectively), or to intermediate forms (D R).

1249 - **Stock-Breeding in Galicia (Spain).** (1). — ARMENDARITZ, J. G. (Provincial Stock Inspector of Lugo), in *La Industria pecuaria*, Vol. XXII, No 709, pp. 435-437. Madrid, October 1, 1921.

Stockbreeding is the fundamental industry of Galicia (Province of Lugo), and the main source of its wealth. The total number of cattle, sheep, goats, horses, and pigs amount to 1 100 000 head, and poultry to 600 000 head ; the value of all the stock is 170 millions of *pesetas*.

The cattle of Galicia provide Barcelona with most of its meat supply, and also furnish a good deal of meat to Madrid. A cattle-train leaves Lugo daily for the interior.

---

(1) Spain is an eminently agricultural country : 84.45 % of the ground being classed as fertile. Of this 35.5 % is devoted to agriculture and horticulture, 2.5 % to vines, 2.0 % to olive plantations, 22.2 % to fruit trees, while 25.3 % consists of natural pasture. Small and average-sized holdings predominate ; they were constituted during the 19th century.

In 1920, the areas under the most important crops and the yields obtained were as follows. wheat 4 198 000 hectares, 38 327 000 quintals — barley 1 768 000 hectares, 20 012 000 quintals — oats 650 000 hectares, 5 571 000 quintals — rye 737 000 hectares, 7 153 000 quintals — maize 478 000 hectares, 7 147 000 quintals — millet 2000 hectares, 21 000 quintals — mixed cereals 44 000 hectares, 296 000 quintals — rice 49 000 hectares, 2 950 000 quintals — coloured haricot beans 198 000 hectares, 1 865 000 quintals — white haricots 323 000 hectares, 1 913 000 quintals — peas 62 000 hectares, 429 000 quintals — Chick peas 230 000 hectares, 1 422 000 quintals — lentils [illegible]3 000 hectares, 257 000 quintals — common vetch 200 000 hectares, 1 407 000 quintals — other vetches 67 000 hectares, 583 000 quintals.'

In 1920, there were 2 141 000 hectares under vines ; they produced 43 438 180 quintals of grapes from which were obtained 32 128 850 hectolitres of ordinary red and white wines.

The sheep and goats that stock the markets of Northern Spain come principally from the mountainous part of the country; these animals are in great demand because owing to their small size, they furnish for the same net weight of meat, double the quantity of offal and skins obtained from other breeds.

The chief aim of the horse-breeder is to rear mares which are mated with donkeys of the Zamora breed, in order to insure a plentiful supply of mules.

Pigs are the most generally kept domestic stock and their meat, which is very delicate, is the staple animal food consumed by the rural population.

The author lays stress on the desirability of improving the poultry breeding, and establishing genuine industries founded on animal products, as at present this branch of trade is practically non existent.

As regards methods of improving the live-stock, the introduction of foreign cattle has never given good results and in order to succeed, it would be necessary to devote a considerable amount of special attention to the question. In the author's opinion, such efforts would be better directed to the selection of native breeds with the object of fixing and perpetuating desirable qualities. He advises the holding of Shows and Competitions, the formation of artificial pastures, and preventive inoculation against epizootic disease.

During the last 10 years, the systems of sales have become far more practical, and there is a marked tendency towards the constitution of co-operative societies in order that the meat may be sold directly to the centres of consumption.

The olive plantations occupied 1 590 000 hectares and produced 18 421 950 quintals of olives from which 3 417 000 quintals of oil were extracted.

Amongst the other products should be mentioned esparto, hemp, flax and vegetables; a considerable number of oranges and hazel-nuts are exported; wine making and fruit-growing are important industries. Silkworm rearing is practised in Valencia, Murcia and other provinces. There are 28 factories of cane sugar and 46 of beet root sugar; in 1919 the former produced 6 278 tons of sugar and the latter 104 949 tons.

In 1919, the number of stock was estimated as follows: horses 594 351 — mules 1 069 408 — donkeys 1 014 026 — cows 2 396 573 — sheep 19 337 427 — goats 3 970 656 pigs 6 228 964 — camels (in the Canary Isles) 5083.

At Cáceres and Huelva, there are rich deposits of phosphates, which in 1919 yielded 25 095 tons worth 755 782 *pesetas*. There are other important industries, especially in Catalonia; the cotton industry (which employed 2 614 500 bobbins in 1910), the wool industry (662 000 bobbins), paper making (about 144 factories), cork (in 1917, 60 000 tons of cork were worked worth 58 millions of *pesetas*). *The Statesman's Yearbook* 1921. Macmillan and Co., London. (*Ed.*)

1250 – **The Cattle of Sardinia** (1). — DORIA M. (Osservatorio zootecnico della Provincia di Sassari), in *Allevamenti*, Year II, No. 9, pp. 274-276, 5 figs. Palermo, September 1, 1921.

Cattle-breeding has made great progress of late years in Sardinia.

There are 3 breeds of cattle in the island: 1) the Plain breed, which to a large extent consists of imported animals descended from the Sicilian draught cattle; 2) the Milk breed, descended from the Brown Swiss breed; 3) the Mountain breed (native).

In Sardinia, cattle like all other domestic animals, are kept in the open. Even in places where, in order to obtain some premium or subsidy granted by the Ministry of Agriculture, the owners have constructed byres or scientific cow-sheds, these remain empty.

The Plain breed is found in Planargia, and Campidano d'Oristano. These are essentially draught animals, and have a special aptitude for their work. The coat is wheat-coloured, black or coal black, the cattle are strongly built, symmetrical and well-shaped for draught purposes.

The Milk breed, which is thoroughly acclimatised, and to be found throughout the island, may be termed Schwyz-Sardinian. The centre of its production is Ozieri. These cows are symmetrical with soft, thin skin, and well-shaped udders. Although living in the open, and having to subsist on the natural herbage, which at certain seasons is very scanty, they yield plenty of rich milk from which excellent butter, a much-prized article of export, is made.

The Mountain breed, or the Sardinian breed proper, much resembles the cattle in the mountains of Dalmatia. The animals are of small size, with delicately-shaped muzzle, short, very pointed horns, small, bright eyes and variegated coat. They weigh on an average not more than 80 to 90 kg. The cows give little milk, but their flesh is excellent. These cattle live half-wild in the lentisk woods amongst wild-boars and goats and no breeder has ever tried to improve them.

The author lays stress on the importance of introducing cattle-feeding into the island, in order to insure that the stock is fed regularly throughout the year: he also points out the advantages of partial housing.

1251 – **The "Tuxer" (2) A Race of Tyrolese Cattle in Process of Extinction.** – KUBAT (Chief Inspector of Stock, Innsbruck) in *Suddeutsche Landwirtschaftliche Tierzucht*, Year XII, No. 14, pp. 158-159, Munich, July 1921.

The "Tuxer" race of cattle, which at the end of the nineteenth century was largely represented in the Unterinntal and its transverse valleys from Innsbruck as far as the Italian frontier, is now only to be found in some mountain communes of the district of Halle (Klein-and

---

(2) Or, according to SANSON "Duxer", a word signifying coming from Dux, a place in the Tyrol. (*Ed.*)

Grossvoldersberg, Kolsassberg, and Weerberg), and in the cow-sheds of a few breeders in the district of Innsbruck and the Zillertal (Sprengen, and Fügen).

These cattle although formerly much prized and sought after, have been gradually replaced by the spotted Unterinntal, the Simmental and the Grey-brown Tyrolese breeds.

The Tuxer cow though very strong and hardy, is not a good milker, and at the same time the animals of this breed grow slowly, and cannot compete with the quickly developing Simmentals, or the brown-grey races with heavy milk yield.

They possess the characters of their ancestor *Bos taurus brachycephalus*, and are nearly related to the *Zillertal cattle* (another race that is gradually dying out), and also to the *Pustertal* and *Pinzgau breeds*, their geographical extension being very considerable.

The chief coat colours of Tuxer cattle are dark-brown, brownish-black, or black with a light stripe down the spine. The belly is white; the fore-limb and lower portion of the flank sometimes show traces of white spots. The muzzle, tongue, hoofs and horns have a dark blue pigmentation.

The back in the region of the hindquarters is sloping; the tail being set very high, in the manner characteristic of the primitive Alpine races.

The thorax is enormously developed, and in circumference exceeds that of any other European cattle, thus conferring an unusual degree of resistance to tuberculosis.

These animals fatten well and possess remarkable powers of digestion, but their milk production is not sufficient to satisfy present-day requirements.

Breeders formerly devoted their attention principally to obtaining very strongly-built and heavy animals (600 kg.), and took no pains to improve the milk yield, on account of the small demand for milk or dairy produce.

The cows are very robust and excessively pugnacious; owing to the latter quality organised cow-fights have become a regular sport in the Alps.

In order to prepare the animals for these popular entertainments, the cows were frequently not thoroughly milked. This continual partial suppression of the mechanical function of the udder for many generations, explains the low milk yield of the race.

Whereas however formerly a good fighter ("Moarin", "Hagmoarin"), was more valuable than a good milker, the combative qualities of a cow are now less appreciated, and hence the milk yield is being improved; the average production before the War had risen to 3232 litres per annum. In the case of cows fed on a small quantity of concentrates, in addition to their ordinary ration of hay and green forage, the fat content of the milk is particularly high (3.38 %).

The author in conclusion draws the reader's attention to the great resemblance between the Tuxers and the cattle of the Val d'Hérens (Canton du Valais, Switzerland) (1) as regards shape, performance and qualities. He also mentions the interesting and striking fact, that cow-fights are the custom in the Valais, the victorious animal being dubbed queen of the herd.

It is therefore probable that these two races of cattle are very near akin, and this hypothesis would seem to be confirmed by the fact, that the head of a bronze bull, with all the characters of *Bos taurus brachycephalus*, found in the ruins of the Roman citadel at Martigny (Valais), proves the existence at a still earlier date, of a breed of cattle of which the races still preserved in the Valais and Tyrol appear to be the last representatives.

1252 - **Zebu Breeding in Madagascar** (2). — FAUCHÈRE A., (Inspecteur général des Services agricoles et forestiers de Madagascar), in *Révue d'Histoire naturelle appliquée*, Vol. II, No. 5, pp. 129-132, and No. 6, pp 177-181. Paris, May and June 1921.

I. *Condition and Value of the Stock*. — The products of live stock breeding form an increasingly important item every year in the general trade returns of Madagascar. Thus, whereas in 1907 the value of exported cattle and their produce was 6 591 000 francs only, in 1919 it had already risen to 90 243 000 francs. These figures prove that cattle-rearing is an important source of profit to the island.

The last census, taken in 1918, shows that the Madagascar herds contained nearly 5 million head, the provinces of the West and South-West being the richest in cattle A comparison of the number of the latter with that of the population, shows that Madagascar possesses a larger proportion of cattle per human unit than any other of the stock-breeding countries.

The proper conditions of cattle rearing are little known in the Island, and the most rudimentary methods are followed.

The entire herd composed of zebus, is in the hands of native herdsmen of simple habits and needs.

In 1895, the year of the conquest of Madagascar, no trouble was taken to turn the stock of cattle to full account. Although as many as 400 000 head might have been utilised for local consumption, barely ⅓ of this number were actually supplied, the rest of this potential wealth being either lost or wasted. The price of the zebu was very low, a large ox fetching from 50-60 francs only in most districts, even as late as 1913.

One cause of the small number of cattle, the ritual sacrifices, still exists; formerly it assumed such proportions, that Radama I, towards the end of his reign, limited the number of oxen to be killed on the occasion of the funerals of the Mirana, in order to prevent the destruction of the Imerina herd.

---

Les races Suisses de betail bovin, in the *Vème Congrès international d'Agriculture, Lausanne* 1898, *Mémoires et Documents*, pp. 409 411 — 2) WERNER H., *Die Rinderzucht* pp. 452 and 455. Berlin 1912, published by Paul Parey — 3) HANSEN I, *Lehrbuch der Rinderzucht*, pp. 284 and 335. Berlin, 1921, published by Paul Parey. (*Ed*)

(2) See in *R*. Jan. 1919, pp. 1-12, the Original Article by GEORGES CARLE entitled *Stock Breeding in Madagascar*. (*Ed*)

Since the War, the price of zebus has considerably increased, and the native breeder has learnt the value of his cattle; the total value however of the produce of the herd is scarcely 80 million francs, for though beef costs 3 francs a kg. the breeders get less than 1 franc.

II. *Breeding Conditions and Methods.* — No care is given to the animals, which remain always at grass, and live an almost wild life, exposed to the inclemency of the weather, the owner scarcely troubling even to collect and mark them from time to time.

The cattle are left to fend for themselves. During the rainy season they have abundance of food, but the owners never think of collecting reserves of forage in these months of plenty, in order to tide over the frequently very long and deadly periods of dearth that occur during the dry season.

No choice is made with a view to obtaining good animals for breeding purposes. Calves receive no more attention than adults, and as there is but little milk at their disposal, begin to eat fine grass at a very early age, so that their rate of mortality is high.

The appearance of the herd varies much according to the season. During the rainy months, and up to June and July, it is most satisfactory, there being a relatively large number of fat animals, the hump they bear on their withers is full of fat, and its large size is an indication of their well-being, whereas in the dry season, the cattle become excessively thin.

At this time, the beef-canning factories are obliged to suspend their operations. Many of the cattle are so weak from want of food, that they offer no resistance to disease, and fall easy victims to bacterial anthrax, and tuberculosis.

The Madagascar cattle are small and mature late, not reaching full growth before 7 or 8 years of age, when they may weigh as much as 400 kg., or even more, but the weight of the full-grown zebu never exceeds 300 kg., unless it is specially fattened, as is sometimes the case in Imerina. The process consists in taking adult animals from the herd, and stall-feeding them till they reach the required weight. In this manner, oxen weighing 600 and 700 kg. can be obtained and these are especially suitable for the preparation of frozen meat. Only a few thousand animals however are treated in this way. The meat yield varies from 45 to 60 % of the live weight, according to the condition of the zebu at the time of killing.

The number of head is small in proportion to the area of grazing ground, there being only one animal to 8-10-12-15 hectares. Hence the return from the Madagascar herd is low; it is estimated at about 5 %.

III. *Measures for the Improvement of Cattle Breeding.* — Now that the Madagascar ox has become a valuable animal, zebu beef finding a ready market in Paris, and other circumstances having combined to make the herd the chief source of the wealth of the Colony, it is necessary that the breeding conditions should be improved.

[1252]

To this end the author advises the re-organisation of the Veterinary Service, which at present is not in a position to control even epizootic anthrax, a disease killing at least 100 000 zebus annually.

He has been able to set on foot the building of a laboratory for the use of the Veterinary Services, and of a School for Assistant Veterinary Officers.

In addition, a model farm has been instituted at Antsirabé to take the place of the old Iboaka farm suppressed in 1906. Many buildings have already been constructed, and as soon as the condition of the crops permits, stock for breeding purposes will be turned out on the farm land.

1253 – **A New Method of Selecting Milch Cows.** – MAUPAS H., in *Journal d'Agriculture pratique*, Year LXXXV, Vol. II, No. 33, pp. 151-152, Paris, Aug. 1921.

The correlation, which according to recent researches, seems to exist between chest development and lactic secretion in cows, has long escaped the notice of breeders of milch kine, and instead of selecting for breeding such cows only as were generally symmetrical, it was at one time the fashion to choose animals in which the hind were far more developed than the fore quarters. Hence far from being considered as a defect, a poorly developed, or even narrow chest, began to be regarded as a beauty, while in the same animals a broad pelvis was another much admired characteristic.

The method devised by D^r Paul SCHUPPLI, Director of the School of Agriculture and of Stock Breeding at Grabnerhof (Austria), for classifying the animals to be registered in the Herd Book of the Society during the War has been applied on a large scale by the Gröbning Breeding Syndicate to the Pinzgau breed. Like all such methods, it is based on the general appearance of the animal, after which, this being the important point, the width of the chest is compared with the height at the withers.

Each animal in which the required characters of development are combined, is marked according to a very definite scale of points. The lowest mark that can be givin is 1, indicating that the chest width of the animal examined is $^1/_3$ of its height at the withers. When the chest measurement exceeds this amount (and is over $^1/_3$ of the height at the withers) the cow is credited with another mark for each centimetre of extra width.

As a rule mark 5, which denotes exceptional characters in the animal measured, is rarely given. Investigations carried out under the auspices of the Gröbning Breed Society have shown, that *very many cows were not credited even with 1 mark,* and that such animals *should be excluded from the Herdbook.*

The following Table gives some figures collected by MAYER, an agriculturist of Oberstuttern *before* and *after* this method of selection was adopted, and they seem to confirm D^r SCHUPPLI's views on the question. From 1916, MAYER measured his cows in the manner prescribed by D^r SCHUPPLI, and in consequence, reduced the number of head in his herd to 9; but the latter were all entitled to mark 5.

Year	No. of Cows	Average annual Milk yield	Average fat content of milk
—	—	—	—
1912.	12	2 557 litres	3.85 %
1913.	12	3 065 »	4.01
1914. . . .	12	2 914 »	4.03
1915.	11	2 866 »	4.29
1916.	9	3 507 »	3.97
1917.	9	3 404 »	4.28

It should further be mentioned, that 2 bulls belonging to MAYER and aged respectively 18 months, and 2 years, were marked 5 on their registration in the Herdbook.

The milk yields due to the application of this method are all the more interesting, seeing that the animals kept by MAYER received absolutely no concentrates (cake, grain, etc.) and during the winter were given two feeds of hay, or the aftermath of the natural pastures only per day, while in summer, they lived entirely on the grass they cropped on the meadows belonging to the farm.

Cows of the Pinzgau breed, reared on the mountains in Austria weigh 400 to 450 kg., and yield from 1200 to 1700 kg. of milk only each year; the cows of the valleys weigh from 650 to 750 kg., and give from 2000 to 2800 kg. of milk a year (Prof. WERNER), but even these figures are below those obtained at MAYER's farm.

D^r^ SCHUPPLI and the Breed Syndicates of his district advise the adoption of the above-mentioned measurement method, but also advise an examination of the animals to see whether they are normal as regards width of pelvis, depth of chest, body length, etc. In this connection, the proportions fixed for the milch cow by Prof. DECHAMBRE will be of the greatest use (occipital-coccygeal length as compared with oblique circumference of the chest; the distance between the haunches as compared with width of skull, etc.).

The author hopes that the new method of measuring described above will be tried in those districts of France which are especially interested in milk production.

◆

1254 - **Comparative Value of Root Ration and Silage for Dairy Cows; Experiments in England.** — OLDERSHAW, A. W., and SMITH, F. C., in *The Journal of the Ministry of Agriculture*, Vol. XXVIII, No. 7, pp. 614-621, tables 2, figs. 2. London, Oct. 1921.

In previous experiments it was found that a ration of 60 lb. of silage was equivalent to 60 lb. of mangolds and 7 lb. of straw chaff. There was very little difference in the amount of milk given by cows fed on the two rations.

Since then it has been claimed that owing to the fact that silage contains considerably more albuminoids than roots, it should be possible to reduce the quantity of expensive concentrated food fed when silage is being used.

Experiments were carried out in the Eastern Counties of England, where the system of ensilage has made great progress during recent years (1).

It appears from the results obtained that 60 lb. of oat and tare silage + 10 lb. barley straw chaff + 14 lb. kale (Marrow stem) + 4 lb. mixed concentrated foods (equal weights of decorticated cotton cake and dried grains), give about $^1/_6$ of a gallon of milk per cow less than 60 lb. of mangolds fed with the same quantity of barley straw and kale, but double the amount of concentrated foods. That is to say, 60 lb. of silage is not equal in milk producing capacity to 60 lb. of mangolds + 4 lb. of concentrated foods.

However as regards the cost of the silage ration in the production of milk, this was $^3/_4$ d. per gallon less than that of the root ration.

1255 - Effect Exerted Upon Milk Production by the Age of the Cow at the Time of First Calving (2). **Researches Made in Germany.** — I. SPANN (Weihenstephan, in *Deutsche Landwirtschaftliche Tierzucht*, Year XXV, pp. 261-262. Hanover, June 1921. — II. WOLF, in *Suddeutsche Landwirtschaftliche Tierzucht*, Year XVI, No. 10, pp. 109-110. Munich, May 1921.

I. — This question has not hitherto been made the subject of much careful investigation in Germany, and the results so far obtained do not allow of any definitive conclusions. The author with the view of making a contribution to the study of the problem, has examined and elaborated his observations made on 709 East Frisian cows, the figures being given in Table I.

TABLE I. — *Effect Upon Milk Production of the Age of the Cow at the Time of First Calving.*

First calving at 2 years of age			First calving at 5 years of age		
No. of Cows	Successive ages	Milk yield	No. of Cows	Successive ages	Milk yield
	years	kg.		years	kg
21	4	3628	17	4	3380
35	5	4143	142	5	3783
19	6	4399	118	6	4130
12	7	5017	106	7	4500
12	8	4922	84	8	4788
5	9	4472	52	9	4761
3	10	5198	30	10	4706
1	11	3950	24	11	4752
2	12	4550	14	12	4784
2	14	4460	9	13	4182
1	16	2510	—	—	—
Average 113	—	*Average* 4295	*Average* 596	—	*Average* 4377

---

(1) See *R.* Aug. 1916, No. 880. (*Ed.*)

II. — Researches made on Allgäu cattle, and confirming the truth of Prof. SPANN's statement that the nearer the cows approach the close of their growing period, the greater is the average amount of milk they yield: this is shown by Table II.

TABLE II. — *Effect of the Age of Cows on Milk Yield.*

Age of cow at first calving	No. of cows observed	Annual yield of milk kg.	Fat %	Average number of lactation periods
Up to 28 months	30	2845	3.8	2.5
From 29 to 30 months. . .	646	2847	3.7	2.9
From 37 to 40 months. . .	396	2885	3.69	2.7

The relatively high milk yield of the 30 cows belonging to the first group is explained according to the author by the fact that they came from farms which were above the average, and in such cases the performance of élite parents comes into the reckoning; the animals had moreover grown excessively fast.

SPANN and WOLFF do not however consider the results obtained as absolutely conclusive, but think that investigations of this nature should be carried out on a much larger scale.

1256 - **Results of the Butter Competition at Dieppe, France, in 1921.** — LABOUNOUX (Directeur des services agricoles de la Seine-Inférieure), in *Journal d'Agriculture pratique*, year 55, Vol. II, No. 33, pp. 150-151. Paris, August 20, 1921.

The Butter Competition held this year on the beach at Dieppe is one of a series that the Central Agricultural Society of Seine-Inférieure has organized since 1906.

The results obtained confirm those of previous competitions in so far as they prove the need for a careful interpretation of the results of analyses of milk production.

The differences between the milk yield of different cows were sometimes most striking.

One kg. of butter was made from 16.215 kg. of milk given by one cow, but 26.659 kg. of milk were required in the case of another.

The variations in the fat content of the different milkings were also very marked.

With a general average of fat of 45 gm. per litre on the first day of testing, and 34 gm. on the second in the midday milkings, the fat content fell to 33.4 gm. per litre the first day and 30.3 gm. the second day, to rise again in the evening milking to 46.9 gm. and 48 gm. respectively.

The variations were still more noticeable in different milkings of the same cow, and even in the milk taken at the same hour on different days.

---

(2) See *R.* Oct. 1916, No. 1049 and *R.* April 1917, No. 345 (*Ed.*)

Thus one animal, an excellent butter producer, gave the first day, milk containing only 9 gm. of fat in the morning, 66 gm. at midday, and 38 gm. in the evening, but the fat content of the milk next morning was 18 gm. In the case of another cow, the fat content of the milk was 3 times below 20 gm. (morning milkings) and 6 times above 70 gm. (midday and evening milkings); the maximum being 85.5 gm.

As regards butter yield, all the cows placed in the first class of the second section (cows that had all their second teeth), produced 3.039 kg. of butter in 48 hours; the second and third class animals gave respectively 2.944 kg., and 1.029 kg.

Nine cows gave an average of over 1 kg. of butter per 24 hours and the maximum milk production was 68.200 kg. in 48 hours.

The Competition also proved once again that perfect symmetry and exceptional milk-yielding capacity can be combined in the same animal.

All the cows entered for the milk and butter yielding tests of the Central Agricultural Society of Seine-Inférieure have also to pass the symmetry tests, and the prize is awarded to the animal classed highest in both lists.

At Dieppe, however, the prize was carried off by a cow classed third in the butter competition, and second in the symmetry competition.

The following Table gives the general results of the competition.

General Results of the Butter Competition at Dieppe in 1921.

Classes	No. of animals	Milk production per 24 hours		Butter production per 24 hours (gross weight)	Weight of milk used to make 1 kg. of butter
		weight	volume		
		kg.	litres	gm.	kg.
Prize winners:					
First	8	13 131	12 755	638.56	20.563
Second	18	22 291	21 683	1 072.33	20.787
Total	26	19 473	18 980	938.85	20.711
All the cows taking part in the competition:					
First	8	13 131	12 755	638.56	20.563
Second	24	20 560	19 994	960.20	21.112
Total	32	18 703	18 184	870.79	21.258

When these results are compared with those of the last competition, which was held at Yvetot in 1914, a perceptible improvement is noticed in the amount of butter made in proportion to the milk supplied.

This year, at Dieppe, the average for all the animals competing was 1 kg. of butter from 21.258 kg. of milk, whereas at Yvetot in 1914, 23.971 kg. of milk were needed in order to obtain 1 kg. of butter.

The excellent results obtained by the breeders of the Seine-Inférieure are chiefly due to the efforts of the Milk-Testing Syndicates, and must be attributed to their daily tests, combined with patient and strict selection.

Most of the cows taking part in the Butter Competition were, in fact, chosen from the élite animals registered by the two great Milk Testing Syndicates of Seine-Inférieure: the Normand-Cauchois Syndicate founded in 1908, and the Pays de Bray Syndicate dating from 1912.

It is much to be desired that such useful organisations should increase in number in all cattle-breeding districts.

1257 - **Milk and Butter Competition at Meknès (Morocco) in 1921.** — *Revue Agricole de l'Afrique du Nord*, Year XIX, No. 106, p. 254. Algiers, August 12, 1921.

Milk and butter competitions were held at Meknès for the first time in 1916, and have taken place annually since that date, with the exception of 1920.

The main points in the organisation of these competitions are as follows: they last 48 hours; the cows are brought to the place appointed, on the day before the competition opens, and the inferior milkers are weeded out by a preliminary test, and sent back, thus the maximum number reserved for the actual test is reduced to 40 or 50.

During the two days of the trial, the cows are milked at 6 in the morning, and at 5 30 in the evening. The milk is carefully weighed each time, and its fat content estimated by the GERBER method.

The sum awarded in prizes at each of these competitions is 1200 francs.

In 1921 there were 17 competitors.

During the two days' trial, the mean maximum and minimum milk yields were respectively 8.957 litres, and 6.050 litres. The average daily milk production of the 17 cows, which were the property of 13 natives, was 7.560 litres per head.

In 1919, the average was 7.600 kg., or practically the same, though there were 20 competitors.

In 1916, it was 5.95 kg. per head and per day, but the competing cows numbered 40.

At the 1921 Competition, two cows belonging to Europeans gave respectively 11 litres and 9 litres a day.

According to the GERBER test, the maximum butter production was 560 gm. in 24 hours for a cow placed in the fourth class at the quantity milk testing which had yielded during the 2 days an average of 5.612 litres daily.

The minimum (220 gm.) was produced by a cow giving an average of 6.287 litres a day. The average for all the 17 competing animals was 39 gm. per head and per day.

In the case of the best butter producing cow, 1 kg. of butter represented 15.350 litres of milk, and in that of the worst, 28.570 litres. The average for the 17 cows was 24.160 litres.

1258 - **Pig-Breeding in the Colony of Erythrea.** — TARANTINO G. B., (Osservatorio zootecnico della Colonia Eritrea, Asmara), in *Allevamenti*, Vol. II, No. 10, pp. 306-309, figs. 4 Palermo, October 1, 1921.

In the Colony of Erythrea, the settlers are engaged in domestic pig-breeding, keeping 3 or 4 animals both for their own use and for sale.

Until January 1921, there was, at Sembel (Asmara), a large pig-breeding farm belonging to the firm of *Torrigiani*, and annexed to a Canned Meat factory with a branch establishment at Debarea.

The Caserta breed is the one chiefly represented ; it is well acclimatised, and has the usual characters denoting hardiness ; long rather large, head, small almost straight ears ; black coat and silky mane ; somewhat slow in fattening, especially if the animals are kept at grass ; meat very delicate ; sows very prolific and excellent mothers.

This breed has become quite acclimatised and does not suffer at all from the altitude or climate of the plateau, whereas nearly all the recently imported animals suffer much from the change and often die. The author has also found that pigs born on the plains of Erythrea, if transported to the plateaux, are subject to various diseases, especially to those affecting the respiratory organs.

The author advises selection in preference to crossing as the best means of improving the pigs in the Colony. Crossing should only be effected experimentally with great care, and on a small scale, unless success justifies bolder measures. The Bureau of Colonisation has imported some boars from Reggio Emilia (Italy), but their progeny have not proved successful.

1259 - **Some Feeding Tests with Pigs in Australia.** — PERKINS, A. J., in *The Journal of the Department of Agriculture of South Australia*, Vol. XXIV, No. 12, pp. 981-987, 7. tables. Adelaide, July 1921.

THE NUTRITIVE VALUE OF PIG MEAL AND PIG COMPO (WASTE PRODUCT MEALS SOLD BY THE METROPOLITAN ABATTOIRS BOARD) (1) AS COMPARED WITH THAT OF SKIM MILK. — In these tests which lasted a fortnight, 12 young pigs were taken and divided into 3 groups. The animals received the daily rations given in Table I (page 1597).

In feeding value, ½ lb. of pig meal, or of pig compo corresponds with 5 ½ lb. of skim milk ; the nutritive unit of these two meals is slightly cheaper than that of skim milk.

The mean daily increases in live-weight of the different groups from January 24 to March 6 were as follows :

1) *Barley and skim milk :* Group *A*, 0.87 lb. — Group *B*, 1.02 lb. — Group *C*. 1.35 lb.

2) *Barley and pig meal :* Group *A*, 1.24 lb. — Group *B*, 0.73 lb. — Group *C*, 1.33 lb.

3) *Barley and pig compo :* Group *A*, 0.85 lb. — Group *B*, 1.07 lb. — Group *C*, 1.08 lb

It will be seen from the above results that the two meals in question are very effective substitutes for skim milk when the latter is not available, and that any farmer with no milk at his disposal, who grows grain, can rear healthy young pigs.

---

(1) See *R.* May 1921, No. 544. (*Ed.*)

TABLE I. — *Daily Ration (in lb.) Fed to Young Pigs between January 24 and March 6.*

	Barley	Skim milk	Pig Meal	Pig Compo
January 24–Feb. 6:				
Group A	1.25	2.50	—	
» B	1.25	—	0.23	
» C	1.59	—	—	0.23
February 7-20:				
Group A	1.59	—	0.23	
» B	1.59	—		0.23
» C	1.93	2.50		
February 21–March 6:				
Group A	1.93	—		0.23
» B	1.93	2.50	—	
» C	2.27	—	0.23	

II. — RESULTS OF FEEDING SOWS ON THEIR LITTERS (UNTIL THE YOUNG PIGS WERE WEANED), WITH BARLEY AND WITH BARLEY + ABATTOIR MEALS (PIG MEAL OR PIG COMPO) RESPECTIVELY. — For these tests only 3 sows could be procured so that the results summarised in Table II cannot be regarded as definitive, taking into account the influence of individual temperament, etc.

The litter of sow A fed on barley alone, although containing one piglet less than that of the sow to whose ration pig-meal had been added, attained, during the period of 63 days, mean daily individual increases of 0. 27 lb. only as against increases of 0.41 lb. for the litters of sows supplied with pig-meal and pig compo respectively.

TABLE II. — *Feeding Sows on Barley or on Barley + Abattoir Meals Respectively.*

	Sow *A*	Sow *B*	Sow *C*
	Barley only	Barley+1¼ lb. pig meal daily	Barley+1¼ lb. pig compo daily
Number of piglets	8	9	8
Original total weight of piglets	16.39lb.	18.46lb.	21.29lb.
Mean original weight per head	2.05	2.05	2.66
Total weight at weaning	77.79	123.83	115.44
Mean weight per head at weaning	9.73	13.76	14.42
Total increase in weight (63 days)	61.41	105.27	94.15
Mean increase per head (63 days)	7.68	11.71	11.54
Mean increase per day	0.12	0.19	0.19

The results are equally satisfactory from the point of view of cost of production. When pig-meals formed part of the ration of sows on litters, the young animals developed more rapidly than when the sows received barley alone, and the cost of the feed per 1 lb. increase in live weight, was from $^3/_4$ to 1 d. less when barley only was supplied.

CONCLUSION. — Provided the composition of the pig meal and pig compo is always the same as that of the products now prepared by the Metropolitan Abattoir Board, the following daily rations may be recommended.

1) *For Sows on Average Litters.* — 6 ½ lb. of crushed barley + 1 ½ lb. of pig meal, or pig compo. The daily allowance of barley should be increased each week by about 1 ½ lb. until weaning time.

For Young Growing Pigs:

Live Weight	Barley	Pig Meal
50 lb.	2 lb.	$^1/_2$ lb.
60 »	2 »	$^5/_8$
70 »	3 »	$^5/_8$ »
80 »	4 »	$^5/_8$ »

1260 – Experiments in Hogging Off on a Mixture of Maize and Soya in Indiana (United States). — WILEY, I. R., in *The Breeders' Gazette*, Vol. LXXIX, No. 22-2062. Chicago, June 1921.

Experiments carried out at the end of 1920, on 20 farms in Indiana. The work was done in close collaboration with the Purdue Extension Department. The total number of pigs used was 1524: the results obtained are given in the following Table.

		Averages	Minima and maxima		
Duration of the «hogging-off» period	*days*	45	21	to	87
No. of pigs kept per farm	*kg.*	76	27	»	182
Initial live-weight	»	45.99	21	»	79.65
Final live-weight	»	77.45	37.14	»	115.80
Increase in weight per day and per head	»	0.70	0.33	»	1.32
Amount of maize consumed during hogging off period	»	176	0.59	»	3.33
Yield of maize per hectare	»	3372	15.68	»	47.05
Increase in weight of pigs per hectare of forage crop	»	596.66	385.41	»	846.89
Increase of weight of pigs per 100 kg of maize consumed	»	17.72	11.57	»	28.58
Cash return per quintal of maize consumed	*dollars*	3.53	2.30	»	5.67
Amount of shelled maize required to produce 100 kg increase in live-weight	*kg.*	403.67	248.65	»	613.68
Cost of food required to produce 100 kg. increase in weight	*dollars*	8.27	5.14	»	13.61

The great variations in the increase in live weight and the amount of forage consumed may be attributed chiefly to the following causes: the difference in the weight and vigour of the animals when they were turned out; differences in treatment before turning out; the method of treating the pigs during hogging off.

Thus 60 young pigs which weighed on an average 24.04 kg. when turned out, consumed 586 kg. of maize for 100 kg. of increased live-weight. At the current price of 1.58 dollars per quintal of maize, the production cost of 100 kg. increase in live-weight amounted to 9.24 dollars. On the other hand, an increase of 100 kg. of live-weight can be obtained at the low cost of $5.74 if 37 young, strong, rapidly growing pigs with an average initial weight of 51.26 kg. are turned out to feed for 26 days. Their average weight at the end of this time will be 82.1 kg., which means an increase of 1.18 kg. per head and per day.

A good way of preparing pigs for hogging off on a mixture of maize and soya is suggested by SHRADER, Union Company, Indiana. The litters are farrowed between the last week of March and the middle of April. The sows are fed on ears of green maize (milky consistency) and a mash of ground oats and wheat meal. The piglets which remain with the sows until 10 weeks old are given hulled maize from the 5th week. Later a mash of wheat meal is added to the maize. After weaning, the young pigs receive ground oats and barley, as well as a mash of wheat flour and a limited amount of green maize cobs.

This ration (2.5 kg. of food per 100 kg. of live weight) together with a liberal supply of clover and plenty of water and shelter produces strong quickly-growing pigs in good condition and reduces the cost of the live-weight gains during the maize and soya period.

This period lasted from September 1 to October 23 on the different farms. The cheapest live-weight gains were obtained when the pigs could feed on maize-grain which was nearly ripe and had lost its milky consistency, and on soya which was still to a large extent green, though the pods were beginning to turn yellow.

The soya is eaten more readily and gives higher returns when the beans are not yet ripe. Thus the maize and soya crop should ripen at the same time.

Experiments have proved that in the northern third of Indiana, the soya varieties ripening with the maize are Ito San and Early Brown, and Hollybrook in the centre and south of the State.

In order to prevent the digestive troubles that may result from putting the pigs suddenly on a diet of fresh maize, it is customary to give the animals 1 to 2 cobs a day at first, and then gradually to increase the number till the maize forms a full ration.

1261 - **Wild Manihot as a Pig Food in Brazil.** — LOPES G., in *Secretaria da Agricultura, Commercio e Obras publicas do Estado de São Paulo, Boletim de Agricultura*, Series 22, Nos. 1 and 2, pp. 16-17. São Paulo, January-February, 192[illegible].

The roots of the wild manihot (or Manioc), contain a white, milky juice which is very poisonous when fresh, on account of the presence of hydrocyanic acid. This acid can however be very quickly removed by fermentation, boiling or drying in the sun, and roots thus treated may be fed to stock without risk. They can also be given fresh, especially to pigs, provided that neither the cortex, nor the adherent soil is removed, for the cortex and soil act as antidotes to the poison.

If animals have swallowed fresh manihot juice, they should at once be dosed with whey or a solution of sugar-cane molasses.

D^r^ LANNA, of the Thank-Ba Agricultural Station, has used salt, wine, and ipecacuanha successfully in the case of ruminants. Capsicums soaked in rum are given to human beings suffering from manihot poisoning.

1262 – **Scheme to Improve the Utility Value of Poultry Stock, in England.** — *The Journal of the Ministry of Agriculture*, Vol. XXVIII, No. 7, pp. 583-584. London, Oct. 1921.

With the object of providing small holders, etc. with stock of good quality at reasonable prices, and thus of improving the utility value of the poultry stock, the Ministry of Agriculture has instituted a scheme for the distribution of sittings of eggs and day-old chicks. The number of eggs distributed in 1921 was over 104 000, being a slight decrease on the figures for 1920 (118 000), but an increase of nearly 100 % over those for 1919 (53 000). The number of day-old chicks distributed was nearly 38 000, an increase of about 17 000 over the previous year and 35 000 above the figures for 1919.

The total number of stations engaged in the work of distribution is now 256, compared with 172 in 1920 and 163 in 1919. The number of ducks' eggs distributed was nearly 1500. A beginning was made with the distribution of ducklings, over 200 being distributed by 28 stations.

The scheme is administered by local authorities.

1263 – **Capons Versus Cockerels for the Market in the United States.** — WAITE, R. H., in *The Maryland State College of Agriculture, Agricultural Experiment Station, Bulletin* No. 235, pp. 119-131, 9 figs., 2 tables, bibliography of 17 works. College Park, M. D., March 1920.

With a view to obtaining definite figures showing the relative size and rate of growth of capons and cockerels, the author carried out experiments in 1919, at the Maryland Agricultural Experiment Station. Forty-two White Plymouth Rock cockerels, all hatched on March 28 in the same incubator, were divided into two groups as nearly equal as possible, as regards health and vigour. On May 30, one of the groups was caponised. The two groups were kept entirely separate, and their gain in weight and the food they consumed were recorded.

Until October 1, both groups had access to poultry yards measuring 15 ft. × 125 ft. and after that date, they were confined to open-front houses 15 ft. × 15 ft. in size.

Until January 16, the following dry mash was fed to both groups *ad libitum*: bran 100 lb. — wheat middlings 100 lb. — beef scrap

30 lb. — bone meal 5 lb. — salt 1 lb. A mixture of white maize and wheat was also given as a scratch feed. From January 17, the following fattening ration was fed: Maize meal 100 lb. — wheat middlings 50 lb. — beef scrap 20 lb. — lucerne meal 30 lb. — salt 1 lb. — and in addition, wheat and yellow maize were given twice daily.

From May 28, 1919 to February 7, 1920, the average feed eaten (mash + grain), by the capons and cockerels respectively was 63.28 lb. and 62.00 lb. and the gains made were 6.66 lb. and 5.66 lb.

It was found that during the second period (January 17 to February 7), a less amount of food was required. The author suggests that this may probably be due to the vitamines which are said to be present in lucerne. Another possible explanation may be found in the higher vitamine content of yellow maize as compared with that of the white varieties (1).

A table giving the money gain or loss shows that at the present market price (average for period May 28, 1919 to February 7, 1920 : 4.02 dollars for capon weighing on an average 7.76 lb.), it does not pay to grow these birds if yarded and all the feed purchased, for present prices only just cover the cost of rearing. A fair profit can, however, be reasonably expected, if they are reared on a farm where they can range at will and pick up a fair proportion of their food, the balance of the ration being made up by grain of inferior quality, and feed. In dressing, capons lost 6 % of their weight. The live cockerels lost about 2.6 % of their weight during transport.

1264 - **The Effect of Electric Lighting and Climate on Egg Production' in Canada.** — HERNER, M. C., in *The Agricultural Gazette of Canada*, Vol. VIII, No. 4, pp. 446-448. Ottawa. July-Aug. 1921.

In the report on the Poultry Husbandry Department of the Manitoba Agricultural College (Canada), a description is given of the work carried out by the "poultry plant" branch. In addition to other work still in progress, experiments have been made concerning: 1) the effect of electric lighting on egg laying; 2) the effect of climate on the annual egg production.

I. — EXPERIMENTS ON EFFECT OF ELECTRIC LIGHTING ON EGG LAYING (2). — These experiments extended over 3 winters with White Leghorns and Barred Rocks. The results obtained clearly show that the use of electric light possesses certain distinct advantages for winter laying; the use is limited to the months of October to December, but the birds whose quarters are lighted lay many more eggs for which higher prices are paid, and the total revenue for the year is far superior to that expected from birds not subjected to light.

II. — EFFECT OF CLIMATE ON EGG PRODUCTION. — Experiments made in co-operation with the Poultry Department of the North Carolina Agricultural College at West Raleigh (U. S.). In August 1919, 25 White Leghorn pullets belonging to a heavy laying strain were sent to

(2) See *R.* Feb. 919, No. 231. (*Ed.*)

West Raleigh; 25 pullets of the same age were reserved for the Manitoba Service. Both pens were fed exactly alike; the climate was the only difference. The appended Table shows the number of eggs obtained each month of the year beginning November 1, 1919 and ending November 1,1920.

The difference in favour of the North Carolina climate was 633 eggs or an average of 25.3 eggs per hen more than Manitoba. The observations made during this experiment encourage the hope that it will lead to quite an elaborate system of co-operative experimental work between the poultry departments of the different agricultural colleges and result in much closer co-operation than has existed hitherto.

Egg production for each month of the year.

1265 - **Variation in Fecundity of Domestic Fowls in Relation to the Number of Oocytes in the Ovary.** — See No 1243 of this *Review*.

1266 - **Silk Producing Insects of the Republic of San Salvador: *Eutachyptera psidii* and *Rothschildia jorullo*.** - - CALDERON S., in *Revista de Agricultura Tropical, Organo de la Dirección General de Agricultura e Industria de la República de El Salvador*, Vol I, No. 1, pp. 9-11 figs 4. San Salvador, January 1921.

Among the various silk-producing insects in the Republic of San Salvador, the author mentions the Lasiocampid, *Eutachyptera psidii* Salle, and the Attacid, *Rothschildia jorullo* Westw., as capable of attaining a certain economic importance.

Eutachyptera (Metanastria) psidii lives wild in the oak-woods of the hills surrounding Ciudad Barrios, Department of San Miguel. The species is eminently gregarious, making large nests of white silk that house the colony.

In the "patio de ensayos" (experiment court), of the Agricultural Control Department the author fed the insects on the leaves of the guava (*Psidium Guayava*).

W. Schans, of the United States National Museum, informed Calderon that he has often seen them living in a natural condition on guava plants in the temperate zone of Mexico. The author has also fed the larvae, as soon as they were hatched out, on close-headed cabbage; he was able to accustom them after a time to guava leaves. When the cocoons have been perforated, the bags of silk can be carded. Each female insect lays 250 eggs, and from 23-27 days after oviposition the larvae emerge; they are about 7 mm. long, and cast their skins several times. The species is univoltine.

Rothschildia jorullo makes open cocoons that shine like silver. In his breeding experiments, the author was unable to obtain a single moth, for all the chrysalids were attacked by a parasite called "mosca negra" (*Belvosia analis* Macq.).

1267 - The Influence of the Incubation Temperature Upon the Retention of the Bivoltine Character (1). — Mollo A. (Istituto bacologico della R. Scuola Superiore di Agricoltura di Portici), in *Informazioni seriche*, Year VIII, No. 17, pp. 257-259. Rome, September 5, 1921.

It is well-known that bivoltinism is a very variable characteristic. The bivoltine breeds of silkworms of the Far East, on being introduced into Europe, tend to become univoltine, and the univoltine breeds that have been imported into Madagascar have become polyvoltine.

Toyama (On Certain Characteristics of the Silkworm which are Apparently Non-Mendelian, in *Biologisches Centralblatt*, Vol. XXXII, No. 10) states that voltinism is easily affected by temperature during the embryonic stage. From silkworm eggs exposed to about 80° F. (about 26.6° C.), moths were obtained all of which laid univoltine eggs, whereas if the eggs were kept at about 65° F. (about 18.3° C.) the moths laid either bivoltine or univoltine eggs.

The author, having experimentally tested Toyama's statements, found them to be correct in the main; bivoltinism is retained by incubation at 18° C; it is less certain that this character is lost by raising the incubation temperature to 25° C., for probably other factors also come into play. With an incubation temperature of 18° C. the number of bivoltine caterpillars was 96.9 %, but only 41 % when the temperature was as high as 25° C.

Moths laying non-bivoltine eggs in the rearings from eggs incubated at 25° C., were those that emerged latest from the cocoon. It has also been ascertained that bivoltine eggs become coloured 2 or 3 days only before hatching, while those that have lost the bivoltine character assume a violet-grey hue 3 days earlier.

1268 – **Practical Synopsis of the Different Breeds of Dogs.** — ZWAENEPOEL H., in *Annales de Médecine vétérinaire*, Year 56, No. 6, pp. 264-267. Ixelles-Brussels, June 1921.

The author makes a preliminary division into: I. breeds with normal proportions; II elongated breeds; III. thickset breeds; IV. breeds of the basset type; V. other breeds. The first 4 groups are subdivided according to: *a*) height; *b*) shape of muzzle and fang development: *c*) ears, eye, coat, tail. Such are the characters distinguishing the breeds as given in the annexed table (see page 1605–1608)

FARM ENGINEERING.

1269 – **The Water-Raising Machines and Motor Engines Most Suitable For Land-Drainage Plants.** — CARBONARO D. (Civil Engineer), in *Giornale del Genio Civile*, I. Year LVIII, pp 237-261, figs. 16 Rome, May 31, 1920; II. Year LIX, pp. 409-439, figs. 21. pp 469-496, figs. 22 to 31, July 31 and August 31, 1921.

In his first article, the author refers to the methods which he considers the best to adopt in choosing water-raising engines for land-drainage plants. In the second, he describes the motor-engines used for drainage purposes and the requirements they must satisfy. The examination of each of these engines is preceded by an explanation of the mechanical principles upon which its construction and mode of working are based. He also gives a short description of the types of engines suitable for draining land. This summary contains much practical information and should be a useful handbook both for students and engineers.

I. — The best water-extracting engines for land-drainage plants are those in which the chief water-raising part operates with a free rotary movement in the water.

In such machines the fixed and moveable components are extremely simple and can extract large quantities of water at reduced speed, and hence with regular and steady motion. To this class belong: *a*) water wheels with buckets; *b*) water wheels with float boards; *c*) water-raising turbines and centrifugal pumps. The latter will be in future the water-raising machines *par excellence* for drainage plants.

The author describes in detail the special conditions under which water extracting machines have to work: 1) the constant removal of turbid water, and especially of aquatic plants — 2) the great variation in the depth of the water between the periods of the highest level and those towards the end of the process; 3) the destruction of the metallic parts by the corrosive action of turbid water. Some means of preventing this trouble are suggested.

The author is of opinion, that the machines giving the best results in raising water during drainage operations are water-extracting turbines and centrifugal pumps with vertical axis, next coming centrifugal pumps with horizontal axis.

The latter, usually provided with a siphon, are suitable for low powers (not above 150, and preferably 100 HP.), for fairly clear water, and changes of level not exceeding 4 m. In such conditions, their defects

Practical Synopsis of the Different Breeds of Dogs.

I Breeds with normal proportions.	*A*. Tall	1. Square muzzle flews, well-developed; legs thick.	Ears long and lying close to head; face more or less wrinkled; eye blood-shot (exposing a corner of the mucous membrane of the lower eyelid); appearance powerful; coat short and wiry; tail slender and carried upright.	**St Hubert Dog** and its direct descendant, the *bloodhound*. **Large coursing Dogs**; *Foxhounds, Staghounds, Otterhounds, French, German, Swiss* etc *Greyhounds*.
		2 Blunt muzzle, flews little developed.	Ears average, drooping; face not wrinkled; appearance hardy; coat short and thick; tail usually cropped.	**Draught Dogs.**
	B. Of good height	1. Square muzzle, flews moderately developed.	*a*) Ears long and lying close to head; face normal; handsome appearance	**Shooting Dogs.** Short-haired: *Brachs* and *Pointers*. Long-haired: *Spaniels* and *Setters*. Wire-haired: *Griffons*. Woolly-haired: *Barbets* and *Water Spaniels*.
		2. Pointed muzzle without flews, lips close fitting.	*b*) Ears semi-drooping, face normal (1).	**Retrieving Dogs.** *Retrievers, Irish Water Spaniel, Chesapeake Bay dog.*
			a) Ears erect.	**Dalmatian Hound** (*). **Esquimaux, Greenland, Siberian** or **Laika, Kamchatka** dogs etc. with tail curled over back **Belgian Sheepdogs** with short, long, or wiry coat.
			b) Ears erect or turned over at tip.	**German Sheep Dog** or **Alsatian** Wolf-dog. **Herd-dog** (*) stronger in appearance than the sheep-dog. (Bouvier de Rouless, de Menin (**)
			c) Ears semi-drooping.	**French Sheep dogs** (Beauce and Brie). **Scotch Sheep dog** or **Collie** **Dobermann Pinscher** (**). **Rottweiler.** **Airedale terrier.**

(1) One asterisk signifies that the ears are sometimes cropped; double asterisk that cropping the ears is customary on the continent (the practice is forbidden in England).

Practical Synopsis of the Different breeds of Dogs (see also next page).

		d) Ears drooping.	**English** or **Bob-tail Sheep dog.** **Russian sheep-dog.**
C. Ordinary height	1. Square muzzle	Ears drooping, wrinkled face, stunted form, smooth hair, diminutive of Fox-hound.	**Beagle**: small coursing dog.
	2. Pointed muzzle.	*a*) Ears erect, tail curled over back, diminutive of Esquimaux dog.	**Chow-Chow.** **Spitz** or **Pomeranian.** **Samoyede.**
		b) Ears semi-drooping, diminutive of Airedale terrier.	**Welsh terrier.**
		c) Ears drooping.	**Bedlington terrier.**
D. Small size	1. Muzzle intermediate.	Ears drooping body rather slender.	**Harrier.**
	2. Pointed muzzle.	*a*) Ears erect, cropped tail.	**Louvain spitz.** **Schipperke.**
		b) Ears semi-drooping.	**Stable Griffon** (**). **Black-and-Tan terrier** (*). **White terrier** (*). **Fox-terrier.** **Irish-terrier.** **Kerry-terrier.** **Border-terrier.**
E. Dwarf	1. Normal head with pointed muzzle.	*a*) Diminutive of Spitz.	**Zwergspitz** **Seidenspitz** } Toy Pomeranian.
		b) Diminutive of water-spaniel.	**Lion-dog.**
		c) Diminutive of wolf-dog.	**Chihuahua.**
		d) Diminutive of spaniel.	**Maltese dog.** **Butterfly dog.**
		e) Diminutive of terrier.	**Toy black and tan terrier.**
	2. Head round and muzzle short.	Griffon coat, hair short or long.	**Affenpinscher** (**). **Brussels Griffon** (**). **Brabançon.** **Dwarf Japanese Spaniel.**

Intermediate forms: **Bull terrier**, derived from the White terrier (normal proportions) and the Bulldog (stunted proportions).
Boston-terrier ** of same origin as preceding.
Whippet, derived from the fox-terrier (normal proportions) and the greyhound (slender).

Practical Synopsis of the Different breeds of Dogs (see also next page)

II. Slender Breeds: body of greyhound type, long slender legs narrow head.	*A.* Large	Pointed muzzle	*a)* Ears erect.	**Balnéares** or **Charnigue Grey hound.** **Portuguese** or **Podengo Grey hound.** **Greek Grey hounds,** etc.
			b) Ears semi-drooping.	**Sloughi.** **Grey hound.** **Deerhound.** **Irish Wolfhound.** **Kangaroo-hound.** **American Long-dog.** **Barzoi.**
	B. Small.	Pointed muzzle	Diminutive of Sloughi.	**Italian Greyhound.**

Intermediate forms: the **Whippet** (see preceding group).
the **Ulm** (*) or **German watch-dog,** intermediate between the Greyhound and the Bulldog (thick-set type).

III. Breeds that are thickset with strong jaws and fore parts.	*A.* Large	1. Drooping ears of moderate size; absence of prognathism in lower jaw.	*a)* Very large, rather tall	**Pyrenees dog.**
			b) Very large, nearer the ground.	**St-Bernard dog, Leonberg, Durrenbach dog.**
			c) Very large, thickset.	**Thibet Watch dog.**
			d) Average size, thickset.	**Newfoundland dog.**
		2. Ears erect for ¼ to ⅓ of their length, moderate prognathism.	*a)* Average flews, moderate wrinkles, straight legs.	**Mastiff.**
	B Average size		*b)* Drooping flews, very deep wrinkles, straight legs.	**Bordeaux Watch dog.**
		Ears semi-drooping with prognathism	*a)* Average prognathism, straight legs.	**Boxer,** or **German bulldog.**
			b) Very pronounced prognathism, forelegs crooked.	**Bulldog.**

Practical Synopsis of the Different breeds of Dogs (concluded).

	C. Small	1 Bat-eared.	Derived from Bull-dog.	**French Bull-dog.**
		2. Ears semi-drooping.	Diminutive of Mastiff with tail curled over back.	**Carlin**, or **Pug**, or **Mops.**

Intermediate forms: **Bull-terrier, Boston terrier** and **Ulm Watch dog** (see preceding groups).

IV. Breeds with basset proportions (long body and short legs).	*A*. Average weight.	1. Straight legs.	*a*) Type of coursing dog	**Artois Basset.**
			b) Type of retrieving spaniel.	**Spaniels** Clumber, Springer, Field, Cocker etc.
			c) Terrier type.	**Scotch terrier.** **West Highland terrier.** **Sealyham terrier.** **Skye terrier.** **Cairn terrier.**
		2 Bandy legs.	*a*) Hair smooth	**Dachshund,** or **Teckel.**
			b) Hair wiry.	**Dandie Dinmont.**
	B. Light weight	1 Legs straight, or slightly bandy.	*a*) Round cat's head, close-lying Spaniel ears.	**Pekinese** and its English derivatives: **King. Charles, Blenheim** etc
			b) Terrier head	**Yorkshire terrier** (*).

V. other breeds: **hairless dog, edible dogs, fur** dogs **wandering** dogs, **wild dogs.**

in working are of little importance, and are set off by their greater simplicity, low cost of installation and easy means of upkeep. In the case of water containing much sediment, in which the differences in level are above 4 m., the HP. required to work the pumps would be very high and the cost excessive.

For very small plants (20 to 25 HP.) where it is wished to lessen the work of supervision as the force is limited, turbines succeed the best, for they reduce the cost of supervision and do not need any starting up. This conclusion might appear to warrant a return to the old water-raising apparatus, in which after water-wheels had been given up, the work had to be done at first by means of submerged turbines with a yield never exceeding 65 %.

It might also be objected, that the continual submersion of the turbines gives rise to high maintenance expenses; that it is not easy to keep the axis perfectly vertical in buildings subjected to the vibration of the machines and erected in alluvial soil in the process of hardening, that the use of check sluices in the discharge canal necessitates costly masonry work; that the check sluices often do not shut closely enough to prevent the introduction of marsh plants or detritus, a defect which may also be due to the sinking of the masonry, etc. These objections however disappear if we consider that: 1) the modern construction of water-raising turbines, thanks chiefly to the introduction of the diffuser, has increased the return to a figure equal to that obtained with the best centrifugal pumps (70 to 80 %); 2) in addition to the great advantages just mentioned, the supposed up-keep difficulties can be turned into means of real economy, if the plant is well studied and the work perfectly executed, so as to avoid the necessity for repairing the submerged parts, valves and the adjustment of the shaft, as well as any danger of the masonry subsiding: the work of supervision would by this means be greatly lightened; 3) the installation expenses are not greater than in the case of vertical pumps and in large plants they might even be less than for horizontal centrifugal pumps.

In future, the use of turbines or vertical centrifugal pumps is likely to become general, for excellent results have been obtained with them in large drainage plants; in this connection it will suffice to mention the extensive drainage operations at Codigoro (Province of Ferrara) the refitting-docks of Venice and Taranto, and the great draining works carried out by the ESCHER WYSS Firm of Zurich.

Finally, the author describes the HUMPHREY and "Stereophagus" pumps. These are based on principles differing entirely from those determining the construction of the apparatus previously examined, and being suitable for large water surfaces and small differences of level, it is probable that they could be used for drainage. CARBONARO concludes by giving a list of the manufacturers of the best and most generally used drainage pumps.

II. — As hydraulic motors (which are difficult to use at the lowest levels of the land to be drained), must be excluded, the motors that can be used in water-raising plants are of 3 types: steam, internal combustion and electric. The author gives a detailed study of these types, and in such order, that each machine described is more suitable for drainage purposes than the one previously mentioned.

Steam Engines. — According to the author, boilers with small water pipes should not be used: the apparatus is complicated, costly and entails heavy installation and maintenance expenses for which the advantage of rapid evaporation does not compensate. Further, this advantage can also be obtained, to the required extent, by using boilers with large water pipes of the 3 types: 1) the Cornish boiler with one or more furnaces; 2) boilers with smoke or flame, pipes; 3) boilers with large water-pipes: the author considers the last and the Cornish boiler the best.

In boilers with smoke pipes the ends of the pipes exposed to the flames wear out more rapidly, and are practically never used for fixed plants, in which the essential quality of these boilers viz., their lightness, is of no advantage.

Cornish boilers, being rapidly freed from incrustation, are especially suited for hard waters if filtering-beds are not to be used. In other cases, boilers with large water-pipes are preferable, because in land drainage work the essential object to be attained is great power of evaporation combined with maximum of security in the case of an explosion. It is always well to use economisers and superheaters.

As regards the motor, the best are: for pressure up to 6-8 HP., monocylindrical engines, for 6-10 HP., double expansion engines, for 10-15 HP., triple expansion engines, for over 15 HP., quadruple expansion engines. For forces above 100 HP. condensation is necessary.

For low speeds, up to a maximum of 100 revolutions per minute, which are much used in drainage operations, distribution by release should be employed, above this limit (in drainage, as many as 200-225 revolutions per minute can be reached), as a rule, distribution by valves is used.

Steam turbines have great advantages over piston engines: a thermic return of 40-60 %, as against 22-30 % per second; total return 95 %, or over, as against 90 %; weight for equal strength ¼, much lower coal consumption etc. They have however not as yet been employed in drainage plants, on account of their great speed, necessitating the use of reducers, either because the return decreases perceptibly with variations in the charge, or because, contemporaneously with the invention and improvement of turbines, DIESEL and electric motors were invented and soon brought to a perfection that made them justly preferred for drainage plants.

Internal Combustion Engines. — The author examines gas engines, liquid fuel engines, DIESEL engines, semi-DIESEL or semi internal combustion engines, and gives, as in the case of the boilers and steam engines, a list of the best-known manufacturing firms.

Electric Engines. — These, whether with constant, or alternating current, or with induction, can all (with the exception of synchronous engines with alternating current), be used in drainage. For speeds of over 150-225 revolutions per minute, reducers causing an average loss of energy of 3 to 5 % are necessary; they are not required for low speed engines, but the latter are dearer. For this reason, especially for low pressure (up to 100 HP.), high power engines are almost always preferred. On each occasion the choice can be regulated by obtaining a specification.

In the case of high pressures, the machines are directly coupled to an electric motor with vertical axis which must be carefully chosen to meet particular requirements.

As regards the type, the output of engines with continuous current is lower than that of the FERRARIS alternating rotatory. They cost more to keep in order, and cannot be used for high powers (above 500 volts), owing entirely to the friction which destroys the brushes of the collectors (these have to be renewed every 2 years), and to sparking. Further, these FERRARIS engines use the least economical form of current, the continuous, which, in long distance transmission would cause great loss of energy.

These advantages, and the almost universal employment of alternating currents in the Central Electric Station, have led to the use of rotatory engines. Of the latter, three phase types are chosen, as the monophase type, owing to the presence of brushes and collectors which are in continuous use during work, have the same defects as engines with continuous current. These troubles are further aggravated by the alternating character of the current; the brushes have to be renewed every 2 months, and the collector every 3 to 4 years; this entails an expense amounting to 15 % of the cost of the engine, and the interruption of the work for 1 to 2 months, often necessitating the keeping of a reserve engine.

On the other hand, the three phase engine combines the following advantages, it is cheaper at the same pressure; its structure is simpler, for it uses the three phase current without any previous transformation; it is stronger, and the spirals are more easily detached; it requires no collectors or brushes, (those needed for starting remaining unused during working; it can stand a constant speed and strong and abrupt over-charges (30 % for several hours, 50 % for half-an-hour and even 100 % for some minutes).

The adoption of three phase currents has made it possible for the force to be transmitted a long distance without any considerable loss; the invention of the rotatory permits the direct use of the force without the necessity of further transformation. These two applications mark the greatest progress hitherto made in industrial electricity.

It now remains to consider the advantages electric engines have over heat engines, and amongst the latter, the DIESEL, which deserves absolute precedence over all the others.

The installation advantages are evident: the low price of the DIESEL which costs, including millwrighting and accessories, 500 to 200 *lire* per HP (pre-War price), for both small and large engines, whereas electric engines with alternating or continuous current, and counting reducers, transformers, accessories, tables, etc., do not as a rule, cost half that amount except for the cable.

The cost of the cable cannot be estimated; it depends upon the distance separating the plant from the Central Electric Power Station or place of current distribution, but in most cases, all cable expenses devolve wholly or in part upon the Station supplying the force and, on the other hand, as the cable can serve for the transmission of the current to several plants, the expense can be divided among the various users.

With electric engines it is possible to divide up the surface to be drained into small areas with separate plants and with differences of levels less marked than is necessary with a single installation. This question, however, requires careful study in each case, and does not admit of a general *a priori* solution, though it is possible to foresee the great economy which might thus be effected:— in hydraulic operations, fewer agricultural canals, collectors and over-flow channels, fewer cuttings and shallower excavations, a reduction, even of several years, in the time needed for draining; less force absorbed by the water raising engines, less time expended in constructional work (small electropumps in a corresponding number of small sheds require less solid foundations and often a total masonry cubage below that of a large Central Station), etc. So much as regards installation.

The advantages as regards maintenance are very plain. Electric motors and transformers are of quite simple construction; break downs which are frequent in the case of the DIESEL are always of rare occurrence, so that the maintenance expenses are hardly ever half of those involved where the DIESEL is used.

Finally as regards actual working, a distinction must be drawn between:

1) Supervision expenses: these are less in the case of electric engines than with the DIESEL, as the former can be handled without any difficulty; one man can superintend several neighbouring plants, and if they are not very large, can set them in motion from a distance. This applies especially to automatic low-power engines with no brushes, or collector. In some cases (as in the drainage of the "dongepolders" in Holland), the engines can be started automatically by means of floats and electric relay substations.

2) The consumption of lubricants: electric engines always need less lubricants than any others, because friction occurs only in the supports, and in the speed reducers, if present.

3) In electric motors, replacements of the lubricant and rags alone are necessary, whereas a constant supply of fuel is required with DIESEL and steam engines.

4) The starting: this is absolutely instantaneous in electric engines, no pumps or compressors etc. being used, as in the case of the DIESEL, and involving a certain loss of power.

5) The cost per HP. hour: this in DIESEL engines is about 3 *centimes* (average oil consumption per HP. hour 0.20 kg. which at 0.10 fr. the kg., makes 0.02 fr., and with the lubricator and losses, about 0.03 fr.), or 3 *centimes* per kilowatt hour (pre-War prices). In order that the electric

engine may show a similar result, the kilowatt-hour must not cost above 3.5-4 *centimes*. A considerably higher cost (3 to 6 *centimes* and over), can however be allowed, owing to the compensation due to the advantages above-mentioned, especially in large plants working only a few months annually.

In any case, the electric Power Stations make different charges according to working hours, the lowest being at night and in the morning when there is less demand for power for other services. If the work of the plant is limited as far as possible to the hours of the night and morning, and if the cost of current is diminished by the construction of large hydroelectric plants, it may fairly be anticipated that electric engines will soon possess all the qualifications necessary to their extended use in land-drainage operations.

In all cases where fuel can be procured on the spot, and its use is advisable from the standpoint of economy, it is certainly desirable to build a central Power Station and work the water-raising apparatus with electric engines.

When used in groups of several units, wind engines can render signal service in assisting the elevators where the current supplied is of weak, or average strength and can serve as trustworthy auxiliaries of heat or electric engines.

The author concludes by giving detailed information on the subject of water-raising plants already at work, or in course of construction, in Italy and other countries.

RURAL ECONOMICS

1271 – **The Farms in Quebec, Canada, Their Yields and Methods of Administration.** — STE MARIE J. A. (of the Cattle Breeding Service of the Federal Ministry of Agriculture, Ottawa), in *Dominion of Canada Department of Agriculture, Experimental Farms Bulletin* No. 96, 14 pp. Ottawa, 1920.

A preliminary enquiry into the condition of Agriculture in six counties in the province of Quebec for the year ended March 31, 1920.

In each county a representative district has been selected, and in each district a survey has been made of 25 representative farms.

Special forms have been used for the collection of the information required, and by this means it has been found possible to construct an inventory, approximately complete and accurate for each farm.

The receipts from various sources were analysed and their total gives the *gross revenue for the farm*.

Expenditure was classified under a number of headings and the total gives the *gross expenditure*.

The work of the farmers' sons, aged 14 years and upwards, is reckoned as of equivalent value to that of the manual labour employed, so that, as regards the *labour income* all can be treated on the same basis.

Depreciation is reckoned at 10 % per annum for machinery and live-stock, and 5 % for farm buildings.

Interest on the total capital is reckoned at 6 %. The balance after deducting the total of expenditure from the total of receipts is called the *labour income*, being in fact the salary of the farmer and his wife in return for management and actual labour.

As, in the farms to which the Enquiry relates, there were several groups, making no labour income the term « *plus labour income* » or *surplus* is used in cases, where receipts are in excess of expenditure to indicate the salary of the farmer and his wife. The term « *minus labour income* » is used in cases where the year's working gives an adverse balance with a deficit in place of a surplus.

Definition of terms. — An *animal unit* is a horse or cow. Young cattle or other classes of live-stock are portions of the unit, greater or less according to the amount of food consumed. The following number is required in each case to make up an animal unit: one or two year old heifers, 2 — calves, 4 — full-grown hogs, 4 — sheep, 7 — fowls, 100. Thus a farm may be said to have 24.5 animal units with a total stock of 3 horses, 12 cows, 1 bull, 8 heifers, 4 calves, 5 pigs, 14 sheep and 50 fowls or their equivalents.

Cash Crop: term commonly employed for all crops sold direct for ready money.

Crop index: the value of all the crops raised on all the farms to which the enquiry relates is totalled and divided by the total number of acres under cultivation. The result gives the basis of comparison and is represented by the number 100. Thus a harvesting index of 120 shows that the value of the acres cultivated on the farm in question is 20 % higher than the average of the farms included in the survey.

A *live-stock index* of 105.5 shows that this particular farm makes a profit on its animal units 5.5 per cent above, while a farm with a *live-stock index* of 78 makes a profit 22 % below the average.

The *tillable area* is the number of cultivated or cultivable acres on the farm.

Crop acres is the number of acres giving crops or pasture.

The terms " five best " and " five worst " farms indicate respectively the farms where the labour income is highest and lowest without qualification or reference to quality of soil or live-stock or amount of capital.

The first table indicates the size of the farms surveyed and the labour income. The conclusions derived from these figures are quite at variance with those resulting from similar surveys made elsewhere in so far as the labour income instead of increasing with the size of the farms and in proportion to their size, shows irregular variations in different groups of farms. For this result two particular groups are mainly responsible.

In the district of l'Assomption, as a result of the system of cultivation practised, the labour income has been generally higher than elsewhere; in the district of Lake S^t John, on account of the high land values, the average working profit is reduced to nil. Thus each time that the farms of these districts are in the majority in a set of returns, the results are modified materially: otherwise they would have been very similar to those obtained from other enquiries of a similar character.

A comparative table of the 5 best and 5 worst farms for each district is given.

The results obtained by the 5 best and the 5 worst farms in the l'Assomption district show that the difference in labour income does not arise from a difference in capital expenditure, signifying poor quality of soil or live-stock, any more than in a difference in the average size of the farm or average

TABLE II. — *Cultivation specialised or general.*

		Dairy Farming plus a Cash Crop	General Dairy Farms	Dairy Farming for City Trade
Number of farms	No.	25	25	25
Average total capital	$	20 610	16 319	19 402
Average size of farms (crop acres) . .	Ac.	141	113	129
Average Animal Unit.	AU	24	22.1	26.4
Average Live Stock index	No.	103.5	100.2	116.5
Average Crop index	No.	125.8	108.5	108.3
Average per cent Gross Return	%	14.4	12.2	13

Average per cent cost of total expenditure	%	12.9	12.6	13.4
Average Labour Income	$	+ 320	— 60	— 70

of the total expenditure. It depends rather upon the very important factor of good management, which is expressed by an average gross return of 23.9 % on capital for the 5 best farms as against a gross return of 9.3 % for the five worst farms. This difference in gross return in favour of the 5 best farms is to be explained by the fact that these farms make 103 *dollars* per animal unit, while the 5 worst farms make 67 *dollars* only. Moreover the 5 best farms make in cash crop profit 14.90 *dollars* an acre, while the same source gives a profit of 2.67 *dollars* only for the poorest farms.

This difference of 14.6 % in the gross return in favour of the 5 best farms gives a labour income of 2 396 *dollars* to the more successful farmers, while the 5 worst farms show a deficit of 708 *dollars*. As these two groups of farms both belong to the same district, work in similar climatic conditions and on similar soil, and are of similar dimensions and similarly capitalized, one is driven to the conclusion that the 5 worst farms do not know how to turn to best account their natural advantages. Other figures also lead to the same conclusion : notably the relative proportion for live stock (live stock index), which stands at 146.2, the relative proportion for crop returns (crop index) which stands at 176 in the case of the 5 best, while for the 5 worst the figures do not exceed 90.6 and 86 respectively. These points deserve the fullest consideration for they are responsible for the remarkable difference in labour income shown by the two groups.

All the groups or districts in which the farms do not make a profit are those in which the live stock index falls below 100.

The survey has proved that the working of a farm costs on the average 13 % of the total capital invested. Hence, unless the various farming operations are so arranged as to obtain a return from the different sources of revenue in excess of 13 %, the farm will show a net loss.

In order to ascertain what branch of farm work contributes most largely towards labour income the author made a study of three groups, each consisting of 25 farms in the three districts showing greatest similarity. A certain number of farms from each district were included in each of the three groups (See Table II).

The first group — dairy farms + a cash crop — includes farms which sell their milk in the form of cheese or butter and in which 70 % of the crops sold consists of fruit, grass and clover seeds, potatoes, maple sugar, tobacco and vegetables, not marketed through the live stock.

The second group — general dairy farms — includes farms which sell their milk through the cheese factory or creamery and in which 70 % of the crops sold consists of hay and grain.

The 3rd group — dairy farms for city trade — includes farms producing and selling their milk for city trade; their cash crop is comparable with that in one or other of the two earlier groups.

An examination of Table II shows that one group only (dairy farms plus cash crop) makes a working profit, while the two remaining groups show a slight deficit.

The average size of the farms varies slightly in each group, but as the amount of capital per *acre* is almost constant throughout, the difference in average size cannot be considered the determining factor, for the results in groups 2 and 3 are almost identical. Similarly the percentage of total cost although somewhat higher in the case of the 3rd group than in the others cannot be regarded as the sole determining factor, for group 2, in which it is lowest, makes no labour income. One can only conclude that group 1 makes on an average a higher labour income by obtaining a gross average return which is 1.4 and 2.2 % higher than that obtained by group 2 and group 3. This is to be accounted for by the fairly satisfactory return give en by its animal units coupled with the return for cash crop which is higher than for the remaining groups.

The farms in group 3, — dairy farms for city trade, — have a larger head of cattle, chiefly cows, than the farms in the two first groups, and these animals are of better quality as is shown by the live stock index figure and the return per animal-unit. However in spite of the high quality of the cattle, the percentage of gross revenue does not reach the average percentage of the total expenditure and labour income shows a deficit. This is due to the fact that the farms in this group pay little attention to the subsidiary lines of work, such as cash crops and the rearing of hogs and sheep. It is to be concluded that specialization in milk-production for town trade is not the most remunerative branch of farm work.

The farms in group 2 — general dairy farms — may be regarded as of intermediate type. The cattle in these farms are of inferior quality as is shown both by the live stock index and the receipts per animal unit. At the same time, as the sale of hay is the chief cash crop, fewer cattle are kept, fewer hands employed, there is less expenditure on cake and thus working expenses are on a lower scale. Hence, while the gross revenue of these farms falls below that of the other groups, the net results are practically the same as those of group 3 though they are inferior to those of group 1, the only group which shows really successful working.

The examination of the three types of farm makes it clear that in order to reckon on obtaining a working profit, the average gross return must be at least equal to 14 % of the total capital employed on a farm.

Many speakers and writers have urged the importance of employing sires of pure strain and high quality for all classes of cattle, if these are to give satisfactory returns. With the object of ascertaining the exact value of a good sire, the author divides all the dairy herds covered by the survey into three groups as follows: group 1 includes the herds in which a few or all the cows are of pure stock as also the sire; group 2 includes grade and high-grade cows served by a pedigree bull; group 3 cows and bull of common type The results are given in Table III.

TABLE III. — *Quality of the bull, production per cow and labour income.*

District	No. of farms	Pure bred and High grade cows headed by pure bred sire	Average Milk Revenue per Cow	Average Labour Income	High grade cows headed by pure bred sire	Average Milk revenue per cow	Average Labour Income	Common cows and sire	Average milk Revenue per cow	Average Labour Income
		average No.	$	$	average No.	$	$	average No.	$	$
L'Assumption	25	25.0	108	+1 746	12.8	97	+1 248	12.0	85	+ 91
Lachute.	25	16.2	126	+ 28	12.3	134	— 136	14.3	110	— 884
Aubrey	23	10.9	108	+ 39	9.0	87	+ 313	8.8	70	— 269
Bedford.	22	15.0	90	—1 011	18.8	67	— 630	16.5	67	— 119
Montmagny	24	10.4	82	— 388	7.5	61	— 336	9.1	63	— 542
St Gedeon (Lake St. Jean)	26	16.0	66	—1 127	21.3	65	—1 931	11.5	51	— 1 384
Average of total.	24.2	15.0	101	— 110	14.0	89	— 321	12.0	72	— 487

None of these groups shows a working profit. The quality of the cows is not the sole factor contributing to this result, although the loss on working tends to increase almost in the same ratio as the quality of the cows deteriorates. It will be seen that group I, composed of pure bred or high grade cows shows an average yield of 101 dollars per head. In group 2, in which the cows are half-bred or high grade with a pedigree bull, the average yield is 89 dollars, and in group 3 (common type of cow and bull), 72 dollars only per head. Thus in the average yield per cow, there is a difference of 12 dollars as between groups 1 and 2, and of 29 dollars, between groups 1 and 3.

As on the average the herds in group 3 consist of twelve cows, the average annual difference in return is 348 dollars as between groups 1 and 3, *i. e.* in favour of the cattle of pure stock when compared with the common type served by a bull of similar class without taking into account the results in the future generations. At least 65% of the milking herds in the province (which, in 1919 numbered 756 512 cows) are served by a bull of common breed.

General conclusions. — 1) A farmer who aims at making a plus labour income must so work his holding as to obtain a gross receipt above 13 % of the total capital invested and keep his working expenses below this figure.

2) In order to obtain a return in excess of the 13 % of capital in the prevailing conditions, each livestock unit on the farm must show an average return of 90 dollars or over, and to this must be added the receipt from a cash crop return, that is the sale of field crops

3) To secure an average return of 90 dollars or more per live-stock unit, the stock must be of good breed liberally fed and well tended.

4) the cash crops sold to increase the gross return should be of such a kind as not to cause any marked reduction in the number of live-stock units maintained.

5) Farms which make a plus labour income are those in which the live stock index and the crop index is 100 or over.

6) Farms with a high live-stock index use invariably sires of pure breed and good quality.

7) Farms with a live stock index of 100 or over generally return a plus labour income index.

9) Farms with a crop index of 100 or over and a live stock index below 100 always show a deficit.

9) The size of the holding is not the sole factor making for success or otherwise in farming.

10) General dairy-farming and dairy-farming for city-trade do not give such satisfactory returns as dairy-farming combined with a cash crop.

11) The yield from cows varies with the quality of the bull employed. Bulls of common breed or low quality cause in the province of Quebec an annual net loss of over 11 million dollars.

AGRICULTURAL INDUSTRIES

1272 - **Wine Making in Peru.** — See No 1230 of this *Review.*

1273 - **Fermentation of Electrified Distillery Musts.** — MEZZADROLI G. (Sotto-Direttore della R. Stazione Sperimentale della Coltura della Barbabietola, Rovigo), in *Bollettino dell'Associazione Italiana delle Industrie dello zucchero e dell'alcool,* Vol. XIV, No. 6, pp. 120-121. Bologna, Sept. 1921.

In one of the large distilleries of South Italy, the must used was electrified for a fairly long period (about 20 days).

The cellar was fitted with iron vats connected by several charge-pipes which enabled the electric current to be transmitted from one vat to another. The contact was made by means of the conducting wires carrying the light to the lower part of the cellar; in this way, the receptacle and the must flowing into the iron vats were electrified, only some of the vats being left untouched.

The author was unable to measure the amount of electric force supplied to the vats and musts; some idea of its strength could however be obtained from the fact, that if a person dipped his finger into the fermenting liquid, or into the must flowing into the vats, the electric shock was more than he could stand.

Microscopic and chemical examination revealed no alteration in the fermentation process, or deterioration of the ferment in the electrified vats as compared with the unelectrified barrels.

A very large number of investigators have made experiments with a view to determining the action of electricity upon fermentation, but it is rare to find an experiment carried out on such a large scale as that just described (where 900 hectolitres of must were treated daily) and continued for a sufficiently long period.

The microscope showed: a quite clear, pure alcoholic ferment free from all foreign microorganisms, the cells being turgid and transparent, neither granular nor corroded at the edges. The fermentation was such as takes place in the presence of a high acid content. The multiplication of the microorganisms was slightly reduced, but not to the point of endangering the progress of fermentation; the author therefore saw no necessity to lower the density, and increase the oligozymogenetic salts, in order to obtain a larger quantity of yeast, and hence greater enzymic activity.

From the chemical point of view it was noticeable that towards the end of fermentation, less acid was formed as might be expected in the absence of foreign microorganisms and especially of butyric bacteria. No special determination was made of the quantity and quality of the products obtained from these electrified musts, for the laboratory possessed the means for a superficial test only. The alcohol was also quite satisfactory in rectification plants.

The substances fermented were fig-juice followed by carob-juice; both were fairly clear, having been first filtered.

The author mentions this case, for, if the experiment were repeated at another distillery, it would be desirable to test the effect of the electricity and also have some means of measuring the amount of electrical energy applied to the must, in order to know whether the process could be profitably adopted as an easy and convenient means of obtaining pure fermented liquids.

1274 - Grape-drying: Construction and Working of Evaporators in California (1).

— CRUESS, W. V., CHRISTIE, A. W., and FLOSSFEDER, F. C. H., in *College of Agriculture, Agricultural Experiment Station, Berkeley, California, Bulletin* No. 322 pp. 421-471, figs. 11, Tables 8, Berkeley, Ca., 1920, and in *Monthly Bulletin of the Department of Agriculture, State of California*, Vol. X, No. 2, pp. 60-66. Sacramento, Ca., February 1921.

I and II. — Evaporators of many types have been used with varying degrees of success for many years. From the experience gained in the use of these evaporators and from observations and measurements taken by scientific investigators certain principles have become recognised. Lately however, some of the older theories are being discarded or seriously modified. Most of the data here reported were obtained in the commercial evaporator at the University Farm, Davis, California, although a great many small scale experiments were made in the experimental evaporators at Berkeley.

---

(1) See *R*. Dec. 1918, No. 1101; *R*. August 1921, No. 858; *R*. September 1921 No. 953. (*Ed*)

An evaporator of the horizontal tunnel air-blast type and of 6 tons of fresh fruit capacity per charge, was constructed during 1919 on the first mentioned farm by funds furnished by the State Board of Viticultural Commissioners and the University. This was used successfully in the drying of grapes and prunes. Plans, cost and general specifications of this evaporator are to be found included in this article. Sketches indicating revised evaporator plans recommended to growers are also given.

Most of the suggested improvements are now being made on the farm evaporator described. The revised plan is given, and the general specifications of an effective type of improved emergency evaporator are shown as follows: —

1. *Tunnel.* — Inside dimensions, 50 × 6 ½ feet wide × 7 feet high. Walls of double thickness with building paper between the walls. T. & G flooring on 2 × 4 inches pine frame.

Air return flue 50 × 6 ½ × 2½ feet of same construction as tunnel to be placed above the tunnel. This to connect to fan discharge and to furnace room. An additional height has been found necessary for efficient operation and rapid drying. Floor of tunnel to be of concrete or of coarse sand and to be 18 in. higher at fan end than at furnace end of the tunnel. A sliding door on one side, one foot from each end of tunnel, 7 ft. high × 64 in. wide. Doors to be hung on overhead track and rollers.

A 24 in. dry yard track of 8 pound per yard rails on 4 × 4 in. ties, 2 ft. on centre, imbedded in the floor. Track to extend between transfer tracks making it 37 ft. in length.

Transfer tracks with rails 42 in., apart to extend through each door connecting at end of tunnel to the tunnel track and to shed track at side of tunnel track (See figure). All wood parts at end of tunnel connecting to furnace room to be covered with double thickness asbestos.

Connection to furnace room to be full size of tunnel.

2. *Furnace Room.* — Six-inch reinforced concrete or hollow tile construction recommended. If a cheaper, but still safe type of construction is desired, use corrugated sheet metal over a frame of 2 in. iron pipe. Do not use wooden framework. Floor of gravel. Room 16 ft. long × 11 ft. high × 8 ft. wide, inside dimensions.

Install furnace and heating pipes before erecting furnace room.

Furnace to consists of an old boiler shell 10-12 ft. long × 36 – 48 in. in diameter (48 preferred), with tubes removed and one head removed. Other head to connect horizontally to 12 in. pipe. All rivet holes or other openings to be sealed smoke tight. Open end of furnace to project through end wall of furnace room opposite tunnel and to be fitted with a motor-driven crude oil or distillate burner if electric power is available;

otherwise with a gravity distillate burner of largest size. Furnace also to have a removable grate, which may consist of several cross bars and 8 or 10 lengths of dry yard rail. This is useful in emergencies to permit burning of wood or brush. An adjustable door 2 ft. × 3 ft. is installed above the furnace in end wall for admission of fresh air.

Heating pipes of 12 in. heavy gauge black sheet iron: 9 pieces 12 feet long arranged above the boiler in three tiers. Pipes to be supported on 1 in. water pipe framework. Heating pipes joined at ends by return bends, except at furnace outlet and stack, where 2 way connections are used. Two 2 way connections: one short piece pipe about 1 ft. long; 7 return bends and 5 elbows will be needed.

3. *Fan.* — Multivane fan with top vertical discharge. Fan wheel of 42 inches diameter and to operate at 450 R. P. M. or greater speed. To be located at end of tunnel opposite furnace room and to be used as a suction fan. The fan outlet to connect to air return flue and to an open air discharge of same cross section as fan outlets. Both outlets to be fitted with adjustable dampers so that any desired proportion of the air may be recirculated. A 20 h. p. motor or engine is necessary for power.

It is assumed that a tractor or some means of power used for other purposes will be used to operate the fan. This fan will cost over $500. It may be replaced by a 7 foot disc fan to operate at 400 R. P. M. This is much cheaper but is less satisfactory.

4. *Cars.* — Twenty Fresno County style dry yard cars with wooden frame. Frames 3 ft. × 6 ½ ft. long and to be placed at right angles to the track upon which the cars operate. Two uprights of 2 in. × 4 in. pine to act as tray guides in centre.

Cars to be fitted with bumpers to permit clearance of wheels.

Two lower steel transfer cars for 42 inch track.

The tunnel cars should have strips of rubber matting nailed to bottom of frames to prevent passage of air below the cars.

5. *Trays.* — The cars designed for 2 ft. × 3 ft. raisin trays with 1 in. × 2 in. cleats at ends. When stacked on the car there will be an open space of 2 inches between trays.

6. *Shed.* — Shed 60 ft. long × 20 ft. wide, to cover drying tunnel and to provide protection for unloading dried fruit. Shed may be of "lean to" design and should be at least 7 ½ ft. high at eaves.

7. *Modifications necessary for 8-Foot Trays.* — The tunnel must be made 8 ft. 3 in. wide for 8 ft. trays. The cars must have frames 8 ft. × 3 ft. No other changes necessary. The trays to be stacked crosswise of the tunnel.

When the trays are stacked on the cars it will be necessary to place strips at least 1 ½ inches high between them to permit passage of air.

8. *Modifications necessary for 6 × 3 Foot Trays.* — No centre guide posts will be needed on the cars for these trays. This is the only change necessary. It will be found advisable to place high cleats across ends and centres of trays to permit passage of air.

9. *How Plant May be Cheapened.* — The tunnel walls may be made of heavy roofing paper double thickness. The furnace room may be made of corrugated metal. A disc fan made to order for $100 or less may be used, but this will reduce the efficiency of the plant. The shed over the drier may be covered with roofing paper. It is strongly recommended that the furnace room, drying tunnel and air return flue be built in the proportions indicated and that no reductions be made in the size of the fan or the air heating system.

USE OF THE EVAPORATOR. — It is assumed that the evaporator is only to be used in unfavourable drying weather. Therefore no provision has been made for sulphuring houses, dipping equipment, etc.

1. *Stacking Trays.* — In case of rain it is still necessary to stack the trays in order that the fruit may be as little damaged as possible before it reaches the drier. The evaporator is able to deal with a limited amount of fruit only at each loading.

2. *Sulphuring Wet Fruit.* — In cases where a very large proportion of the fruit is still on trays and where the fruit is severely wet with rain it is advisable to sulphur all of such fruit which the drier can not attend to for 3 or 4 days. This will check mould and fermentation. Sulphur hoods such as those described by BIOLETTI and WAY (1) may be quickly made of light wooden frames and roofing or building paper. These are placed over the stacks of trays. Raisins are sulphured 30 minutes, and prunes 1 to 2 hours.

3. *Loading the Cars.* — Muscat field trays with side cleats and with ends open would be stacked crosswise of tunnel on the cars and with 1 ½ inch strips between them to permit passage of air.

Trays 6 ft. × 3 ft. and 8 ft. × 3 ft. would be stacked crosswise of tunnel on the cars, and 1 ½ inch strips placed between them.

4. *Heating the Fruit.* — After the tunnel is filled, the burner is started. About 15 minutes later the fan may be started. Until the fruit is thoroughly heated and the air at the furnace end of the tunnel reaches 160° F., the fan is allowed to discharge into the return flue and all of the air is recirculated. The preliminary heating will usually require about an hour.

5. *Continuous Operation.* — After the fruit is heated the fan should then be adjusted so that about three-fourths of the air is recirculated and one-fourth allowed to escape.

The temperature should not rise above 165° F., although 160° F. may be used safely.

It will be found difficult to determine when the fruit is sufficiently dry. This is best done by removing a small sample of the fruit from trays at the furnace end of the tunnel and allowing it to cool for 15 or 20 minutes. Its degree of dryness can then be determined fairly accurately. There is a tendency for most operators to over-dry the fruit.

6. *Air Baffles.* — Should there be a tendency for the trays near the top of the tunnel to dry more rapidly than those nearer the floor, sheet

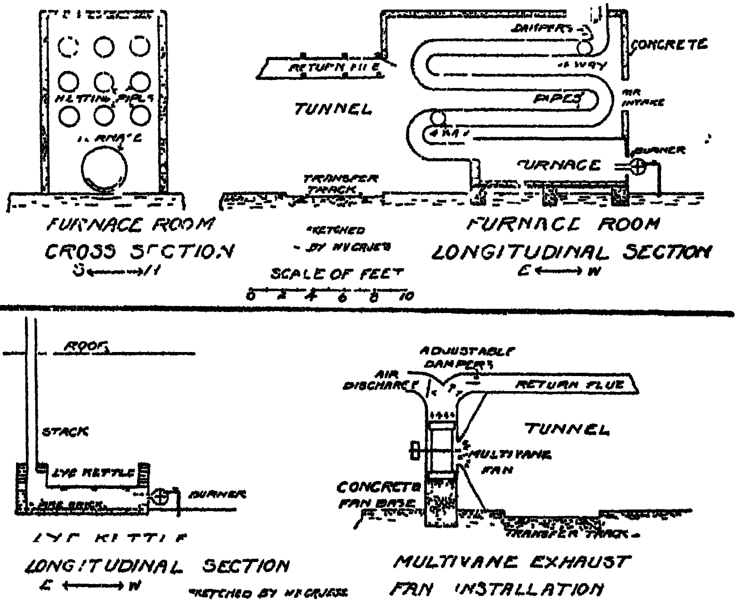
Longitudinal section of Evaporator.

metal adjustable baffles may be placed across the opening between the tunnel and the furnace room. The upper half of the opening may be covered in this way and the baffles adjusted at an angle which gives even distribution of the air.

Air tends to flow between the stacks of trays and the walls of the tunnel, and above the topmost tray and beneath the trucks more rapidly than it does between the trays. Should such air leakages be evident it will

Fig. 2. — *Revised University Farm Evaporator.*



II.

be necessary to nail flexible baffles to the walls and ceiling to force the air between the trays. Rubber door matting or second-hand rubber belting may be used. Such baffles are usually necessary and their use must not be neglected if efficient drying is desired.

Dipping the grapes in a dilute boiling lye solution approximately doubled the rate of drying. Most wine-grape varieties and Muscat grapes required a lye solution of 2 to 3 % to obtain successful results. Tokays and Thompson's Seedless required only a ½ % solution.

The suction type of fan proved more satisfactory than the blast type. The multivane fan was found to be much more efficient than the disc type. The air-blast distillate burner was more satisfactory than the gravity burner, although both were used successfully. An air blast progressive tunnel type of evaporator with furnace equipped to burn oil or wood, and with cars and trucks to facilitate handling of the trays, is recommended. A small stack evaporator is recommended for smaller farms: —

General Specifications of Small Stack Evaporator: — 1) Four drying compartments each 10 ft. long × 7 ft. high × 37 in. wide, above a fire pit. Compartments open above pit and to ventilator.

2) Each compartment equipped with 15 horizontal tray runways of 2 in. × 2 in. material; runway 10 ft. long and nailed to 2 in. × 4 in. studding.

3) Partitions between compartments open, except for tray runways.

4) One folding door, 7 ft. × 38 in., for each compartment.

5) Outer walls of dryer of 1 in. × 12 in. material surface one side, double, with 3 in. sawdust-filled space between.

6) Roof of lean-to construction, lower side at height of top of drying compartments, higher side about 4 feet above top of compartments.

7) Ventilator, 12 ft. × 2 ft. and 6 ft. high above centre of roof.

8) Fire pit 14 ft. long × 10 ft. wide, 4 ft. below ground line, and 4 ft. above. Walls of 6 in. concrete. Several 1 ft. × 1 ft. openings at ground line for admission of air. Would be better if air were admitted at bottom of pit instead of at ground line.

9) Furnace of old boiler shell 6 ft. long and 3 ft. in diameter. Bottom lined with fire brick. Excavation and steps leading from ground level to furnace floor level.

10) Burner, large stove distillate type. Fed from tank above by gravity.

11) Air heating pipes: One 16 in. pipe connecting to furnace at one end of chamber and to 20 in. drum at other end. This 20 in. drum in turn connects two 9 in. pipes which return to the furnace end of room. At the furnace end of room these two pipes connect by vertical elbows to two 9 in. pipes which return to opposite end of pit. They are here joined by a T joint to a 9 in. pipe returning above centre of pit to the smokestack. There is, in all, one 16 in. pipe about 6 ft. long; one 20 in. drum, about 8 ½ ft. long, and five lengths of 9 in. pipe, each about 13 ft. long. One end of each 9 in. pipe projects through the cement wall and is covered with a soot cap to facilitate cleaning.

12) Trays: Ordinary 8 ft. × 3 ft. dry yard trays are used but 2 ft. × 3 ft. field trays may be placed in the drier. In the compartments, tray No. 1 should be placed against the rear wall, No. 2 against the door, No. 3 against the rear wall, and so on for the other trays. This arrangement will force the air to flow across the trays.

It is necessary to shift the trays from the top of the compartments downward, one tray ar a time, as the lowermost tray becomes dry, for the reason that the fruit on the trays near the top of the compartment dries very much more slowly than that on trays nearer the furnace.

Recirculation of a large proportion of the exhaust air from the evaporator greatly reduces final consumption without reduction of the rate of drying. Recirculation prevents overdrying of the fruit and permits regulation of moisture content of the dried product. It is believed that higher temperatures of drying may be employed where the humidity of the air used in drying is increased by recirculation.

The rate of air flow through the evaporator, and especially over the trays, determines the rate of drying. An anemometer is used to measure the velocity of the air currents.

Dried grapes of 25 %, or less, moisture kept perfectly; those of 30 % or over were spoiled unless heavily sulphured. The dried product equalised rapidly in moisture content, and stemmed satisfactorily within a few hours of drying, when dried to about 10 % moisture. Flat-bottom trays were found to be distinctly preferable to screen trays for many reasons.

No definite constant difference in yield could be found between sun-drying and evaporation. The colour and flavour of the juice obtained by soaking sun-dried grapes in water, was much inferior to juice obtained from evaporated grapes. Temperatures up to 190° F. were used successfully on red wine grapes, although it was found necessary to remove them from the evaporator as soon as dry, to avoid injury to colour and flavour. A temperature of 165° F. may be used in regular practice.

1275 - **The Utilisation of the Stones of Table Fruit.** — TRUELLE A., in *La Nature*, No. 2467, pp. 19-20. Paris, July 16, 1921.

The stones of our principal table fruits are regarded as waste products of no account, whereas in certain cases they could be used profitably either as food or in the orchard, in the various ways described by the author.

RATIO OF STONE WEIGHT TO TOTAL FRUIT WEIGHT. — Our chief table fruits are, in order of ripening: cherries, apricots, peaches and plums The proportion the stone bears to the fruit is little known, but some idea of it can be gathered from the figures taken by TRUELLE from 1) *Recherches sur la composition des fruits frais* by AIMÉ GIRARD, published by LINDET in 1918, in the *Bulletin du Ministère de l'Agriculture* and; 2) from Dr. HOTTER'S papers *Die chemische Zusammensetzung steinischer Obstfrüchte* published in *Landw. chemische Landes-Versuchstation Graz*, in 1906.

The figures found by Aimé GERARD are as follows:

Weight of stones per 100 gm. of fresh fruit.

Cherry English	6.01 gm.
» Royal	8.60 »
» Montmorency	6.01 »
Apricot Auvergne	7.12 »
» Blanc de Paris	5.50 »
» De plein vent	6.40 »
Peach Midi	8.38 »
» Montreuil	5.20 »
» Perpignan.	6.19 »
Plum Reine Claude	4.07 »
» Monsieur	1.77 »
» Mirabelle	5.65 »

HOTTER states that the weight of the stones per 100 gm. of fully-developed fruits varies in cherries, from 4.4 gm. to 15 gm.; in apricots, from 6 to 11 gm.; in peaches, from 8.5 gm. to 13 gm.; in Reine-Claude plums, from 5.3 gm. to 9.1 gm.; in Mirabelles, from 4.7 gm. to 12 gm.

It is found that in Styria the variations in the proportion of the stones for the same kinds of fruits are even greater than in France. If certain natural variations are disregarded, the figures show that these fruits, as regards the proportion of the weight of stones to total weight, may be arranged in the following ascending order: plums, apricots, cherries, peaches

USE FOR TABLE. — With the stones the confectioner, and even the housewife, can make creams, distilled waters, essences, hippocras, ratafias and sherbet. As the special flavour characterising hippocras and ratafia is due to the hydrocyanic acid and oil of bitter almonds produced by the decomposition of the amygdaline present in the kernels, which takes place in the presence of water, the stones of peaches and cherries especially, must not be used to excess, as they contain much more of the acid than those of the other fruits.

HIPPOCRAS. — The ancient tonic drink known by this name was made with sweetened red wine in which cinnamon was infused. Fruit-kernel hippocras is a kind of ratafia made of white wine containing the fresh kernels of apricots, peaches, and occasionally of plums, but never of cherries. The following is a recipe for 5 litres of white wine:

Take 15 stones of the above-named fruits, crack without injuring the kernel, soak for 24 hours in 25 centilitres of brandy (alcoholic strength 50°) add 300 gm. of sugar dissolved in white wine, leave the mixture to stand for 48 hours: strain and filter through filtering-paper to obtain a clear liquid.

RATAFIA. — This can be made in two ways; with kernels only or with the entire stones. The first method is the better with apricots and peaches, and the second with cherries and plums. The following is a recipe for 1 litre of brandy (alcoholic strength 60°).

From 75 to 100 gm. of kernels should be taken, whatever stones are chosen, but three or four kinds may be used, provided the total weight does not exceed this amount. Thus 30 gm. of apricot, peach and plum kernels can be used, and 10 gm of cherry kernels. If peach and cherry kernels are used alone, it is better to keep to the minimum quantity of 75 gm.

Blanch the kernels in hot water, and put them into a bottle containing 1 litre of brandy (alcoholic strength 60°); cork, and leave to soak for 10 days. Then strain or filter through paper, adding to the liquid a clarified syrup made by heating 500 gm. of sugar with half a litre of water. If this produces slight turbidity, filter again to obtain a perfectly clear liquid. Keep in well-corked bottles in a room with average temperature.

USE FOR HORTICULTURE. - *Collecting the stones.* This must be done in such a way as to leave the integument intact and clean. When the stones of the four fruits are used industrially in large quantities for the preparation of essences, syrups or wines, care must be taken whatever means of extraction are used to see that all the kernels, which are not absolutely entire, are allowed to pass out of the press together with the refuse pulp. The best results are obtained with the different implements used by confectioners for the purpose.

PRESERVATION. — Fruit stones may be used in two ways: 1) sold to seed merchants; 2) sown for seed. In the first case, the stones are washed as soon as procured, and put to dry on a screen in a rather strong current of air or in the sun, but not in a drying stove, as the heat would affect their power of germination. They are then shut up in wooden or tin boxes in a dry, well-ventilated place, to prevent the growth of moulds, and the attacks of insects and rodents.

The author does not know the sale price of stones, which varies according to the kind of fruit, quantity, quality etc. The following prices taken from trade catalogues will however give a general idea: apricots 3 fr.; cherries 3 fr.; ordinary peaches 5 fr.; Montreuil peaches 10 fr.; plums 2.50 fr. to 4.50 fr. per kg.

When the stones are kept for sowing at the right season, the best way of preserving them is "stratification." This means placing the stones in layers alternating with beds of damp sand, or fine soil.

The beds then made are 3 to 5 cm. thick according to the size of the stones. The object of this method is not only to preserve the stones in good condition until they are planted, but also to prepare them for germination by softening the integument and thus encouraging the growth, and extrusion of the radicle.

In the country, horticulturists requiring a limited number of plants can put 20-30-40 stones in layers in a flower-pot, on any earthenware jar. When however it is desired to make a small nursery, a box should be used, or with a great number of seeds, a conical heap should be made in the open air the stones being arranged in layers on raised dry beds of soil, as already described.

It is best to arrange the stones in layers at once, and then protect them from the weather and rodents. The receptacle containing the stones may be placed in a cellar, or store-room where the temperature is low and regular, and covered with a tile or a sheet of glass, or if the heap is buried at the foot of a wall, a little mound of soil 0.40 m. high can be piled over it to protect the stones from frost and rain. With a large number of stones intended for sowing, the soil should be 0.50 m. deep and covered with a layer of straw 0.10 m. thick, the straw being kept in position at the top by an inverted flower-pot. A circular trench round the mound completes the arrangements. Under favourable conditions, germination begins in March, and when the temperature is suitable, the seeds can be planted in well-prepared soil from March-April.

1276 - **The Commercial Utilisation of Cotton Stalk.** — *Bulletin of the Imperial Institute*. Vol. XIX, No. 1, pp. 13-18. London, 1921.

The question of the most economical method of disposing of the enormous quantities of cotton stalks which are left after the crop has been harvested is one that has received much attention. The destruction of the stalks is particularly important if they are liable to harbour insect pests, which might otherwise be carried over from one season to the next. In most cotton growing countries it is usual to use the cotton stalks as fuel and their utilisation in any other direction would therefore depend on their local value for this purpose.

I. — SOURCE OF FIBRE. — Experiments have been made in the United States and in Egypt to test the possibilities of utilising cotton stalks as a source of fibre. Results appeared to indicate, however, that the extraction of fibre from the bark of the stalks would not prove a profitable undertaking, as the work involved in handling and retting the stalks and preparing the fibre would not be repaid by the price obtainable for the product. In this connection it may be roughly estimated that with a yield of 1000 lb. of stalks per acre, it would be necessary to collect and treat the stalks from 10 acres to obtain ½ ton of fibre, the value of which would be only about half that of Bengal jute.

II. — PAPER MAKING TRIALS. — Trials carried out by the United States did not give encouraging results; the pulp was found difficult to bleach on account of its dark outer bark, and the yield varied from 35 to 43 % with a short and weak fibre. Cotton stalks however under recent examination at the Imperial Institute and coming from the Punjab and Central Provinces in India proved more promising. Results showed that when treated by the caustic soda process these Indian cotton stalks yield a paper pulp of fair quality, which can be bleached to a pale cream tint. The yield of pulp is rather low (34 to 41 %) and it has been found necessary to employ larger quantities of caustic soda than in the case of esparto and similar grasses, but the results are sufficiently promising to justify further consideration.

III. — DISTILLATION TRIALS. — Preliminary trials have been carried out recently at the Imperial Institute with a view to determining the possibility of utilising cotton stalks for the production of charcoal, pyroligneous acid and other products, by the process of dry distillation. The stalks used came from the Central Provinces, India, and the results, expressed in percentages by weight on the stalks as received are shown as follows:—

Weight of material distilled, 3 lb.; Time required for distillation 3 hours; % Charcoal 35.4; crude pyroligneous acid 41.1 (containing: acetic acid 3.0, dissolved tar 2.6, crude wood napththa (100 %), 1.5); tar separate 7.6 (containing acetic acid, 0.4). Total yield of tar 10.2, total yield of acetic acid 3.4

The tar obtained was a fairly thin readily mobile liquid of brownish-black colour; the charcoal obtained could only be ranked as fuel charcoal; the acetic acid yield was rather below the average quantity obtained from hard-woods but the yield of wood naphtha was about normal.

The feasibility of distilling cotton stalks successfully in India would depend, on finding local markets for the products, especially the charcoal and tar. Regarding the cost of distillation, attention is drawn to the fact that as cotton stalks are bulky materials, they would require large retorts even if they were cut in pieces and compressed before treatment.

1277 - **Utilisation of West African Corkwood, *Musanga Smithii* for the Manufacture of Paper Pulp, etc.** — *Bulletin of the Imperial Institute*. Vol. XIX, No. 1, pp. 10-13. London, 1921.

Two logs of corkwood, *Musanga Smithii* R. Br., were sent recently from Sierra Leone to the Imperial Institute for examination.

The wood was found to be soft and easily worked, but possessing a short coarse grain. Owing to the exceptional lightness of the wood, experience has proved the unsuitability of using this material for the manufacture of artificial limbs, as originally suggested. However, as a source of paper pulp the wood appears to be a promising material. The wood required rather drastic treatment but gave a good yield of pulp which possessed satisfactory felting properties.

The wood treated with caustic soda resulted in a pulp which was in some cases difficult to bleach and in others bleached to a cream colour.

Wood treated by the sulphite process was found to yield 56.25 % of dry pulp as compared with 50 % by the caustic soda process, and the pulp although slightly darker in colour, bleached almost white. The papers made from the bleached and unbleached pulps obtained by the sulphite process were not quite so strong or as soft as those from pulps prepared by the soda process, but it should be possible by modification of the sulphite treatment to obtain pulp which will furnish a good white paper.

It is not likely that corkwood could be profitably exported from Sierra Leone as a source of paper pulp but if a pulp mill were established in the country, corkwood could be utilised for the manufacture of paper pulp for export.

1278 - **Studies in Milk Analysis.** — I. Mac Inernly, T. J., and Troy, H. C. A Comparative Study of Some Methods for Determining the Fat Content of Skim-Milk, in *Cornell University Agricultural Experiment Station, Bulletin* 401, pp. 69-85. Ithaca, New York, January 1920. — II. Machens A., and Cordes F. R., Un nouvel appareil pour la determination de la catalase dans le lait, in *Milchwirtschaftliche Zentralblatt*, p. 25. Hanover, February 1, 1921; *Le Lait*, Year I, No. 2, p. 84. Lyons, 1921.

I — A COMPARATIVE STUDY OF SOME METHODS FOR DETERMINING THE FAT CONTENT OF SKIM-MILK. — The accuracy of the Babcock test for determining the percentage of fat in skim-milk has been questioned for several years. On comparing the fat percentages obtained by this method with the percentages found by the Adams gravimetric method, it was found that the latter gave higher results. The slight modifications introduced into the technique of the test also caused the percentage of fat to vary, and it was clear that considerable losses of fat might occur without detection when the ordinary Babcock method was used. For these reasons, the authors decided to make a fresh study of the problem, and to make a comparative test of the following methods; Adams (Official and Provisional Methods of Analysis, *United States Bureau of Chemistry Bulletin* 107 [revised] 1908, p. 120); Roese Gottlieb (Report of the Committee on Editing Tentative and Official methods of Analysis, *Association of Official Agricultural Chemists*, 1916, p. 289); Mojonnier; Leffman-Blam modified (Henry Droop Richmond, *Dairy Chemistry*, 2nd Edit., pp. 221-228, 1914); Babcock.

The results of these experiments prove that the following modifications should be made in the Babcock test when it is used in determining the fat content of skim-milk.

1) At least 25 cm³ of sulphuric acid should be used. If the size of the bottle permits, as much as 28 cm³, can be used to advantage.

2) The temperature of the testing machine should be at least 82 C (180° F).

3) A *centrifuge* having a disk 15 inches (38 cm.) in diameter, and strong enough to be run at a minimum speed of 1 800 revolutions a minute without danger, is recommended. The diameter of the disk is determined by measuring the distance between the bases of the opposite cups when in a horizontal position.

4) The milk should be *centrifuged* for 10-2-1 instead of for 5-2-1 minute periods.

II. — NEW APPARATUS FOR DETERMINING THE CATALASE IN MILK. — MACHENS and CORDES have devised a new apparatus to take the place of FUNKE's apparatus which did not give very accurate results, and those invented by LOBECK, and by LOBECK and OTTOKER, which appear to be rather difficult to handle.

MACHENS and CORDES' apparatus is composed of two bottles; one (*A*) containing the milk and oxygenated water, the other (*B*) in communication with a graduated tube and serving as a gasometer. *A* and *B* communicate by means of a tube furnished with a tap having 3 outlets. The zero level at 37° C is determined in the gasometer at 37°, and the milk is put into flask *A* when the temperature has reached 37° C; flasks *A* and *B* are put into communication with the external air, the oxygenated water is added to tube *A*, and *A* and *B* connected. The change of level in the graduated tube allows the amount of oxygen liberated to be measured.

If the catalasimetric degree of the milk is very high, and too large a quantity of oxygen is liberated, *A* and *B* are isolated by a turn of the tap, the level is again readjusted in tube *B*, *A* and *B* are once more placed in communication, and the new level reached is added to the first.

1279 - **Studies on Variation in the Reaction of Freshly Drawn Milk.** — I. VAN SLYKE L. L., and BAKER, J. C., in *New York Agricultural Experiment Station, Geneva, N. Y., Technical Bulletin*, No. 70, pp. 1-9. Genoa, N. Y., June 1919. — II. BAKER, G. C., and BREED R. S. in *The Journal of Biological Chemistry*, Vol. XLIII, No. 1, pp. [illegible]. Baltimore, Md., 1920.

I. — CONDITIONS CAUSING VARIATION IN THE REACTION OF FRESHLY DRAWN MILK. — The most sensitive method of measuring the reaction of milk is by measurement of the hydrogen-ion concentration. This method has been employed by several investigators (FOA, 1905; VAN DAMM, 1908; ALLEMAN, 1912; TAYLOR, 1913; DAVIDSOHN, 1913; MILROY, 1914; CLARK, 1915, and it has also been utilised in the work here reported.

The results of the experiments made by earlier investigators showed that milk, when freshly drawn, has a reaction, expressed in terms of hydrogen-ion concentration (pH) varying from 6.39 to 6.81, the usual range being between 6.50 and 6.65.

The present authors propose to ascertain the extent of variation of reaction in large numbers of milks obtained directly from the cows and to discover, if possible, the cause of such differences. The following points are considered : 1) the extent of variation of reaction in cow's milk ; 2) variation in different quarters of the udder ; 3) relation of reaction of milk to composition ; 4) effect of abnormal conditions in the udder.

More than 300 samples of fresh milk were examined, and the reaction expressed in terms of pH values varied between 6.50 and 7.20 ; being under 6.76 in 80 % of all the samples.

In the case of 20 cows, it was found that the pH value of the milk from different quarters of the udder varied considerably, but in most cases the variations were negligible.

The pH value varies with the composition of the milk. In general with a decrease of acidity, there is a marked tendency towards a decrease in specific gravity, and in percentage of fat, total solids, solids minus fat, casein and lactose, but an increase in proteins other than casein and in ash and chlorine.

These changes in composition are such as would be expected if flood serum or lymph were added to normal milk. Similar abnormal conditions in the udder may cause such an addition.

Examination of abnormal milks of low acidity having a pH value above 6.80, indicates that the reaction, is accompanied by the presence of large numbers of leucocytes, though in such cases, the reaction may be neutralised by the presence of large numbers of acid producing streptococci. While the theory of the presence of blood serum or lymph in such milk is supported by several considerations, a careful test for glucose proved negative. It is concluded therefore that the glucose in the blood-serum must undergo a change in the udder.

II. — REACTION OF MILK IN RELATION TO THE PRESENCE OF BLOOD CELLS AND OF SPECIFIC BACTERIAL INFECTIONS OF THE UDDER. — BAKER and BREED have made observations concerning the leucocyte and streptococcus content of a number of samples of milk, with a view to the verification of the hypothesis put forward by VAN SLYKE and BAKER, who suggest that decreased acidity of fresh milk is due to the direct filtration of blood serum owing to lesions of the blood vessels or to bacterial action.

From the new data here collected by the authors, and from histological and physiological considerations, it appears that a more exact statement of the case would be that infection causes the entrance of a serous exudate derived by the gland cells directly from the lymph rather than from the blood. This serous exudate is neither similar exactly to blood serum nor to milk. When the infection has so advanced that actual rupture of the vessels occurs, then the unchanged lymph and blood enters. The modifications in the secretions may be due to a weakening of the secretory activity of the cells, or the exudate may have a definite protective function acting against the bacterial infection, or both conditions may hold good simultaneously.

The changes in the secretory processes seem to be accompanied by wastage from the glandular epithelium.

1280 – **A Method for the Preliminary Detection of Abnormal Milk Based on the Hydrogen Ion Concentration.** — BAKER, J. C., and VAN SLYKE, L. L. (Chemical Laboratory of the New York Agricultural Experiment Station, Geneva) in *The Journal, of Biological Chemistry*, Vol. XL, No. 2, pp. 357-371. Baltimore, M. D., Dec. 1919.

The method described by the authors is based upon the use of the dye, brom-cresol purple previously suggested by CLARK and LUBS as a substitute for litmus for use in milk cultures (1). A drop of a saturated water solution of the dye is added, and the colour is then observed. In the case of average milks of normal character, the colour becomes bluish-grey. If the colour is distinctly lighter or darker, there is ground for suspecting the quality of the milk. The colour ranges from a bright yellow at one extreme to a deep blue at the other. The colour is made lighter by the presence of acids, acid salts, formaldehyde solution, and also by heating above the usual point of pasteurisation. It becomes a deeper blue in the case of milk from diseased udders, watered milk, skimmed milk, and milk containing additions of alkali or an alkaline salt.

Attention is called to certain conditions which modify the characteristic colour given by brom-cresol purple solution with average normal milk. The presence of extra fat (5 % or more) gives an appreciably lighter colour than is the case with ordinary market milks containing 3 to 4 % of milk fat. Skimmed milk gives a darker colour than the same milk before the removal of fat. With milks drawn directly from the cows on fresh pasture, the colour is a decided yellow which modifies the colour reaction with brom-cresol purple.

The utility of this method has been demonstrated by the testing of 570 samples of market milk.

The authors emphasise the fact that the application of the brom-cresol purple test is not to be regarded as final but only as preliminary and suggestive. Milks giving a normal coloration will then be considered as normal; and a sample showing an abnormal coloration can be put aside and submitted to careful examination in the laboratory. The chief value of the brom-cresol purple test lies in the fact that when properly used, it will greatly minimise the work involved in official milk inspection.

1281 – **The Value of the Reductase Test in the Dairy Industry** (1). BARTHEL CHR. (Bacteriological Laboratory of the Central Station of Agricultural Experiments, Experimentalfaltet, Sweden), in *Le Lait*, Year I, No. 2, pp 62-66. Bibliography of 10 works. Lyons, 1921.

Among the methods of testing milk, the methylene blue reductase test has again become the subject of much discussion. Two main objections have been raised viz., 1) in the case of milk from isolated cows, discoloration sometimes takes place very rapidly, although the milk contains but an insignificant number of bacteria; 2) it is not a perfect method for determining the number of bacteria present in milk.

---

(1) See *R.* Aug. 1918, No. 908. (*Ed.*)

(2) See *R.* 1913, No. 176. (*Ed.*)

The author in discussing these criticisms states, that as regards the first, a thorough examination has shown, that all milks which changed colour very rapidly (that is to say before 2 hours had elapsed); were abnormal. They had a high catalasimetric index, an abnormal number of leucocytes, or were the products of cows that were in the very last lactation period.

LIND (1) has made similar statements. As, however, in the dairy industry the reductase test is applied exclusively to mixed milk, the product of several cows, the first objection has no real weight. As regards the second, the author urges that the reductase test is purely practical. Further, if the results obtained by BREED or SKAR (2), by directly counting the bacteria under the microscope, are compared with BARTHEL and ORLA-JENSENN'S computation based on the length of the methylblue reaction (1), it will be found, that in about 90 % of the cases the estimated number of bacteria in the milk is identical. This is a fairly good proof of accuracy; moreover when the milk of different retail sellers has been subjected several times to this method of examination, the discrepancies have in practice proved to be negligible.

In the case of milk supply to towns and large dairies, the first *desideratum* is that the methods adopted should be practical and simple, so that a large number of samples can be examined at once, especially from the point of view of their keeping properties. Hitherto no method has for this purpose proved superior to the reductase test. In addition, this method could serve as a basis for payment according to quality, on the condition, that the price be fixed by the average number of marks accredited to each seller during a certain period of consignment. In this way, the small irregularities inseparable from the method are eliminated, and have no effect upon the final verdict.

1282 - **Carbonic Acid and Carbonates in Cow's Milk.** -- VAN SLYKE, L. L., and BAKER J. C., in *New York Agricultural Experiment Station, Geneva, N. Y., Technical Bulletin*, No. 66, p. 1-9. Geneva, N. Y., June 1919.

The amount of carbonic acid present in cow's milk has been the subject of several investigations (HOPPE, 1859; SETSCHENOW, 1861; PFLÜGER, 1869: THÖRNER, 1894; MARSHALL. 1902). The results obtained by thes investigators vary from 1.84 to 7.65 % of CO_2 by volume. The methods employed varied from extraction by means of a vacuum pump to expulsion by heat and have been more or less inexact. Consequently the authors have started fresh work on the subject on the following lines: 1) determination of CO_2 using VAN SLYKE'S method (*Journal of Biological Chemistry*, Vol. XXX, p. 347, 1917); 2) relation of pasteurised milk to CO_2 content;) the form in which CO_2 exists in milk; 4) the tension of CO_2 in milk.

---

(1) LIND *Maelkeri Tidende* 1915, p. 291 and 1920, p. 207. (*Ed*)

(2) BARTHEL CH., Die Methoden zur Untersuchung von Milch und Molkereiproducten. Berlin, 3rd Ed., pp. 113-121

Milk is drawn from the udder into a 100 cc. cylinder, completely filled in such a way as to avoid mixture with air or loss of CO_2. For the determination of CO_2 2 cc. of milk were forced from the cylinder into the VAN SLYKE apparatus and a 20 % solution of lactic acid was added to free the CO_2 in carbonate form

In the case of 25 samples of milk drawn from each quarter of the udder, the CO_2 varied from 7 to 86 % by volume; the pH value varied generally with the CO_2 content (6.50 to 7.16). With increase of pH value the general tendency of the CO_2 is to increase while the degree of acidity as measured by titration decreases.

In comparison with other workers, higher CO_2 values were obtained by the authors. The CO_2 content of normal milk appears to be about 10 % by volume.

It was found possible to remove the CO_2 completely from milk by vacuum exhaustion, provided the milk was spread in a thin layer and agitated.

When milk was pasteurised, the CO_2 content was decreased, but the pH value remained unchanged; but if the CO_2 was completely removed before pasteurisation, the pH value appeared to decrease slightly.

CO_2 exists in milk as carbonic acid ($H_2 CO_3$) and probably as sodium bicarbonate (Na H CO_3); the ratio is about 1 pt. $H_2 CO_3$ and 2 pts $NaHCO_3$. The CO_2 tension of milk is calculated to be about equal to 50 to 55 mm. of mercury, in the case of 0.01 N solution, pH 6.6 at 20°C, that is to say slightly above the CO_2 tension value in blood, which is 47 mm.

1283 - **Determination of Watering and Skimming in the Case of Samples of Altered Milk** (1). — ANDOYER, G., in *Comptes rendus de l'Académie des Sciences*, Vol. 173, No. 15, pp. 588-589. Paris, October 10, 1921.

Samples of milk submitted to experts for inspection are frequently kept too long and in an advanced state of decomposition. The milk has become a coagulum containing fat, insoluble mineral elements and albuminoid substances. This coagulum floats in a serum in which are present mineral salts, lactose and its decomposition products, together with different substances producted by the alteration of the casein.

The author estimated the nitrogen content of the coagulum after the removal of the fats and the subtraction of the mineral elements. From a large number of samples, he repeatedly obtained an average figure of 15.6 %. This percentage of nitrogen is exactly that of the casein; thus instead of estimating the nitrogen, all that is necessary is to determine the weight, after subtracting the butter and salts.

This discovery facilitates the application of KLING and ROY's method of analysing altered milks and allows in addition for the determination of the ash.

The authors named determine the casein by obtaining the nitrogen content of the sample (by KJELDAHL's method), which they disintegrate with sulphuric acid. The mode of operation proposed by the Author is as follows :

---

(1) See *R.* 1912, No. 506; *R.* 1914, Nos. 65, and 509; *R.* 1917, No. 371; *R.* 1920, No. 123. (*Ed.*)

The sample, after having been slightly acidified by the addition of acetic acid, is passed though an old filterbed. After several washings with distilled water, aliquot parts of the filtrate are taken and the following determinations made : 1) of the soluble ash (the material being desiccated and incinerated) ; 2) of the albuminoids rendered soluble by the alteration. In order to obtain this second result, the total nitrogen content is found, by the KJELDAHL method and the figure obtained is multiplied by the factor 6.39.

Another portion of the coagulum, after desiccation, is exhausted with ether, in order to separate the fats, weighed after the solvent is removed and then incinerated.

These various operations allow of the determination of the butter, of the portion of the casein that may be regarded as unaffected, and of the insoluble ash. The results, added to those obtained from the filtered serum, give the amount of butter, casein and ash in the milk tested, and make it possible to calculate the degree of watering and skimming.

The author tested the accuracy of this method as compared with that used by KLING and ROY. He obtained very satisfactory results which are given in the following table.

		Fresh milk analysed according to the official method	The same milk (altered) after being kept for 7 months	
			KLING and ROY method	Proposed method
I	Butter . . . in gm. per litre	34.60	34.45	34.40
	Casein . . . » » »	31.10 (per total N)	31.00	31.20
	Ash . . . . . » » »	7.20	?	7.15
II.	Butter	29.10	28.80	28.80
	Casein	26.15	26.35	26.30
	Ash	6.15	?	6.15

1284 - **Determination of the Keeping Quality of Milk.** - I. BAKER, J. C, and VAN SLYKE, L. L., in *New York Agricultural Experiment Station, Geneva, N. Y., Technical Bulletin* No. 72, 8 pp. Geneva, N. Y, June 1919. — II. COOLIDGE, L H, and WYANT, R W., in *Journal of Dairy Science*, Vol. III, No. 2, pp 156-160. Baltimore, 1920.

By the keeping quality of milk is understood the length of time milk remains sweet, and suitable for direct consumption.

Various methods have been proposed for measuring the keeping power of milk : 1) determination of acidity by titration ; 2) estimation of the amount of impurities in suspension ; 3) biochemical tests ; 4) bacteriological examination. Such methods, while useful in determining certain factors relating to the cleanliness and sanitary character of the product, are not satisfactory, at least in the forms used as a means of measuring how long milk will keep. Titration methods are not sufficiently sensitive to changes of reaction. The degree of impurity in the milk is primarily a measure of cleanliness but does not bear any relation to its keeping qualities. Bacteriological examinations have been used chiefly to determine the cleanliness and wholesomeness of milk, but as the authors have found, yield results that are generally of value in measuring the keeping quality especially in relation to acid production. The technical character of a bacteriological examination limits its use to trained workers. A simple method is still needed that can be relied upon to give sufficiently accurate results.

The method proposed by the authors is the brom-cresol purple test (described in *Technical Bulletin*, No. 71, of the New York Agricultural Experiment Station and in the *Journal of Biological Chemistry*, Vol. XL, No. 2, p. 307, 1919) (1) with the following simple modifications: the test-tubes and pipettes are sterilised before use, and the milk in the tubes is incubated for a fixed period at a definite temperature (18° to 20° C). Every 24 hours, the changes in the colour of the milk are noted. The principal factor affecting the keeping quality of milk as measured by this test is the production of acid; other changes can also be noticed such as the coagulation of casein, digestion of casein, formation of alkaline salts, production of gas and the development of abnormal odour or taste.

The changes of colour allow 4 successive stages of acidity to be distinguished: greyish-blue (normal milk); greyish-blue interspersed with yellowish, or greenish-yellow shades (distinct, but weak acidity); greenish to greenish-yellow (marked acidity); pure yellow (great acidity).

A comparison of the results of this test with those obtained by microscopic examination show that the increase in acidity corresponds fairly well with the increase in the number of bacteria present. The other factors affecting the keeping property of milk (digestion of casein, production of gas, of alkalis, abnormal odour or taste), are readily seen, but often do not appear until after 24 hour's incubation.

II. — COOLEDGE and WYANT carried out a long series of experiments in the hope of finding a satisfactory method of determining the sanitary condition of milk, as all which had hitherto been adopted were open to much criticism. They used the colorimetric hydrogen ion determination. The results obtained with the Brom thymol blue indicator proved the method to be a simple and accurate means of measuring the activity of bacteria and enzymes present in the milk. The poor samples of milk can be detected at the end of one hour (the lower the keeping quality of the milk, the sooner the results are obtainable). The best samples give their proper grade at the end of 8 hours. Over 100 samples of milk may be easily examined each day, if the comparator designed by COOLEDGE (*Journal of Industrial and Engineering Chemistry*, 1920), is used. This examination is rendered easier by the use of a table, which at present the authors regard as provisional only. It classifies the milk according to the purposes for which it is suited, the determination been based on the results of the test.

---

(1) See also No. 1280 of this *Review*. (*Ed.*)

[1284]

In this table the milks are divided into 17 classes: the 3 first (pH = 5.8 after 1-2-3 hours of incubation) are condemned as useless; the 6 following classes (pH = 5.8 after 4-5-6-7-8 hours of incubation) are milks for skimming and butter-making; the 2 following (pH = 6.0 and pH = 6.1 after 8 hours) are milks suitable for condensing; the 12th class (pH = 6.2 after 8 hours) can be used for cheese-making; the 5 last classes (pH, respectively = 6.3 — 6.4 — 6.5 — 6.6. — 6.7 after 8 hours) consist of milks suitable for the ordinary market.

1285 - **Comparison of Fat Test in Milk as Determined by a Cow-Testing Association and by a Creamery.** — TROY, H. C., in *Cornell University, Agricultural Experiment Station, Bulletin* No. 400, 66 pp, bibliography of 12 works. Ithaca, New York, Jan. 1920.

Of recent years, the practice of selling milk wholesale on a weight and fat-percentage basis has become general throughout the State of New York. The members of cow-testing associations usually compare the fat percentage found by the association tester with the percentage found by the purchaser. Both the tester and purchaser generally determine the fat content by the BABCOCK method, but use a different method for obtaining the test sample and the average fat percentage for each month.

Variations in the fat percentages determined by the two tests frequently occur, as can be seen on comparing the herd record books of cow-testing Associations with the creamery records.

The author compared the milk and fat percentage records of 22 herds as found by a cow-testing association with similar records obtained at the creamery belonging to the College of Agriculture of Cornell University, in the hope that by showing the range and frequency of variations between the results of the two tests, a source of dissatisfaction might be removed.

The records of the testing association showed that when the fat percentage of milk was determined once a month in two successive milkings, it frequently varied more than 0.5 %, and sometimes more than 1 % from the results of the preceding or following monthly test.

The fat percentage variations found in the herd milk by the association tester were similar to those found in the milk of individual cows, but the range of variation in herd milk was narrower.

The average fat percentage in the milk given by a herd at two successive milkings as found by the association tester, ranged usually from 0.2 to 0.3 % above or below the fat percentage for the month as found by the creamery.

In herd milk, differences of over 0.5 % were not uncommon between the monthly fat percentage as found by the association test, and the creamery test respectively.

The differences between the fat percentages found by the two tests were less than 0.1 in 59.375 % of the 32 complete annual records; they were between 0.1 and 0.2 % in 31.25 % of the records, and were greater than 0.2 % in 9.375 % of the records.

When all the milk produced during a year by a herd in a testing association is delivered to a creamery and the average difference between the association test and the creamery test exceed 0.1 % of fat for the year, an effort should be made to determine the cause of the difference.

Some of the milk tested by the association is used on the farms and, if precautions are not taken to have the fat percentage of this milk the same as that of the milk delivered to the creamery, frequent variations in association and the creamery tests may result.

These two tests agree fairly well in recording fat-percentage changes due to an advance in the period of lactation where the record covers a production period of several months, but the daily fluctuations of the fat percentage in herd milk, and the association method of accepting the fat percentage in two successive milkings as the average for the month, do not insure a close agreement between the two tests for monthly periods.

The association practice of testing monthly throughout the year, two successive milkings of each cow in a herd, permit a fair estimate to be made of the fat content of the milk produced by the herd during the year.

1286 - **The Alcohol Test as a Means of Determining the Quality of Milk for Condensed Milk Factories.** — DAHLBERG, A. O., and GARNER, H. S. (U. S. Department of Agriculture, Research Laboratory, Dairy Division), in *United States Department of Agriculture, Bulletin* No. 944, 13 pp. Washington, May 12, 1921.

The urgent necessity for some means of determining the quality of milk received at condensed milk factories and other dairy manufacturing plants has resulted in the continued use of the acid test, even after its defects have become generally recognised.

This test is based on the assumption that a titratable acidity above the normal for fresh milk indicates an increase in acidity due to bacterial action. It is well known however that a certain part of the alkali added to milk is combined with constituents of the milk which are not acids (casein, phosphates), but it has not been generally realised how great a variation in the apparent acidity may be due to this cause. The authors own experience has shown that not infrequently milk that was rejected because of high acidity was fresh milk, in which bacterial action was highly improbable.

The most essential property in milk destined for the condensed milk factory is its capacity of withstanding without coagulation a temperature sufficiently high to insure sterilisation. While acidity is an important factor in determining the coagulating point of concentrated milk, other factors such as the ash composition also play a considerable part.

The alcohol test has been used to a limited extent for determining the quality of milk with special reference to its sanitary condition. The test is practical and easy to make : 1 cc. of milk is added to 1 cc. of alcohol in a small test tube, and mixed. Any sign of coagulation is then noted ; the gradation of the process is shown by the size of the curd particles formed.

By means of a series of experiments carried out at Grove City Creamery and in 2 factories of condensed milk, the authors were able to determine the relative value of the alcohol and acid tests. Their conclusions are as follows:

1) The acid test as ordinarily used will eliminate a portion of the unsatisfactory milks, but on the whole it is unreliable and inadequate as a means of determining the quality of milk for condenseries where evaporated milk is manufactured.

3) There is no direct relation between the coagulation of milk with alcohol and its titratable acidity, but milks high in titratable acidity as a result of fermentation, will in the majority of cases show coagulation with alcohol.

3) The alcohol test is a practical and reliable means of determining the quality of milk for condenseries making evaporated milk. It is believed that it can be used with advantage in a large majority of average condensed-milk factories.

1287 - **The *Sporogenes* Test as an Index of the Contamination of Milk.** — AYERS, H. S., and CLEMMER, P. W., in *U S. Department of Agriculture Bulletin.* No. 910, 20 pp., bibliography of 15 works. Washington, April 25, 1921.

The *sporogenes* test is based on the characteristic milk reaction produced by certain anaerobic spore-forming bacteria which are widely distributed in nature and are particularly common in faecal material. *Bacterium enteritidis sporogenes* Klein; *B. aerogenes capsulatus* Welch (= *B. Welchii* Migula), *B. perfringens* (Veillon and Zuber) and *B. Saccharobutyricus immobilis* (Schattenfroh and Grassberger), are either identical or very closely related species producing in milk under anaerobic conditions what is known as "stormy" fermentation and coagulating the casein in 24 hours at 37° C. This reaction has been used in order to detect the presence of *B. enteritidis sporogenes* (not be to confused with *B. sporogenes* of METCHNIKOFF), which indicates contamination by faecal matter, or at least want of cleanliness in production. This test is called the *sporogenes test*, for it consists in searching for *B. enteritidis sporogenes*. It has the advantage of being equally applicable to fresh and to old milk, and even to milk that has been pasteurised. Should it prove reliable in gauging the cleanliness of production and be relatively accurate, it would be extremely valuable in milk control work. There seems however to be a difference of opinion among investigators as to the value of the *sporogenes* test, some (WEINZIRL and VELDEE) consider there is a distinct connection between the stormy fermentation due to *B. enteritidis sporogenes* and the cleanliness of milk, while according to others, this test has limitations (SAVAGE), is of little value (RITCHIE), or is even useless (BARTHEL). This induced the authors to give the test a thorough trial under controlled conditions,

SAVAGE carried out his trial in the following manner. Small. narrow tubes about 4 inches by ¼ inch were used in series of [illegible]. The tubes were sterilised and 2 cc. of milk were poured into each. The milk was heated to 80° C for 10 minutes, then cooled and incubated under anaerobic conditions at 37° C. After 48 hours, the tubes were examined. each tube which showed stormy reaction was regarded as positive: 0 or 1 positive tube = good milk; 2, 3 or 4 positive tubes = unsatisfactory milk; 5 or more positive tubes = bad milk.

WEINZIRL employed the following method.

From each sample to be examined 5, 10, 15 cc. of milk were taken. The milk was heated at 80° C for 10 minutes and melted paraffin poured on to it so as to make a layer $^1/_8$ inch or more in thickness. The tubes were then cooled and incubated at 37° C.

From his examination of cow manure, WEINZIRL calculated that there were probably 10 000 *sporogenes* per gram of manure in the partially dried condition in which it usually enters milk. A positive reaction in the 5 cc. tube indicates 1 gm. of manure in 50 litres of milk; a positive reaction in the 10 cc. tube indicates 1 gm. of manure in 100 litres of milk, and a positive reaction in the 15 cc. tube indicates 1 gm. of manure in 150 litres of milk.

The authors conclude from the results of their experiments that SAVAGE's method is not sufficiently delicate to be of great value, not enough milk being used in each tube.

WEINZIRL's method does not appear to show the quantity of cow manure in the milk. This seems to be due to the variation in the number of *B. enteritidis sporogenes* spores in the manure.

The authors' experiments indicate that the majority of the *B. enteritidis sporogenes* spores gain entrance to the milk by means of cow manure. Dirty utensils do not, as a rule, introduce the spores of this microorganism into the milk. With 10 tubes and 20 cc. of milk in each tube, the *sporogenes* test carried out according to SAVAGE's method shows a fairly definite relation to conditions of production. This relation is more definite than was shown either by the SAVAGE, or the WEINZIRL test.

None of the tests, however, showed a definite correlation between the number of positive tubes and the quantity of manure in any given sample. But with 20 cc. doses of milk and discounting individual variation (*i. e.*, the variation in the results of each test), there is a general trend of agreement between the results of the test and the amount of manure in the milk. As a rule, the *sporogenes* test with 10 tubes and 20 cc. of milk shows a large number of positive tubes when the milk is produced under dirty conditions; if the conditions are clean, the test is apt to be negative, or to show only a few positive reactions. This test therefore tends to differentiate between extremes in method of production, and naturally most milk will fall within these limits. The nearer the conditions of production approach one extreme or the other, the more accurately will the *sporogenes* test indicate the conditions. No reliance can be placed in one test with one sample. In the case of each milk examined it is necessary, in order to eliminate individual variations, to make a series of tests and on a number of samples. When the limitations of the tests are understood and the results properly interpreted, its use should furnish considerable information as to cleanliness of production, but the results ought to be verified by an actual inspection at the farm.

[1287]

1288 – **A Pseudolactic Ferment of Frequent Occurrence in Milk "Glaireous Lactic Streptococcus."** — VIOLLE H., in *Annales de l'Institut Pasteur*, Vol. XXXV, No. 3, pp. 216-229, figs. 2. Paris, 1921.

There is often present in milk and its derivatives a microrganism described by the author under the name of "glaireous lactic streptococcus". It probably exists in all dairies, being introduced by water, soil and food substances. Its development is extraordinarily increased by adding nitrites to the culture medium.

This bacterium is a streptococcoid in shape; its cultures on gelatine have the appearance of broad glassy streaks. It forms lactic acid with most sugars and also assumes a viscous gelatinous aspect in sugar media.

The fact that this streptococcus is not pathogenetic, together with the appearance of its cultures, and some of its biological characters distinguish it completely from the forms inducing disease in man and cattle, streptococcus pyogenes, and the streptoccus of contagious mammitis respectively.

It also differs in certain respects from the lactic streptococci, and should therefore be classed among paralactic or pseudolactic bacteria.

1289 – **Causes and the Preventive Treatment of "Buttons" in Sweetened Condensed Milk.** — ROGERS, L. A., DAHLBERG, A. O., and EVANS, A. C., in *The Journal of Dairy Science*, Vol. III, No. 2, pp. 122-129, 2 tables separate from the text. Baltimore, March 1920.

The authors give the results of observations made at the Laboratory of the Dairy Division of the United States Department of Agriculture on the subject of the hard, brownish-red masses of coagulum found in sweetened condensed milk and known in commerce by the name of "buttons".

They are usually the result of enzymes produced by *Aspergillus repens*, but may also be caused by other moulds. It is probable that the milk becomes contaminated after leaving the condenser.

An effective method of preventing the formation of "buttons" is to seal up the tins under a low pressure (508 mm.), for moulds develop only when they have a good supply of oxygen at their disposal.

1290 – **"Mottles" in Butter, Their Causes ans Prevention.** — HUNZIKER, O. G., and HOSMAN, D. F. *Journal of Dairy Science*, Vol. III, No. 2, pp. 77-106, figs. 19. Baltimore, March 1920.

Butter instead of being of a uniform colour, is sometimes traversed by waves or streaks of different shades, or covered with patches. In the latter case, when deep-yellow translucent blotches interspersed with whitish opaque spots make their appearance, the butter is said to be "mottled".

Although mottles in butter have no effect upon its flavour, keeping quality and wholesomeness, they greatly depreciate its market value.

The authors give a summary of the previous investigations made for the purpose of discovering the causes of this defect, and afterwards describe their own experiments which consisted in: churning at different rates, stopping churning in all cases when the granules of butter had attained the size of wheat grains; washing or not washing the butter; salting it or not salting it; examining under the microscope the product obtained.

It was found that mottles appear in salted butter in which the working had been incomplete or lacking in uniformity. In mottled butter, the deep-yellow patches contain relatively few and rather larger water droplets, while the white patches contain large numbers of very minute droplets. The authors conclude that salt disturbs the emulsion of water-in-fat in butter, and that the uniformity of the emulsion can be restored by the proper working of the butter.

In order to prevent mottling, butter must be worked sufficiently to accomplish the fusion and re-emulsification of the water and brine. This point is usually reached when the butter has been reduced by working into a thick plastic and tough consistency. The working must be uniform throughout the churning; therefore sufficient workers should be employed to deal with the amount of butter to be made.

1291 – **Casein Industry and Production in Denmark.** — *Journal de la Société Nationale des Agriculteurs de Belgique*, Year III, No. 10, pp. 315-316 Brussels, Oct. 1921

The casein industry in Denmark came into being during the winter of 1909 and the spring of 1910. At that time, the condition of the Argentine market had caused a great rise in the price of casein, and the price of Danish cheeses was so low, that the dairies in Denmark suffered heavy loss. The industrial manufacture of casein seemed to offer an excellent solution of the problem arising out of this crisis, as by this means, the large superfluous quantities of skim milk thrown on the market by the collapse of the local cheese trade could be turned to good account.

Owing to the various ways in which casein is used, the product found a ready sale in many directions and for a certain time its price rose. The importance of the industry grew rapidly and before the War, the output exceeded 2 million kg. The manufacturing process is methodical and scientific.

The quality of the casein is good, but is still somewhat inferior to the French product (1) which is considered the best in the world, the Danish manufacturers however have every hope of attaining this standard of excellence. It is thought, that the casein industry will regulate the price of Danish cheese on the market. As no local cheeses are exported if the prices are low, more casein is then made and the price of cheese is raised and *viceversa*. The work is distributed as follows: the dairies ("Mejerier") make the great mass of curd ("Ostemasse") and the casein is obtained from the "Ostemasse" at the drying-houses ("Torrerier"). Some dairies, however have their own drying plant.

In Denmark, several methods are used in the drying process.

1) Skabsystemet," or closed cupboard method;

---

(1) See *R* Dec [illegible] No [illegible] (*Ed.*)

2) " Kanalsystemet, " or conduit method (adopted in France) ;

3) " Forestner par Bakken Systemet, " in which small desiccators on troughs are employed.

There are now 15 casein factories of which the chief are at Rudjobing, Kjerteminde, Aarhus, Jylland, Logstor and Hjorring.

Nearly all the casein made in Denmark is exported, most of it going to Hamburg, New York and Boston, either by way of Copenhagen or Aarhus.

Danish and Swedish casein is " Maelkesyre Kasein, " or lactic acid casein (1) a much prized article of commerce outside Denmark, being used in the manufacture of paper, gelatine, and galalith, and also as an article of food. There is, however, some idea of starting a factory in Jutland for the industrial treatment of casein.

Casein is sold by sample, in sacks containing 50, 75 or 100 kg.

1292 - The Separation of Sound Beans From those Attacked by Bean Weevi (*Acanthoscelides obtectus*).

— BROCQ ROUSSEU (Directeur du Laboratoire militaire de recherches vétérinaires), in *Bulletin de la Société scientifique d'Hygiène alimentaire et d'alimentation rationnelle de l'Homme*, Vol. IX, No. 5, pp. 332-335. Paris, 1921.

The number of weevil-infected seeds in a collection of beans may be very variable ; the author found the percentage of diseased seed varied from 1 to 67 in the samples he examined.

When the proportion of infected seeds is low, they can be easily sorted, and little trouble is occasioned.

Where however it is high, the infected beans are almost useless, on account of the large number of larvae and adult insects contained.

In such cases, it would be advantageous to have some practical means of separating the sound from the diseased beans. This could be done by employing liquids of such density as will allow the separation to take place automatically, the infected beans rising to the surface, and the sound sinking to the bottom of the vessel. Since however, solutions of very high specific gravity are required and the necessary density may vary with each species of bean, the problem is not always easy to solve.

For a lot of white beans belonging to the variety known as " prolifique nain sans parchemin " (prolific dwarf sugar beans), of which 67 % contained weevils, the author had to use a 50 % solution of nitrate of sodium, with a density of 1.418. The healthy beans can be washed immediately, in order to remove the nitrate of sodium, and are fit for eating. If this treatment were carried out on a large scale, it is easy to imagine the series of receptacles necessary for effecting the separation. The only trouble in this case would be the cost of the sodium nitrate.

Other varieties of lower specific gravity are more easy to treat as regards the question of solvent.

---

(1) See *R* July-Aug. 1920, No. 801. (*Ed.*)

The author investigated 3 lots of red beans, attacked in the proportions of 1 %, 6 % and 20 %. For these he used a 25 % solution of sea salt (spec. grav. 1.26). Separation took place automatically as before.

It is thus necessary, in the case of each variety of bean, to discover the solution required to bring about the separation of the sound seeds. The author is of opinion that nearly all varieties could be treated with solutions varying within the limits he has mentioned; often a solution of sea-salt will suffice.

In this way infected beans can be eliminated easily and at small cost, and without danger to their food value.

PLANT DISEASES

DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS

1293 - **Behaviour of Certain Cereals Towards Rust in Algeria. — See No. 1212 of this *Review*.**

1294 - ***Phalaris bulbosa*, Forage Grass Resistant to Disease, in Argentina. — See No. 1215 of this *Review*.**

1295 - ***Helminthosporium gramineum*, a Hyphomycete Injurious to Wheat in Emilia, Italy** (1). - BASSI F., in *L'Italia Agricola*, Year LVIII, No. 10, pp. 298-301, figs. 2, Piacenza, October 15, 1921.

Wheat in the district of Plaisance was found on the eve of harvest to be suffering from a widespread and very serious attck of *Helminthosporium gramineum* (Rabh.) Erikss., a parasite which had hitherto been regarded as of limited occurence in Italy. It had been observed formerly on crops of seed wheat, but these were only sporadically infected. It usually attacked barley, and was even considered to be a parasite of barley rather than one proper to wheat.

The field infected in 1921 had a superficial area of 10 hectares; it had been sown with the wheat "semi duro del Fucino," following broken up permanent pasture. Although greatly reduced by lodging, the crop would have been fairly good, but for the fungus, which completely destroyed it.

A careful examination of the wheat culms and ears attacked by *H. gramineum* revealed the discoloured and stunted appearance characteristic of diseased plants. Ears though apparently normal, were either empty, or else contained a large proportion of badly nourished, and hence atrophied, caryopses, while the culms broke at the first node, if gently pulled.

The author, basing his remarks on the results of experiments carried out in the United States, gives concise information on the symptoms and course of the disease and the methods of its control.

---

1296 - Control of "Damping Off" and " Food Rot" of Tomatoes, Caused by *Phtyophhtora parasitica, Phyt. cryptogea* and *Rhizoctonia Solani* in England. — BEWLEY, W. F., in *The Journal of the Ministry of Agriculture*, Vol. XXVIII, No. 7, pp 653-654. London, Oct. 1921.

Sterilisation of the soil, seedboxes and pots by means of heat or formaldehyde have previously been proposed as adequate methods for control of the serious disease of tomatoes, known in England as " damping off " and " foot root ", caused by *Phytophthora parasitica* Dastur (1), *Phyt. cryptogea* Pethybridge (2) and *Rhizoctonia Solani* Kühn (3). These methods, however, do not suit many growers and as a result, another remedy has been put forward, which has been named " Cheshunt compound ", investigations relative to this compound having been made at the Experimental and Research Station, Cheshunt.

This compound contains 2 oz. of copper sulphate, and 11 oz. of ammonium carbonate, reduced to fine powder and thoroughly mixed. The mixture may be stored in the dry state in an airtight receptacle, without which it gradually loses ammonia and becomes less potent.

The dry mixture should be stored for 24 hours in a tightly corked glass or stone jar before using. The solution is then prepared by dissolving 1 oz. of the dry mixture in a little hot water and making up to 2 gallons with water.

The solution must not be put into vessels of iron, tin or zinc, as it would corrode them and lose its strength. Only just as much as is required for immediate use should be prepared.

Plants already attacked receive no benefit from the solution and eventually die, unless the healthy tops are cut off above the diseased part and treated as cuttings. It is possible however to kill the causal organisms by watering infected soil with the solution, after which immediate planting may follow without harming the plants. It is possible also to treat infected soil with plants *in situ*. The solution destroys the disease organisms and at the same time increases the vigour of the plant.

When the soil is suspected of being infected, the following methods should be adopted :

a) *Seed-boxes*: the soil should be thoroughly watered with the solution after sowing and covering the seeds. Generally 1 pint per box (14 × 9 × 2 in.) is sufficient.

b) *Pots*: the young seedlings should be planted and watered with the solution immediately afterwards. To enable each plant to receive sufficient solution, the level of the soil should be 1 inch. below the level of the pot. If left overnight before treatment, many plants become infected and the treatment is rendered useless.

c) *Houses*: each plant should be removed when attacked, the hole watered with 1 pint of solution, a healthy plant inserted and watering with the solution should be repeated.

(1) See *R.* Sept. 1913, No. 1106. *(Ed.)*
(2) See *R.* Apr. 1919, No. 537. *(Ed.)*
(3) See *R.* Sept. 1913, No. 1105 ; *R.* Jan. 1916, No. 123 ; *R.* Jan. 1921, No. 107. *(Ed.)*

This solution has a beneficial effect in the case of many seedlings besides the tomato, also attacked by "damping off". In the case of very delicate seedlings however it is necessary for the solution to be more diluted. Preliminary experiments with the compound upon other root diseases have also given satisfactory results.

1297 - **Studies on *Pseudomonas Pruni*, a Bacterial Disease of Plum, Peach and other Rosaceae in Japan.** — KUWATSUKA, K., in *Annals of the Phytopathological Society of Japan*, Vol. I, No. 4, pp. 12-19. Nishigahara, Tokio, July 1921.

The study of *Pseudomonas Pruni*, E. F. Smith has chiefly been made in the United States and has also been described in Japan as the cause of black spot of the plum or bacterial disease of stone fruits. The author reported in 1919, a serious outbreak of this disease on the peach in Shizuoka; since then inoculation experiments have been made on the plum and peach, on many other species of the genus *Prunus* and on several Rosaceae. Observations were also made on the influence of soil moisture upon the infection of the causal organism.

A number of strains of *Ps. Pruni* were isolated, leaves, branches, and fruits of diseased peach and plum trees being taken, and their virulence was proved by many inoculation experiments on normal leaves or fruits. It has been proved that these species cause not only the shot-hole disease on the leaf, but also the black spot on the plums. The results of inoculation experiments with plums (variety Terada) has led to the supposition that the causal organism hibernates through the winter in the infected tissue of the twigs under field conditions, and if it is not destroyed, it serves in the spring as a central source of infection.

As regards the susceptibility of Rosaceae to *Ps. Pruni*, the results of inoculation experiments indicate that almost all species of the genus *Prunus*, both cultivated and wild, and also *Sorbus japonica* are subject to attack. The following plants have recently been noted as liable to infection: *P. Buergeriana*, *P. crassipes*, *P. donarium* sub. sp. *elegans* var. *glabra*, *P. Itosakura*, *P. japonica*, *P. Mume*, *P. Mume* var. *microcarpa*, *P. Mume* var. *Bungo*, *P. triflora* and *S. japonica*.

When the inoculations are made on the stems of the genus *Prunus*, there is generally a formation of some canker-like or sunken parts, while on *Sorbus japonica* small galls develop at the point of inoculation.

An inoculation experiment made in a green house with Early Rivers two year old peach trees, has demonstrated that soil moisture plays an important part with respect to *Ps. Pruni* infection. Apparently the influence is more accentuated than that associated with atmospheric moisture. It is therefore probably advisable in orchards, having high level of underground water, to attend carefully to the drainage, which is an important point in the prevention of this disease.

1298 - **Diseases and Pests of the Vine, in Peru.** — See No. 230 of this *Review*.

1299 - *Phylaspora baccae*, Ascomycete Injurious to the Vine in Japan. —

NISHIKADO, Y., in *Annals of the Phytopathological Society of Japan*, Vol. 1, No. 4, pp. 20-42, pl. 1. Nishigahara, Tokyo, July 1921.

Report of studies on a disease of grapes made in Japan 1911 to 1916. This disease has been prevalent for the last 10 years in Okayama prefecture and in a few other places where the vine is cultivated.

The peduncle, pedicel and berries of *Vitis vinifera* are infected, but the leaf and stem remain immune. The disease is known locally under the names of " Fusagare " (cluster rot) or Zikugare " (peduncle rot).

The pycnidial stage of the causal fungus is identical with *Macrophoma reniformis* (Viala and Rav.) Cav., the recognised cause of black rot in the Caucasus. The perithecial stage is identical with *Guignardia baccae* (Cav.) Jaczewski (the perithecial stage of *Macr. reniformis*), except for the fact that the paraphyses exist among the asci in the case of the fungus in question in Japan.

This last-mentioned fungus does not belong to the genus *Guignardia*, but to *Physalospora*, because the existence of the paraphyses in the perithecia cannot be denied. Therefore the name *Phys. baccae* Cav. (changed by JACZEWSKI to the name *Guign. baccae*) is adopted in this report.

The fungus develops very rapidly on such cultural media as boiled potato or boiled rice, giving rise to many black aerial mycelia, and occasionally even producing pycnidia. The pycnidia are not similar in their outer appearance to those found on the host. With regard to the pycnospores however the author has found no great difference between them.

The parasitism of this fungus has been fully demonstrated by previous investigations. However, the inoculation experiments conducted by the author have not up to the present led to any conclusion.

1300 - Diseases of the Douglas Fir (*Pseudotsuga Douglasii*) in Scotland. -

WILSON, M., in *Transactions of the Royal Scottish Arboricultural Society*, Vol. XXXV; Pt. 1, pp. 77-78. Edinburgh, Sept. 1921.

Since the recent publication of the paper on *Phomopsis Pseudotsugae* (1) observed on *Pseudotsuga Douglasii*, the author's attention has been drawn to a parasite, notified twice previously in Scotland, in Ayrshire, (1896-1898) and Aberdeenshire (1911). Although identified as *Phoma pithya* Sacc. this parasite of the fir, being given the symptoms associated with its appearance, corresponds most probably in the author's opinion to *Phom. Pseudotsugae*. It may therefore be concluded that *Phom. Pseudotsugae* has been in existence in Scotland for a considerable number of years. Judging from the small number of records, however, it appears that at first the disease was not widespread. In fact it is only within the last ten or twelve years that its occurrence in various localities has been notified. There is little doubt that the actual damage done by the parasite has increased recently and that this cannot be altogether due to the increased area now under *Ps. Douglasii.* This view has received confirmation by the discovery of *Phom. Pseudotsugae* in various localities in England (1).

---

(1) See *R.* Jan. 1921, No. 110. (*Ed.*)

Botrytis Douglasii (2) recorded several years ago in Scotland on *Ps. Douglasii* is widespread. This disease is also described as common in England.

INJURIOUS INSECTS AND OTHER LOWER ANIMALS

1301 – **A Forest Insectarium in Spain.** — *Revista de Montes*, Year XLV, No 1065, p. 166-167. Madrid, November 1, 1921.

One of the duties devolving upon the " Comisión de la Fauna Forestal Española " was the institution of an Insectarium for the purpose of experimental researches having as their principal object the study of the parasites attacking the insects most injurious to forest trees.

This Insectarium, which was recently opened, has been working from the beginning in a forest at Torrelodones, and has already obtained good results.

It is about to be transferred by permission of the King, to " Plantío de Infantes ", on the estate of the " Real Casa de Campo y Bosque del Pardo ", where the conditions for research work are excellent. The great forest surrounding the " Plantío ", and also the vicinity of the Court, are both circumstances tending to facilitate the teaching and cultural work of the Insectarium.

1302 – **Insects Injurious to Cultivated Crops in the Philippines** (3). — WOODWORTH, H. E., in *The Philippine Agriculturist*, Vol. X. No. 1, pp. 9-35. Los Baños, Laguna, Aug. 1921.

Systematic enumeration in alphabetic order and with botanical name of plant host, of insects injurious to cultivated crops in the Philippines, including all the authentic and definite records, published and otherwise, up to the present time

The scientific names of the plants are accompanied by their popular names whenever possible.

Many of the insects enumerated are recorded for the first time as injurious to the crops in the Philippines. By far the larger part of the host plant records are new in this island

The author does not claim to have made a complete list; his intention has been simply to furnish a basis for further records, which should undoubtedly be quickly increased.

1303 – **Method of Control of Cotton Stem Weevil, and Bollworm Recommended in Cambodia.** — See No. 1221 of this *Review*.

1304 – **Control of Cotton Parasites in State of São Paulo, Brazil.** — See No 1220 of this *Review*.

1305 – **The Pink Bollworm of the Cotton Plant *(Platyedra [Pectinophora] gossypiella)* Recorded for the First Time in Porto Rico** (1). – LEGRAND, J. F., in *Revista de Agricultura de Puerto Rico*, Vol. VII, No. 3, pp. 9-13. San Juan P. R., September 30, 1921.

Platyedra (*Pectinophora*) *gossypiella* has been found in the island of Porto Rico, in the district of Humacao on a plant of cotton " Caravonica. "

Further researches have revealed the presence of this dreaded micro-lepidopteron in the neighbourhood of Arecibo, Hatillo, Camuy, Quebradillas and Isabela.

The " Departamento de Agricultura y Trabajo at once took all the measures in its power for the control of the pest.

The author gives information as to the geographical distribution of this insect, its life-history and the means adopted for combating it.

1306 – **Insects Injurious to the Cotton Plant, in Brazil.** — DE FREITAS MACHADO, L., in *Lavoura e Criação*, year VI, No. 8, p. 189. Rio de Janeiro, August 1921.

The following are the insects that have up to the present been recorded as injurious to the cotton plant in Brazil.

Lepidoptera: *Platyedra gossypiella*, popularly known as " lagarta rosea ", *Alabama argillacea* (" curuquerê ") ; *Utetheisa ornatrix* ; *Ut. bella* ; *Exphestia cautella* ;

Coleoptera: *Colaspis* sp. ; *Spermophagus hoffmannseggi* ; *Gasterocercodes gossypii* (" bróca ") ;

Rhyncotes: *Dysdercus ruficollis* ; *Plociomera* (?) sp., *Oncopeltus* sp. ; *Gorgophia* (?) ; *Aphis gossypii* ; *Saissetia depressa* ; *Hemichionaspis minor*.

Gast. gossypii attacks the plant in the region of the collar ; *Saiss. depressa* and *H. minor* injure the stem ; *Alab. argillacea*, *Ut. ornatrix*, *Ut. bella*, *Colaspis* sp. and *A. gossypii* injure the leaves ; *Ph. gossypiella*, *D. ruficollis*, *Plociomera* sp., *Oncopeltus* sp. and *Gorgophia* sp. attack the bolls ; *E. cautella* and *Sperm. hoffmannseggi* destroy the seeds.

1307 – **Insects Injurious to the Coco Palm in Porto Rico** (2). CATONI L. A., in *Revista de Agricultura de Puerto Rico*, Vol. VII, No. 3, pp. 21-25. San Juan P. R., September 30, 1921.

The coco-palm in Porto Rico is attacked by :

1) *Aspidiotus destructor* (" queresa destructiva ") ; this insect lives on the adult leaves and is controlled by cutting and burning all the

---

(1) See also *R.* May 1921, No. [illegible]87 ; *R.* June 1921, No. 671 ; *R.* Aug. 1921, No. 870 ; *R.* Nov. 1921 No. 1160. (*Ed.*)

(2) See also *R.* June 1917 ; No. 607 ; *R.* July Aug. 1920, No. 834 ; *R.* Sept. 1921, No. 912. (*Ed*)

leaves attacked, if possible, or else by spraying with an emulsion of petroleum and soap;

2) *Vinsonia stellifera* ("queresa a forma de estrella"); found on the leaves; the same methods of control are applied as in the case of the preceding species;

3) *Pseudococcus nipae* ("chinche harinosa"'); on the leaves; spraying with a very dense emulsion of oil and paraffin, or else of soap and petroleum;

4) *Aleurodicus cocois* ("mosca blanca del coco") is found on the leaves. Remedies, spraying with whale-oil soap in the case of young palms, if the trees are older, the infected leaves should be burnt;

5) *Eutermes morio* ("comején »); this insect makes its nest at the base of the palm leaves, excavating galleries along the petiole; it feeds on the fibrous tissues of the tree. It can be controlled by destroying its nests, or using poisoned baits consisting of a mixture of arsenic and sugar, or a sebaceous mixture with ten parts of sugar and one of Paris green; these baits are placed at different points in the galleries;

6) *Strategus quadrifoveatus* ("caculo rinoceronte del coco"); in the larval condition this parasite destroys the internal tissues of the coco-palm. The best means of controlling the adult insect is to destroy all its possible refuges; light-traps can also be used. Above the light, a small vessel containing a tar-solution is placed into which the insects attracted by the light readily fall. Poisoned baits are useful in destroying the larvae, which are sometimes pursued and caught by birds.

7) *Phyllophaga portoricensis* ("caculo común, or gusano blanco"); this insect destroys the tissues of the palm, it can be combated in the same manner as the last named;

8) *Metamasius hemipterus* ("gorgojo barreno del tallo"); the larvae live on the fibrous tissue of the stem. The palms attacked must be completely burnt. Light traps are efficacious against the adult insects and the larvae are destroyed by their natural enemies.

9) *Platypus* sp. "perforador de la palma de coco"; an insect making holes in the trunk. Light-traps are useful for catching the adults; and the trunk can also be smeared with a poisonous mixture. Trees badly attacked should be destroyed.

1308 - ***Phthorimaea (Ita) ocellatella*, a Microlepidopteron Injurious to Beetroots in Germany** (1). WILKE S., in *Nachrichtenblatt für den deutschen Pflanzenschutzdienst*, Year I, No. 5, pp. 33-34. Berlin, November 1, 1921

In September 1921, the caterpillars of *Phthorimaea* (*Lita*) *ocellatella* Boyd. were so numerous in the neighbourhood of Gross-Gerau (Hesse), that entire fields of beetroots were invaded by them, and the growth of the plants seriously menaced. The larvae attacked and destroyed the central leaves and the region of the root-collar.

This microlepidopteron was recorded for the first time in Germany in 1866, when it was found near Wiesbaden.

---

(1) See also *R.* Nov. 1918, No. 1315 and *R.* March 1920, No. 600 (*Ed*).

The author gives information regarding the life-history and geographical distribution of the insect, and describes the measures taken for its control.

1309 - *Gyropsylla ilicola* n. gen. and n. sp., Rhynchote Attacking Mate (*Ilex paraguariensis*) in the Republic of Argentina. BRETHES J., in *Universidad Nacional de La Plata, Revista de la Facultad de Agronomia*, Vol. XIV, No. 2, pp. 62-80, figs. 6. La Plata, 1921.

A morpho-biological description of a new representative of the family *Psyllidae* (*Gyropsylla ilicicola*, n. gen. and n. sp.), discovered by the author, who obtained his data from material sent from Concepción de la Sierra de Misiones, where the parasite causes a deformation of the leaves on the maté (*Ilex paraguariensis*), which had been noticed already for several years in Argentina.

This rhynchote spoils the maté crop by producing atrophy of the leaves. As a result of its action, the two halves of the blade fold together lengthwise, bending over more or less at the same time, and finally adhering and forming a kind of bag of varying dimensions, harbouring a colony of the insects. Several pouches can be made on the same leaf, or one may be formed on a small portion of the blade, the rest of the surface remaining more or less normal.

The insect cannot be controlled during the larval stage, for it lives enclosed within these leaf pouches, where insecticides can only penetrate with difficulty, if at all. It is of little use to combat the adult rhynchotes, for when they attain their final stage of development, they may be found on other plants besides the maté. The most propitious moment for their destruction appears to be as soon as the larvae hatch out, and before they have had time to ensconce themselves in the leaf pouches.

Of the various insecticides, a 2 % solution of tobacco extract might be selected for trial. The best time for spraying is, in the author's opinion, about October, when the new shoots are from 5 to 8 cm. long. The proportion of extract to be used and the date of treatment must be determined by the farmers themselves. Should rain fall after the insecticide has been applied, it would of course be necessary to repeat the dose.

1310 - The Cabbage Seed Stalk Weevil (*Ceutorrhynchus quadridens*) in Long Island, New York State (1). — VOGEL, I. H., in *The Canadian Entomologist*, Vol. LIII, No. 8, pp. 169-171. Guelph, Aug. 1921.

Ceuthorrhynchus quadridens Panz. the European insect reported in the United States for the first time by SLINGERLAND (1894) as infesting cabbage seed stalks on Long Island, was in 1920 the subject of special study made by the author in the cabbage fields in the vicinity of Mattituck in the same island. The life history of the insect was observed from the egg to the adult stage.

---

(1) See *R.* Nov. 1917, No. 1084. (*Ed.*)

In general, the cabbage seed growers on Long Island have either failed to recognise this insect or confused it with the larval stage of the cabbage maggot (*Phorbia brassicae* Bouché) It is due to this confusion that little information has been secured concerning its distribution and destructive activities in the past

The distribution of this weevil in the cabbage seed fields in the vicinity of Mattituck seemed quite general in 1920.

The losses to the grower may be attributed to the fact that the larvae of *C quadridens* burrow in the pith of the main stalks and branches, and the plant is thus weakened and liable to rupture at the point attacked, and consequently to premature death.

In order to ascertain to what extent the weevil occurs and to determine the extent of loss caused, records were taken in five fields It was found that 47 % of the plants were attacked. At harvest time, 100 normal plants and 100 plants attacked were threshed in order to secure the seed. The amounts obtained are shown as follows

	Weight of seed before cleansing	Weight of seed after cleansing	% of seed lost in cleansing
100 normal plants . . .	109.2 oz	97.4 oz	11
100 attacked plants .	74.3 »	64.8 »	13
loss due to insect		32.6 »	

Plants not attacked yielded therefore about 33.5 % more seed than the attacked plants. If [illegible] of the plants were attacked, the loss would be 16 % of the crop.

The seed yield was approximately 250 lb. per acre, in 1920, and consequently the loss occasioned by the weevil was 40 lb per acre, valued at 50 dollars. Even greater losses have doubtless occurred seeing that a cabbage seed contractor and some growers have reported cases where in previous years this insect has been the cause of the loss of entire crops.

[1310]

ALFREDO RUGGERI, *gerente responsabile*
